Features of ^{31}P MRS in Tissues

General Properties of ^{31}P

^{31}P is one of the most sensitive of the NMR nuclei. It has spin ½, a gyromagnetic ratio of 1.083×10^8 rad/s/T, and a natural abundance of 100%, giving a sensitivity of 6.63% relative to ^{1}H. Since many metabolites of biochemical interest are phosphorylated, ^{31}P MRS is a useful probe of tissue biochemistry. Spectra *in vivo* are relatively uncrowded as the number of ^{31}P-containing metabolites of sufficient concentration are relatively few. Properties of the individual metabolites of major interest are given below, while the abbreviations used for the various metabolites referred to in this chapter are given in Table 1. Note that there are nucleoside triphosphates (NTP) in addition to adenosine triphosphate (ATP), so in general we have followed the convention of referring to the corresponding peaks as NTP rather than as ATP.

Spectral Dispersion. In general ^{31}P gives rise to spectral peaks covering a wide range of frequencies. However in tissues most peaks of interest lie within a 30 ppm range (see Figure 1). Chemical shift is often referenced relative to phosphocreatine (PCr) at 0 ppm *in vivo*, or to H_3PO_4 in tissue extracts *in vitro*.

Dependence of Chemical Shift on pH. Many ^{31}P metabolites have a pKa in the range that makes the chemical shift dependent on tissue pH. The classic example of this is the equilibrium between the two forms of inorganic phosphate (Pi) in tissue [1];

$$H_2PO_4^- \Leftrightarrow HPO_4^{2-} + H^+ \qquad pKa \cong 6.7$$

Since this is a dynamic equilibrium between two forms of phosphate with different chemical shifts, the net shift of the observed Pi peak depends on the relative concentrations of the two species and hence on the hydrogen ion concentration (pH). Measurement of the chemical shift of the Pi peak relative to a peak that does not shift significantly with pH (usually PCr is used) provides a non-invasive way to measure intracellular pH, as most phosphate is intracellular. Some other ^{31}P metabolites also demonstrate sensitivity to pH, in particular phosphocholine (PC) and phosphoethanolamine (PE) (see Figure 2).

Other Factors Affecting Chemical Shift. Chemical shift is also affected by factors such as ionic strength and metal ion binding. In particular the β and γ peaks of ATP are sensitive to the magnesium concentration in the tissue [2,3].

Homonuclear J-Coupling. The main example of homonuclear coupling is found in NTP. In ATP this leads to α- and γ-ATP being observed as doublets, while β-ATP is a triplet, with a coupling constant of about 16 Hz. Homonuclear decoupling is not generally required. However, allowance for coupling is necessary when measuring the T_2 of coupled metabolites, such as ATP [4].

Heteronuclear J Coupling. The phosphomonoesters (PE, PC) have weak (6–7 Hz) 3-bond coupling to ^{1}H nuclei, forming a triplet, while the phosphodiesters couple to two-proton pairs, producing quintets (Table 1). Nearly all preclinical systems and a few of the more advanced clinical scanners have the facility to perform ^{1}H-decoupling to collapse these multiplets back to singlets (see below). A few research systems can also perform more complex double resonance measurements for further sensitivity enhancement.

Metabolites Observed in Tissues

Most of the metabolites detectable with ^{31}P MRS in tissues can be seen in Figure 1, while the structures are shown in Table 1. Metabolites are involved in either energy production (high energy phosphates—ATP, PCr, sugar phosphates; NADH) or in membrane metabolism (phosphomonoesters—PC, PE; phosphodiesters—GPC, GPE; membrane phospholipids). The reactions involved are summarized in Figure 3. For more details a biochemistry textbook should be consulted [5,6].

Graham A. Webb (ed.), Modern Magnetic Resonance, 1143–1161.
© 2008 *Springer.*

Table 1: Summary of main metabolites detected by ^{31}P MRS *in vivo*

Metabolite	Abbreviation	Structure	Chemical shift relative to PCr (ppm)	*J* coupling[a] (Hz)
Phosphoethanolamine	PE		5–7	7.19
Phosphocholine	PC		4.2–6.5	6.25
Inorganic phosphate	Pi		3.5–5.5	Singlet
Glycerophosphoethanolamine	GPE		3.6	b
Glycerophospocholine	GPC		2.96	6.03
Phosphocreatine	PCr		0	Singlet
Adenosine triphosphate	ATP		α-7.5 ppm β-16–19[c] γ-2–7.5[c]	

Notes: [a]The coupling quoted is the main $^{3}J_{PH}$ coupling. Additional J_{HH} couplings are often present. [138]; [b]This was not measured. It will be similar to that of GPC. [c]Depends on magnesium concentration.

Additional Notes on Specific Metabolites

Phosphomonoesters—phosphocholine and phosphoethanolamine. These metabolites are involved in membrane synthesis and degradation (Figure 3B [7]). PC is also involved in cell signalling [8,9]. The chemical shifts of both are pH sensitive (Figure 2).

Phosphodiesters—glycerophosphocholine (GPC) and glycerophosphoethanolamine (GPE). These are produced by the action of phospholipases A_1 and A_2, or phospholipase B on the corresponding phospholipids (Figure 3C). The chemical shift does not depend on pH. When interpreting a "PDE" peak one must be careful to distinguish phosphodiesters from the peak of the broader phospholipid component (see below).

Broad Resonances from Phospholipids and Bone. In unlocalized spectra of brain a large broad (~750 Hz

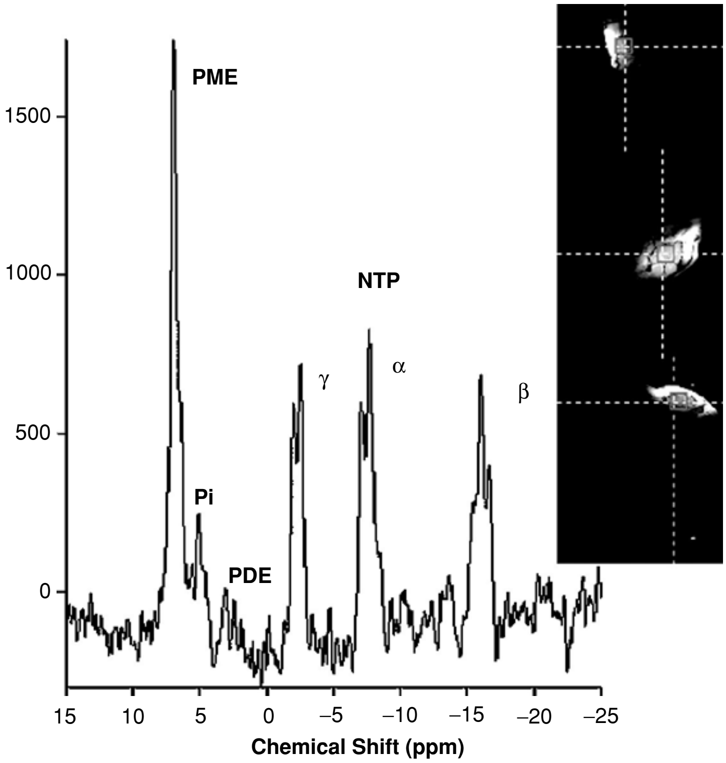

Fig. 1. Example of a ^{31}P MR spectrum from a non-Hodgkins lymphoma in the groin of a patient, measured at 1.5 T. Note the absence of PCr at 0 ppm.

width) symmetric resonance is observed due to immobile phosphates in bone [10]. In localized spectra of brain, liver, and kidney a broad asymmetric resonance is observed that decreases in amplitude with increasing magnetic field strength, and therefore suggesting a strong influence of chemical shift anisotropy. It has been demonstrated that the peak is produced by membrane lipid bilayers and that it may be eliminated by off-resonance presaturation [11].

Nucleoside Triphosphates. In most systems the dominant contribution is from ATP. As mentioned above, the chemical shifts of the β and γ peaks are sensitive to magnesium concentration.

Fig. 3. Simplified biochemical pathways of main compounds visualized by ^{31}P MRS in tissues. (A) Metabolism of high energy phosphates. (B) Synthesis and degradation pathways of main membrane phospholipid. (C) Sites of action of the phospholipases on phosphatidylcholine. Phospholipase B can also bring about the successive removal of both fatty acids. (See also Plate 90 on page XVI in the Color Plate Section.)

Adenosine Diphosphate (ADP). The concentration measured by NMR is much lower than that measured biochemically after freeze-clamping of the tissue. This suggests that much of the ADP is tightly bound to larger structures leading to rapid transverse relaxation such that the peaks become invisible by NMR.

Metabolite Concentrations and Relaxation Times

Some published measurements of concentrations and relaxation times of various metabolites in different tissues are summarized in Tables 2 and 3.

^{31}P MRS of Tissue Biopsy Samples

Methods

Extraction Methods

The type of extraction method to be selected depends greatly on the nature of the investigation and the analytical methods involved. To analyze cellular lipids and/or their water-soluble metabolites, it is necessary to use extraction procedures that quantitatively recover the metabolites of interest. Currently available methods include the following.

Perchloric Acid (PCA). This is widely used for extraction of water-soluble cell components [12].

Modified Folch's Method. The extraction of cellular lipids using organic solvents, usually chloroform and methanol [12].

A Combined Extraction Technique. The above two methods performed on the same cell batch [13].

The Dual Phase Extraction Method (DPE). The recovery of both the lipid and water-soluble fractions from the same biological sample by a single extraction method [12].

Chemical Shift and Concentration Referencing for ^{31}P MRS

The separation of resonance frequencies from an arbitrary chosen reference frequency is termed the "chemical shift", and is expressed in terms of the dimensionless unit parts per million (ppm). Depending on the phase of the extracts and the type of nucleus detected, different solvent systems and references (internal or external) are used.

Aqueous Fraction. An example of stock solution used is D_2O with 10 mM ethylenediaminetetraacetate (EDTA) adjusted to pH 8.2 with tris (hydroxymethyl)-methylamine (Tris) (0.5 M, pH 10.4), and methylene-diphosphonic acid (MDPA) ($\delta = 16.8$ ppm) calibrated against GPC ($\delta = 0.49$ ppm @ pH 7.2) for referencing.

Notes: ^{a}Spin echo with $T_E = 1/J$; ^{b}Selective echo 90-T_E/2-2(6)6(2)-Te/2-acquire; ^{c}These measurements have not allowed for modulation owing to homonuclear J coupling.

Lipid Fraction. A 2:1 mixture of $CDCl_3$ and 40 mM methanolic EDTA (200 mM EDTA in water adjusted to pH 6.0 with CsCl, and further diluted fivefold with absolute methanol) [14]. Examples of internal references are: GPC ($\delta = -0.13$ ppm) which is soluble in chloroform solutions, although it can be extracted with water and triphenylphosphine oxide ($\delta = 33.5$ ppm when PtdCho $\delta = 0.0$ ppm) or phosphocholine ($\delta = 3.5$ ppm when PtdCho $\delta = 0.0$ ppm) which is used as an external reference.

In all cases, metabolic contents are quantified by integration, normalized relative to the reference peak, and corrected for the number of live cells extracted and cell size in cases when treatment is expected to modify cellular size.

Acquisition Hardware and Condition

Measurements are usually performed in vertical superconducting magnets, with field strengths in the range 7–14 T. Manufacturers provide a wide range of RF probes, that are usually equipped with a deuterium lock to ensure the field does not drift over the time of the measurement, and with a separate ^{1}H coil in order to perform ^{1}H decoupling. Most measurements will use 5 mm NMR tubes, although 2.5 mm and even 1 mm tubes are becoming available.

Acquisition conditions will depend to some extent on the system and concentration being studied. The following conditions are an example of those used for cellular extracts of $0.5 - 2.0 \times 10^8$ cells measured on a 500 MHz spectrometer [15,16]. Some example spectra are given in Figure 4.

Spectra are acquired at room temperature with proton broad-band decoupling to eliminate ^{1}H-^{31}P NMR multiplets (decoupler power "on" during acquisition and "off" during the interpulse delay in order to prevent the building of NOE enhancement), spectral width of 100 ppm (aqueous) and 20 ppm (lipid), 32K data points and 4K transients accumulation. The sample spinning rate is 20 Hz. Exponential multiplication to give a line-broadening of 1–2 Hz is applied before Fourier transformation.

Spectral Analysis

Most spectrometers include software for processing and analysis of data. For off-line processing several packages are available, such as MestRe-C software (available free from Javier Sardina Research Group, University of Santiago de Compostela, Spain (http://qobrue.usc.es/jsgroup/MestRe-C/MestRe-C.html)). In addition to the measurement of peak areas directly, when large numbers of samples are available it is possible to look for patterns characteristic of different sample groups using automated pattern recognition techniques [17].

MRS of Intact Tissue Samples

While virtually all MRS measurements of biopsy samples are performed on tissue extracts, it has recently become possible to perform high resolution MRS directly on samples of intact tissue using the technique of magic angle spinning [18]. While most studies have used ^{1}H MRS, high resolution ^{31}P MR spectra may also be obtained [19]. Unlike extract studies the enzymes are still active, so it is necessary to perform measurements at low temperature (usually about 4° C). The high-energy phosphates are usually not visualized, but the metabolites involved in membrane metabolism (phosphomonoesters and phosphodiesters) are found to be reasonably stable.

Applications using ^{31}P MRS of Tissue Extracts

In practice, ^{31}P MRS of biopsy samples *ex vivo* is not as widely used as ^{31}P MRS *in vivo*, owing to the wide variety of alternative analytical techniques available for evaluating tissue samples. However the high resolution permits the identification of many more metabolites than is possible *in vivo*, for example, 14 different phospholipids were identified in a study of malignant breast tumors, several of which (sphingomyelin, PtdCho, PtdSer, phosphatidic

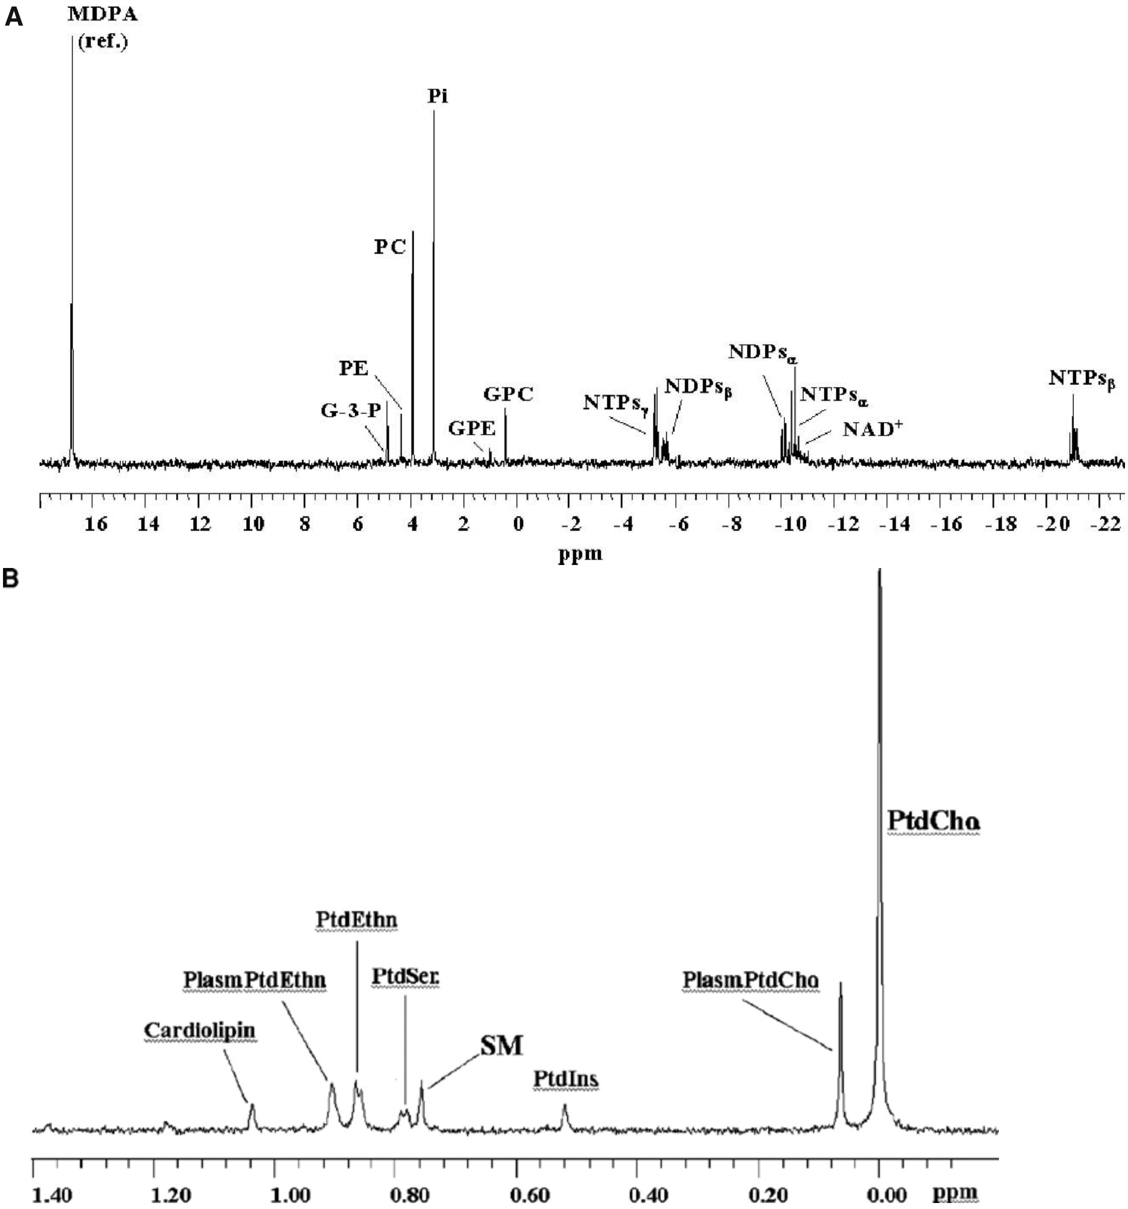

Fig. 4. Example spectra from cell extracts. All measurements were performed at 9.4 T. Spectra were plotted and analyzed using MestRe-C version 1.5.1 software. (A) ^{1}H decoupled ^{31}P MR spectrum of the water soluble fraction of Jurkat T-cell extracts (*G-3-P* = glycerol-3-phosphate, PE = phosphoethanolamine, PC = phosphocholine, Pi = inorganic phosphate, GPE = glycerol-3-phosphoethanolamine, GPC = glycerol-3-phosphocholine, NDPs = nucleotide diphosphates, NTPs = nucleotide triphosphates. NAD$^+$ = nicotinamide adenine dinucleotide). Spectrum is the result of 1280 scans plotted with line broadening of 2 Hz. (B) ^{1}H decoupled 31P MR spectrum of the lipid fraction of Jurkat T-cell extracts. Spectrum is the result of 1280 scans plotted with line broadening of 0.1 Hz and zero filling to 64 K data points (Plasm.PtdEthn = plasmalogen phosphatidylethanolamine, PtdIns = phosphatidylinositol, Plasm.PtdCho = plasmalogen phosphatidylcholine, SM = sphingomyelin, PtdCho = phosphatidylcholine, PtdEthn = phosphatidylethanolamine).

Table 4: Relative merits of tissue extracts and *in vivo* ^{31}P MRS measurements

	Tissue Extracts	*In vivo*
Tissue biopsy required?	Yes	No
Sample preparation required?	Yes	No
Max measurement time	Unlimited	Approx. 1 h
Measurement co-registered with anatomical image?	Not usually	Yes
System disturbed?	Yes	No
Capacity to follow kinetics	No	Yes
Spectral resolution	∼0.01ppm	∼0.1 ppm
Sensitivity to motion	N/A	Depends on tissue and method
Complexity of NMR sequence	Decoupled pulse-acquire	Requires localization
Field strength generally available	7–14 T	1.5–3 T
Coil design / availability	Good range of commercial coils	Few commercial coils; most need to be custom-built
Safety issues	Biopsy	MR Hazards (esp. RF heating from surface coils)

acid, phosphatidylglycerol and alkylacylphosphatidylcholine) predicted tumor characteristics such cellular infiltration, lymphatic invasion and necrosis [20].

In other studies biopsy specimens from patients with chronic ductopenic rejection [21] and liver cirrhosis [22] showed elevated PE and PC, and reduced GPE and GPC, reflecting altered phospholid metabolism [21]. In malignant hyperthermia-susceptible patients PCA extracts of vastus medialis muscle showed elevated GPC/(PCr+Pi) but no histological differences, suggesting GPC could be a marker of impairment [23]. PCA extracts of transurethral prostate samples show statistically different ratios of PE/totP, PC/totP and GPC/totP in prostate cancer samples compared with those from patients with benign prostatic hyperplasia [24]. In extracts of breast tumors no correlation was found between levels of GPC, GPE, PC, and PE and with indices of tumor proliferation, but higher PC levels were found in high grade tumors [25].

PCA and lipid extracts from kidney show that oncocytomas (benign tumors) have a biochemical composition between healthy and malignant tissue [26].

Blood samples are easier to obtain than tissue samples. One application is in thyroid cancer, where plasma levels of sphingomeylin and PtdCho have been found to be reduced in patients with remnants of thyroid tissue, and are even lower in patients with metastatic thyroid cancer, compared with patients in remission [27].

^{31}P MRS *In Vivo*

Introductory Comments

Given the difficulty and limited patient acceptance of obtaining tissue biopsy samples, the option to perform the spectroscopy measurements on the tissue *in vivo* is clearly very welcome. While the sensitivity and spectral resolution can never approach those obtained *in vitro*, the possibility of obtaining biochemical information from tissues non-invasively, repeatedly if necessary, provides the opportunity to monitor aspects of tissue biochemistry and response to treatment. Table 4 lists some of the main differences between measurements *in vivo* and *ex vivo*. A direct comparison of spectra of breast tumors from extracts and *in vivo* is given in [28].

Magnets

Most ^{31}P MRS studies on human subjects are performed in clinical NMR systems using horizontal bore superconducting magnets at a field strength of between 1.5 and 3T. Since sensitivity increases with field strength even higher fields would be advantageous but are not yet widely available. Since clinical scanners are normally designed for operation at a single frequency (for ^{1}H MR imaging) it is necessary to add or modify the RF hardware (coils, frequency source, transmit amplifier, receiver preamplifier, filters etc.) to permit operation at the ^{31}P resonant frequency.

RF Coils for *In Vivo* Studies (see also Chapter "Radiofrequency Coils for Magnetic Resonance Spectroscopy")

Appropriate RF coils of high sensitivity are essential for acquiring good ^{31}P MRS data. Because *in vivo* ^{31}P MRS is largely a research activity, with users having different specifications and applications, at present the choice of commercial coils is very limited. Unlike ^{1}H coils, for which the vendors of the MR systems provide a good range of options, commercial ^{31}P coils are often supplied by specialist coil companies, while many researchers design and build their own. Some good reviews on coil design principles can be found in [29–32]. Again in contrast to ^{1}H coils, almost all ^{31}P coils are used in transmit/receive mode—principally because there is no ^{31}P body resonator to provide a uniform transmit field. Occasionally a small surface coil receiver (to optimize sensitivity) is used together with a larger transmit coil (to optimize transmit field uniformity).

Surface Coils

Apart from studies in the brain, ^{31}P MRS measurements are usually performed with surface coils because of their superior sensitivity in superficial tissues [33]. There is a huge variety of designs, with the main differences being shape (e.g. circular or rectangular; mounting on a flat or curved surface), number of turns, material for construction (e.g. wire or foil), type of tuning network (e.g. simple LC circuit or balanced match), and whether there is a complementary ^{1}H coil to provide imaging and dual resonance capability. Surface coils are characterized by a spatial variation in the RF field. During transmit this leads to non-uniform excitation within the field of view of the coil. For small regions of interest that are not too close to the coil conventional amplitude-modulated RF pulses are often used, calibrated to give the required flip angle at the centre of the volume. However larger volumes are often of interest. In this case it is necessary to use adiabatic RF pulses to achieve uniform excitation over the region of interest (see below).

The non-uniform transmit field of surface coils also leads to non-uniform RF power deposition, which can be very high close to the coil itself. This is hard to measure experimentally, so sophisticated models (e.g. using finite element analysis) are required to calculate the expected power deposition [34]. International guidelines specify limits to RF power deposition for local and whole-body irradiation [35]. In practice the high RF power deposition near surface coils does limit the minimum repetition time or pulse amplitude in some studies, especially where double-resonant techniques are being used (see below).

Volume Coils

Volume coils are characterized by a more uniform RF field than surface coils, but usually at the expense of lower sensitivity. The most common designs for clinical studies are co-axial pairs of surface coils (often loosely called "Helmholtz pairs" but in fact having a separation larger than the radius), or birdcage coils [36]. Birdcage coils can be circularly polarized (which reduces RF power and improves receive sensitivity) and also double-resonant ($^{1}H/^{31}P$) [37].

Double-Resonance Coils

When performing ^{31}P MRS studies a ^{1}H capability is also usually required to obtain localization MR images, to shim, and sometimes to acquire complementary ^{1}H MR spectra (sequential or interleaved) or for double resonance studies (NOE, decoupling, polarization transfer). The hardware required depends on whether both ^{1}H and ^{31}P need to be used simultaneously.

Double Resonance Coil Options

(a) Two separate coils—such as ^{1}H body coil and ^{31}P surface coil or co-axial surface coils [38,39]. It is necessary to ensure they do not interact, in particular that ^{1}H transmit fields do not induce currents in the ^{31}P coil (leading to signal drop-out and local heating).
(b) Single coil, either with wide tuning range to permit sequential tuning to ^{1}H and then ^{31}P (e.g. 63 MHz and 25 MHz at 1.5 T), or that has two independent tuning networks may be switched to tune to each frequency.
(c) Single dual-resonant coil, for which the tuning circuit has resonances at both ^{1}H and ^{31}P. Depending on the design, the ^{1}H and ^{31}P connections may be on the same input [40] or different ones [31].

System Options

(a) Single channel with wide frequency range to permit transmit and receive operation at ^{1}H followed by ^{31}P in separate measurements. Some systems permit operation at specific frequencies only (e.g. at ^{1}H and ^{31}P). No double resonance experiments are possible.
(b) As (a) but with rapid switching of the transmit frequency. This permits irradiation at the ^{1}H frequency during the recovery time of ^{31}P measurements, and hence ^{31}P signal enhancement by the nuclear overhauser effect (NOE).
(c) Two-channel system that is able to transmit at one frequency (e.g. ^{1}H) while receiving on another (e.g. ^{31}P). Such systems can perform ^{1}H -decoupling (see below) as well as NOE studies.
(d) Two-channel system with full transmit and receive capability on two channels simultaneously. This permits both sequential acquisition at different frequencies [41–43] and also more complex double-resonance measurements such as polarization transfer [44,45].

Other Hardware for Double Resonance Studies

If there are no transmit pulses during signal acquisition then the only requirement is that the coils and frequencies do not interact. However for decoupling studies, where ^{1}H irradiation is applied during ^{31}P receive, it is necessary to apply a high level of isolation (~80 dB) between the channels. If this is not done the main problems are (1) saturating the receiver, leading to lower receiver gain, and (2) introducing extra noise into the receive channel, which again reduces the signal-to-noise ratio. Isolation is normally achieved in three steps, (i) use a coil that has a sharp resonance at the frequency of interest (e.g. ^{31}P) and negligible response at the other frequency (e.g. ^{1}H) (ii) a narrow band-width ^{31}P preamplifier, to minimize impact of ^{1}H irradiation, (iii) narrow bandwidth filters on both ^{1}H transmit and ^{31}P receive paths.

Adiabatic RF Pulses for *In Vivo* Studies with Surface Coils

Adiabatic RF pulses have the useful property that once a threshold transmitter amplitude is exceeded they produce uniform excitation over the sensitive region of the RF coil. In general they are characterized by a modulation of the frequency (or phase) as well as of the amplitude. For example the sech/tanh pulse ("hyperbolic secant pulse") widely used for slice-selective inversion [46] is described by

$$\mathrm{Amp} = \Omega_0 \,\mathrm{sech}(\beta t)$$

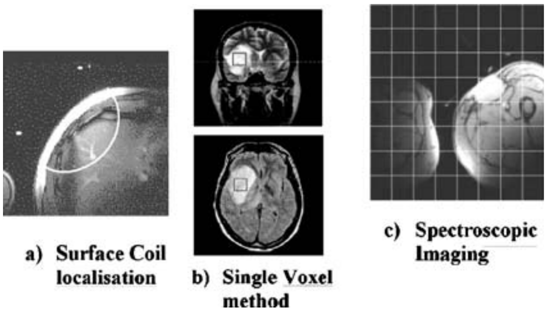
$$\mathrm{Freq} = \mu\beta \tanh(\beta t)$$

A variety of adiabatic pulses have been developed. Helpful reviews are available [47]. Other useful pulses include the tanh/tan pulse for 90° excitation [48] and the BIR4 or BIRP pulses for excitation by smaller flip angles to reduce partial saturation effects [48,49]. While there are adiabatic pulses suitable for many purposes some applications are particularly difficult, for example slice-selective excitation (for which the subtraction of two measurements is required [50]) and spin-refocusing [51].

The major disadvantages of adiabatic RF pulses compared with conventional amplitude-modulated pulses is that they are often (but not always) longer and/or requiring of a higher peak or total power.

Localization Methods for *In Vivo* Studies

For most studies *in vivo* it is necessary to select signal from a specified volume, usually identified from MR images acquired on the same occasion. A schematic representation of the three classes of technique is shown in Figure 5. An ideal acquisition method would have a sharp edge profile matching the requested target volume on the MR images, acquire signal from the selected volume with 100% efficiency, and include no contamination at all from elsewhere. The relative merits of the different acquisition strategies available are discussed briefly below.



a) Surface Coil localisation **b) Single Voxel method** **c) Spectroscopic Imaging**

Fig. 5. Schematic illustrating the different methods of spectral localization.

Surface-Coil Localization

The relative sensitivity of an RF coil in receive mode at a particular point in space is proportional to the relative RF field produced at the same position by the coil in transmit mode [52]. Thus the sensitivity falls away with distance from a surface coil, limiting the sensitive volume. An indication of this region is shown in Figure 5, although in practice the boundary is not well defined. However, the localization method is simple and has the maximum available sensitivity for a given coil. It is normally only used alone (i.e. without further localization) when the sensitive region is almost entirely occupied with the target tissue, and when the signal losses associated with additional forms of localization cannot be tolerated.

Single Voxel Localization Methods

Single voxel methods make use of a series of frequency-selective RF pulses in combination with slice-selective B_0 field gradients. These define three intersecting slices that are usually but not necessarily orthogonal. Of the wide range of strategies that have been developed over the years, only three are in widespread use—PRESS [53], STEAM [54] and ISIS [55]. ^{31}P MRS has been demonstrated to work with STEAM [56] but ISIS has been the method of choice. While PRESS and STEAM have the great advantage of achieving localization in a single measurement, they both include echo times during which significant losses occur for nuclei which are characterized by short transverse time constants, such as are observed in most ^{31}P metabolites. As technology advances and shorter minimum echo times become possible this will become less of a problem.

PRESS and STEAM. PRESS is conceptually the simplest single voxel method and uses a $90° - 180° - 180°$ double spin echo sequence (Figure 6A). The first 90° RF pulse excites a slice of spins (e.g. transverse). The first 180° refocus pulse affects an intersecting slice (e.g. sagittal), so that only spins with the column defined by the intersection

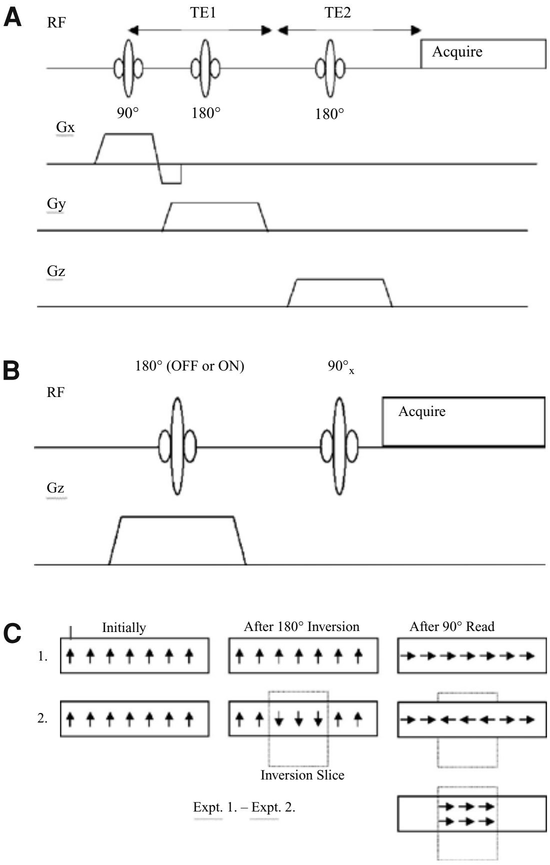


Fig. 6. (A) The PRESS localization sequence. (B) The ISIS localization sequence in 1 dimension (C) Schematic illustrating the effect on spins inside and outside the selected slice in the two measurements when performing ISIS localization in one dimension. The difference of the two measurements leads to signal addition within the slice and signal cancellation outside the slice.

of the two slices are refocused. The second 180^o pulse affects a third slice that intersects the other two, so that spins within the intersecting cuboid are refocused while other spins are dephased.

The STEAM sequence is similar to PRESS except that it uses a $90^\circ - 90^\circ - 90^\circ$ stimulated echo sequence instead of a double spin echo, with corresponding changes in timings and gradient patterns. It also localizes in a single measurement. However the maximum signal obtainable is 50% of the available magnetization.

ISIS. Localization with ISIS in one dimension requires two acquisitions (Figure 6B). In the first, a broadband RF pulse excites signal from the whole sample. In the second measurement the excitation pulse is preceded by a slice-selective inversion pulse. Subtraction of the two measurements causes cancellation of signal from outside the slice, but addition of signal from spins within the slice (Figure 6C). Three dimensional (3D)-Localization requires the appropriate addition/subtraction of eight separate measurements with all possible on/off permutations of slice-selective inversion pulses in the three intersecting slices.

Table 5: A summary of the relative merits of STEAM, PRESS, and ISIS for single voxel acquisition of ^{31}P MR spectroscopy data.

	STEAM	PRESS	ISIS
Surface coils	Poor	Poor	Good
Volume coils	Good	Good	Poor
Short T_2 metabolites	Moderate	Poor	Good
Single-shot	Yes	Yes	No
Edge definition	Good	Improving	Good
Sensitivity	<50%	Good	Good
Use use for shimming	Yes	Yes	Need other method

Relative Merits of the Different Single Voxel Localization Schemes for ^{31}P Acquisition. A summary of the relative merits of the three main single-voxel sequences is given in Table 5. The main advantage of the PRESS and STEAM schemes is that they are single-shot, thus reducing the problems of subtraction artefacts. However because the spins spend significant time in the transverse plane these methods are sensitive to signal loss from T_2 relaxation. With ISIS all magnetization is longitudinal till the final read pulse, thus reducing this problem. ISIS also has the advantage that it can be used easily with transmit surface coils by incorporating adiabatic RF pulses (usually hyperbolic secants); both STEAM and PRESS require slice-selective RF pulses, for which good adiabatic pulses are not available.

Spectroscopic Imaging (Chemical Shift Imaging)

Spectroscopic imaging (SI, also known as Chemical Shift Imaging—CSI) produces spectra for each member of a 2d or 3d grid, using a single excitation RF pulse followed by phase-encoding gradients [57]. For 2D-SI a slice-selective RF pulse is required, while for 3D-SI a non-selective pulse is used, which is better for use with surface coils. In principle it is possible to measure peak areas for a given metabolite in each cell and create a metabolite map. However with the voxel sizes often used for ^{31}P SI (e.g. 3 cm) this is not always useful.

Unlike single-voxel techniques the grid can be shifted after acquisition to make a cell line up with a target tissue

Table 6: Comparison of CSI and Single voxel techniques

	Single voxel	CSI
Specification of VOI		
Number of volumes	1	Typically ~512 (i.e. 8 × 8 × 8)
Voxel specification	Must be specified before measurement	1. Many voxels available 2. Grid shift can be performed retrospectively
Voxel shape	Dimensions adjustable; also tilt	(Usually) orthogonal grid e.g.$(2\text{cm})^3$ voxels
Voxel Integrity		
Edge definition	That of slice	Point spread function effects
Chemical shift displacement artefact	Yes (in each direction)	No
Sensitivity		
Relaxation losses	T_2 (STEAM, PRESS)	Negligible (basic implementation)
Other losses	Imperfect RF pulse profiles and flip angles. STEAM loses 50%.	Phase-encoding loses 13% in each dimension
Conformation to target	Usually good	Sometimes poor. Addition of small voxels does not recover SNR of the larger corresponding voxel.
Other aspects		
Minimum number of acquisitions	1	Many
Use with Tx/Rx surface coils	ISIS OK; STEAM and PRESS not good	OK with adiabatic excitation pulse

of interest. However the edges of the cells are blurred by a process known as Fourier bleed, which leads to signal leakage into adjacent voxels [58]. In the presence of motion this can cause leakage into quite distant voxels [59,60]. Some of these effects can be mitigated by suitable apodisation before the spatial Fourier transform [61] or by weighting of the number of acquisitions for each phase-encoding step [62].

For an N × M array it is necessary to acquire N × M individual transients into a data matrix, from which the spatial information is recovered by a 2D (or 3D) Fourier transform. Thus the minimum number of transients for an 8 × 8 × 8 matrix is 512, giving an acquisition time of about 8.5 minutes if TR = 1s.

A summary of the relative merits of single voxel methods and spectroscopic imaging for ^{31}P acquisition is given in Table 6.

Double-Resonance Acquisition Schemes

Double resonance methods excite spins of a different species (e.g. ^{1}H) in addition to those that are being detected (^{31}P) within the same measurement sequence. In the context of *in vivo* spectroscopy the aim is usually to improve the signal-to-noise ratio, although they can also be used for spectral editing. Not all scanners are capable of performing these studies. The main classes of sequence are outlined in Table 7; the references should be consulted for a more detailed description.

Table 7: Features of double resonance techniques

Name of technique	Method	References	Mechanism	Result
Nuclear overhauser effect	Saturation of ^{1}H spins during ^{31}P recovery	[169,170]	Dipolar coupling	Signal enhancements of up to 50%
Decoupling	Saturation of ^{1}H spins during ^{31}P acquisition	[171,172]	*J* coupling	Collapse multiplets to singlets e.g. phosphocholine improves resolution and sensitivity
Polarization transfer	Simultaneous pulsing of ^{1}H and ^{31}P (large range of different schemes, e.g. INEPT, DEPT, cross-polarization etc.)	[44,45]	*J* coupling	Signal enhancements on coupled spins

Spectral Analysis

Chemical Shift Referencing

For measurements *in vivo* it is necessary to have an internal peak as a chemical shift reference. Historically PCr was used (defined to be 0 ppm), as the pKa is 4.3, and therefore the chemical shift change is very small in the range of pH values found in tissue. Many of the early *in vivo* ^{31}P MRS studies were performed in muscle in which PCr is a dominant peak. For tissues that do not contain PCr (for example liver, and many tumors) alternatives include the phosphodiester peaks (GPE at 3.6 ppm and GPC at 2.96 ppm), and α-NTP (-7.5 ppm). Where ^{1}H spectra are also acquired, the signal from tissue water can also be used as a reference [63].

Measuring of Peak Areas

A large range of methods have been suggested for the measurement of the peak areas in MR spectra. In the early days both cutting-and-weighing and "triangulation" (approximating the peak as a triangle, and calculating the area from measured base and height) were used. When used consistently these gave quite reasonable results. However, both these methods perform poorly in the presence of overlapping peaks or broad bases to the peaks. Today it is more usual to model the spectrum as a series of peaks of particular shapes, and to fit such a model to the data. This approach can be performed both in the frequency domain and in the time domain. Most scanners are supplied with some frequency-domain fitting routines. A series of time domain methods have been evolving under the umbrella of MRUI (magnetic resonance user interface [64,65]) of which a Java version of the Amares algorithm is the current implementation of choice. This method can utilize quite a large amount of prior knowledge, thus reducing the number of free variables and improving the results of a fit.

A totally different approach, LC Model, uses spectra obtained from real solutions at a given pH and temperature rather than simulated spectra [66]. While principally used for ^{1}H spectral analysis it may also be used for ^{31}P.

Estimating Metabolite Concentrations

For many purposes it is sufficient to measure the area of one peak relative to another. This is simple and avoids the errors introduced by trying to obtain absolute values of the concentration. However it does not define which peak has changed, requires good agreement on acquisition conditions before results acquired at different institutions may be compared, and does not permit comparison with results of biochemical measurements.

Calculation of absolute concentrations requires

1. knowledge of the peak area relative to the area from a compound of known concentration;
2. correct values of T_1 and T_2 of both compounds to correct for relaxation effects during the sequence;
3. knowledge of the relative spatial distribution of both compounds and of the sensitivity of the RF coil, to correct for differences in excitation and receive efficiency.

In practice this is far from straightforward [67–72]. The known compound may be an external sample measured in the same study, or a test object measured in the same location as the tissue of interest in a subsequent measurement. Endogenous compounds (e.g. concentration of NTP) are also sometimes used, although one can never be quite sure that the concentration or relaxation times have not changed. Measurements with surface coils are particularly problematic owing to the spatial variation of the RF field, although in principle it is possible to correct for this [73].

Examples of ^{31}P MRS *In Vivo*

Some measured values of metabolite concentrations in different tissues are given in Table 2.

Skeletal Muscle

Muscle is characterized by high PCr, NTP and Pi. ADP is largely bound to macromolecules and is therefore largely MR-invisible.

One particular feature of ^{31}P MRS studies of muscle is that by exercising the muscle (usually within the magnet) dynamic measurements are possible. Thus many protocols measure resting metabolite levels, followed by exercise and recovery to permit measurement of fluxes in the metabolic pathways involved. Exercise is sometimes performed with cuff ischaemia to evaluate non-oxidative phosphorylation. Reviews are available in [74,75].

^{31}P MRS has been used to study many factors influencing muscle metabolism. These include,

- obesity [76] and level of fitness [77];
- age (Pi/PCr increases, ATP/totalP falls) [78];
- gender—the energy cost of contraction is twice as large in untrained women as men [79]; females have lower resting pH [78];
- creatine supplementation leads to increased muscle PCr but there with no change in recovery rates of ATP, Pi, pH, PCr, or muscle strength and endurance [80];
- muscle fibre distribution by analysis of Pi width at end of exercise [81];
- muscular dystrophy—less acidic than controls, pointing to deficit in glycolytic lactate production (perhaps owing to reduced glucose availability) [82];
- evaluation of reported weakness and fatigue, e.g. in juvenile variant of dermatomyositis significant metabolic abnormalities were observed—mean ATP and PCr

35–40% below normal, suggesting defective oxidative phosphorylation in mitochondria of diseases muscles [83];

- Studies of muscle energy metabolism, including coupling of ADP levels to glycogenolysis to regenerate ATP [84], non-oxidative ATP metabolism and acidosis [85];
- McArdles syndrome, a lack of phosphorylase activity in skeletal muscle that prevents the production of lactic acid under ischaemic exercise, and is therefore elegantly demonstrated by an absence of acidification with 31P MRS [86];
- peripheral vascular disease—showing larger changes in PCr utilization owing to reduced oxygen supply, and correlation between PCr and NIRS recovery rate constants [87], but that there may be defective metabolism in mitochondria of claudicating calf muscle [88].

Kidney

A major interest of ^{31}P MRS studies in kidney relate to evaluation of renal transplants. Pretransplant assessment of renal viability found a correlation of PME/Pi with clinical kidney function [89]. Storage may be monitored by effect on intracellular pH [90]. The ATP/Pi ratio has been used to evaluate success of implantation; a ratio of ATP/Pi greater than >1.2 has good sensitivity (92.8%) and specificity (100%) for predicting 3-year (5-year) survival, while a ratio >2.5 predicts for 5-year survival [91]. ^{31}P MRS is also used in experimental studies to improve the transplant technique, for example combined pretreatment with lipid-soluble and water-soluble antioxidants has been shown to lead to better restoration of energy phosphates in kidney subjected to ischaemia-reperfusion [92].

Cardiovascular disease is common in patients with chronic renal failure. Measurements have been performed of the phosphorylation potential of heart in renal dialysis patients and show that the PCr/ATP ratio is significantly reduced [93]. Exercise tolerance of CRF patients in muscle has also been performed [94].

^{31}P MRS permits measurements of metabolite concentrations in normal and diseased kidneys *in vivo* [95]. In advanced renal cell carcinoma it has been found that plasma levels of lysophosphatidylcholine are significantly lower than in control subjects [96].

Renal stone patients have low potassium and magnesium status. ^{31}P MRS has been used to assess the effect on intracellular pH, cytosolic magnesium and phosphorylation potential (PCr/ATP) in muscle [97]. Renal stones have also been analyzed with *ex vivo* ^{31}P MAS [98].

Liver

Liver is characterized by absence of PCr but the presence of a large number of sugar phosphates in the PME region [99].

In liver ^{31}P MRS has been used to assess severity of hepatitis C virus-related liver disease without biopsy [100]; the PME/PDE ratio can distinguish between mild, moderate and cirrhosis disease with specificity and sensitivity of 80% [100]. In addition cirrhosis is characterized by altered hepatic gluconeogenesis [101].

Energy metabolism and phospholipid biochemistry has been studied in the liver of patients with obstructive jaundice. Without treatment patients PME/total phosphate ratio is increased by 50% compared with controls [102].

Lung cancer patients have been found to have elevated PME in the liver, reported to reflect increased glucose flux and gluconeogenesis from alanine [103]. ATP infusion restores hepatic energy levels in patients with advanced lung cancer [104].

^{31}P MRS has also been used to evaluate changes in liver metabolism after surgery [105,106].

Studies in experimental models include hypothermia to reduce hepatic failure under hypoxia, progression of chronic liver disease to cirrhosis, and models to assess damage in acute liver failure.

Brain

A wide range of brain disorders have been investigated using ^{31}P MRS. Elevated GPC, GPE and high energy phosphate (PCr) have been observed in the anterior cingulate of brains of patients with first-episode schizophrenia [107,108], while parts of the brain of patients with bipolar disorder are characterized by reduced pH [109].

Lithium, used to treat depression, changes levels of ATP and of PME [110,111]. The pH is also observed to be reduced, but this may be the effect of disease rather than lithium [112]. Lithium is presumed to reduce intracellular *myo*-inositol, and increase levels of inositol monophosphate precursors (included in PME but not resolved).

In alcoholics lower concentrations and enhanced transverse relaxation of white matter phospholipids is observed, reflecting changes in membrane composition and rigidity [113].

While most studies look at resting levels of metabolites, some studies are now looking at the effects of visual activation on high-energy phosphates and pH in normal volunteers and in patients, for example those with mitochondrial disease [114].

A few studies have looked at spectral changes with age. In particular, it has been found that PE dominates in neonate, falling with age (as does PC). GPE, GPC, and PCr increase in concentration with postnatal age [115].

Heart

For review see [116]. In patients with haemachromatosis, often associated with cardiomyopathy, the PCr/ATP ratio in the left ventricle is significantly reduced compared with healthy volunteers, possibly reflecting mitochondrial impairment due to iron overload [117].

PCr/ATP is reported to be reduced with age [118], dilated cardiomyopathy [119], multiple sclerosis [120] and aortic stenosis [119]. The PCr/ATP ratio recovers towards control values in the latter group following surgical valve replacement [121]. In hypertensive patients the unstressed PCr/ATP ratio is variously reported as being normal [119] or reduced [122]. No reduction in PCr/ATP is observed in the non-infarcted septal myocardium of patients compared with controls [123]. Heart transplant patients studied within 24 h of a biopsy showed reduced PCr/ATP compared with controls, but with no strong correlation either with biopsy scores or with subsequent biopsies [124].

Stress tests show that cardiac patients with some forms of ischaemia showed a decrease in PCr/ATP even under light exercise, while no decrease was observed in patients whose hearts were non-ischaemic [122]. (*Note:* ^{31}P MRS measurements in the heart are often contaminated by signal from blood. In particular signal from 2,3 diphosphoglycerate overlaps with Pi signal making it hard to quantify.)

Tumors

A good review of the use of ^{31}P MRS in cancer is given by Negendank [125]. In particular ^{31}P MRS has been important in demonstrating that, contrary to expectation, the intracellular space of many cancers is alkaline [125]. In addition PE and PC have been shown to be elevated in many cancers. The ratio of PME/NTP is now being evaluated as an early indicator of response. There is also increasing evidence that both PME/NTP [126] and NTP/Pi [127] in the pretreatment spectrum may be able to predict response to treatment. Separate studies in patients with non-resectable soft tissue sarcoma have shown that changes in PME/ATP predict response to isolated limb perfusion to permit limb sparing [128].

Patients with non-small cell lung cancer have infusion of ATP to restrict weight loss; an increase in liver ATP (8.8 → 12.2%) is observed [104]. PME levels have also been observed to be higher in the weight-loss patients [129].

In breast cancer, there is an association between transformation and an increase in the phosphomonoesters (PMEs), while a decrease in PME content after treatment is associated with response to treatment as assessed by tumor volume [130]. In normal premenopausal breast a consistent pattern of changes is seen in the ^{31}P MR spectrum during the menstrual cycle, suggesting a potential application in assessing effects of exogenous hormones such as contraceptives or hormone replacement therapy which may increase breast cancer risk [131].

^{31}P MRS can also be used as marker of drug action (based on results of model systems and leading into clinical trials, e.g. 17-AAG [132]).

^{31}P MRS has been used extensively in experimental studies on effects of drugs, optimization strategies (reversing pH gradient, carbogen breathing), radiation etc. on cell systems.

Drug Detection

While ^{31}P MRS is normally used for study of endogenous compounds it also has the potential for monitoring uptake and metabolism *in vivo* of drugs that contain ^{31}P nuclei. The sensitivity is much lower than that of radionuclide labels, but the method has the advantages of being able to follow the metabolism of the drug, is not limited by a radioactive half-life, and makes use of the native compound without further chemistry required to perform the measurement. One example application has been the investigation of the alkylating agent ifosfamide. ^{31}P MRS studies have examined ifosfamide metabolites in body fluids [133], preclinical model systems [134,135], and in patients [136].

Radio Frequency Coils for Magnetic Resonance Spectroscopy

Boguslaw Tomanek
Institute for Biodiagnostics, Winnipeg, Manitoba, Canada

The Requirements

Localized magnetic resonance spectroscopy (MRS) as well as magnetic resonance imaging (MRI) require both maximal signal-to-noise ratio (SNR) and radio frequency (rf) field (B_1) homogeneity. While MRI allows the application of post-processing methods, such as correction of image intensity to correct B_1 inhomogeneities, MRS is more demanding from this point of view leaving very little opportunity for post-processing and requiring mostly hardware improvement. In addition, due to the smaller volume of interest (VOI) and particularly low metabolite concentration, there is less signal available in MRS than in MRI. The time required to obtain good spectra is long pushing the SNR requirements to the limits.

The Issues

Unfortunately, when considering rf probe construction the requirements of high SNR and good B_1 homogeneity usually conflict. The SNR depends on many factors such as the strength of the magnetic field, geometry, resistance and quality factor (Q) of the coil, sample size, filling factor of the coil, type of the reception (linear or circular), etc. The B_1 field distribution depends on the geometry of the coil, its type (transmit and receive or transmit/receive), and the material used for the coil construction.

When designing an rf coil all of these factors plus patient access to the coil and the direction of the magnetic field relative to B_1 must be considered. Therefore whilst a coil may work very well, providing good SNR and B_1 homogeneity, at a low frequency (say 1.5 T) it may not work so well (or even not at all) at a higher frequency (say 3 T). A trade-off amongst all these factors is inevitable and there is no simple, consistent recipe for making a perfect rf coil that fulfills all the requirements for MRS.

With this knowledge of the problems we shall consider some of the requirements for the MRS coil: SNR, B_1 distribution, coil geometry, method of reception as well as some other factors. For this discussion we will be ignoring other potential problems associated, for example, with relaxation times, pulse parameters or even eddy currents induced in the coil, gradients coil, or in the cryostat due to the short TE (fast gradient switching) required frequently in MRS.

The first expression describing the NMR signal was derived by Abragam [1], who showed that the electromagnetic force (emf) induced by the nuclear magnetization in the receiving coil can be expressed as:

$$\Psi_{\mathrm{rms}} \propto K\eta M_0\,(\mu_0 Q\omega_0 V_{\mathrm{c}}/4FkT_{\mathrm{c}}\Delta f)^{1/2} \qquad (1)$$

where K is numerical factor depending on the coil geometry; η is the filling factor, i.e. a measure of the fraction of the rf field volume occupied by the sample; M_0 is the magnetization (proportional to the magnetic field strength); μ_0 is the permeability of free space; Q is the quality factor of the coil; ω_0 is the Larmor frequency; V_{c} is volume of the coil; F is the noise figure of the preamplifier; k is Boltzmann constant; T_{c} is the probe temperature; Δf is the bandwidth (in Hertz) of the receiver. As one can notice, the SNR is proportional to the 3/2 power of the magnetic field ($M_0 \sim \omega_0$). This is true assuming that other factors are independent of frequency. This is an important statement that will be analyzed in detail later.

The above revelation explains the historical tendency to introduce stronger and stronger magnets in an effort to increase SNR. Therefore, magnets generating a magnetic field of 20 T were produced for *ex vivo* MRS, while whole body MRI systems have reached 7 T, and even higher field magnets are under construction.

However, a closer analysis of the dependence of noise mechanism with frequency reveals a less favorable SNR relationship. The rule of thumb is a linear relationship between the SNR and the magnetic field strength. While the Equation (1) gives a reasonable estimate of the SNR, it does not consider other factors such as rf coil shape, preamplifier noise, and other electronic components whose performance depends on, and usually degrades with, the frequency. Thus, innocent engineers constructing rf coils for MRI systems are often blamed for insufficient increase in SNR as expected from MR theory.

Probably the most comprehensive summary of the SNR and its relationship with MR hardware was given by Hoult *et al.* [2,3], who applied reciprocity theory and

Graham A. Webb (ed.), Modern Magnetic Resonance, 1163–1170.
© 2008 *Springer.*

considering the sources of noise they obtained:

$$\psi_{\mathrm{rms}} = \frac{K(B_1)_{xy} V_s N \gamma \bar{\lambda}^2 I(I+1)}{7.12 k T_{\mathrm{s}}} \cdot \left(\frac{p}{F k T_{\mathrm{c}} l \zeta \Delta f} \right)^{1/2} \times \frac{\omega_0^{7/4}}{[\mu \mu_0 \rho(T_{\mathrm{c}})]^{1/4}} \qquad (2)$$

where $K(B_1)_{xy}$ is the effective field over the sample volume produced by unit current flowing in the receiving coil, p is the perimeter of the conductor, l is the length of the conductor. The above factors are dependent only on coil geometry. T_{c} is the temperature of the coil, $\rho(T_{\mathrm{c}})$ is the resistivity of the material from which the coil is made, ζ is the proximity factor, F is the quality of the preamplifier.

From the above equation one can see that SNR seems to be proportional to $\omega_0^{7/4}$. However, in the above equation Q and η have been replaced by a function ζ, that is also ω_0 dependent. Hence, SNR is not always proportional to the 7/4 power of the frequency. A careful reader will also notice that SNR depends on the type and geometry of the coil (factors: K, l, ρ).

The Solenoid Coil and Saddle-Shape Coil

As seen from Equation (1) SNR can be improved by an increase of the Q factor, which depends on the coil resistance and inductance. The Q of a solenoidal coil is proportional to $\omega_0^{1/2}$ only well below self-resonance frequency of the coil, but when approaching the self-resonance frequency the Q drops away from the $\omega^{1/2}$ line and prevents further increase of the SNR as one could expect from Equation (2). The only solution is then to decrease the self-resonance frequency of the coil by the reduction of the coil inductance or/and resistance. This can be achieved by reducing the number of turns for a solenoidal coil. A detailed analysis of solenoidal and saddle-shape coils [2], the most common coils producing very homogenous rf field, yield to the conclusion that the solenoidal coil performance is about three times better that the saddle-shape coil with comparable dimensions. As shown above, a solenoidal coil would be a very good candidate for the rf probe providing good B_1 homogeneity and good sensitivity within a reasonable range of frequencies. However, further consideration should be given when the direction of the main magnetic field is considered. To produce the NMR phenomenon (to flip the magnetization), the direction of the rf field must be perpendicular to the main magnetic field. This creates additional constraints when selecting an rf coil for MRS and MRI. Unfortunately, the direction of the rf field produced by the solenoidal coil (along its long axis) prevents almost all applications for horizontal bore magnets. Such a coil could not be made for a human head, for example, since it would require the head to bend by 90°.

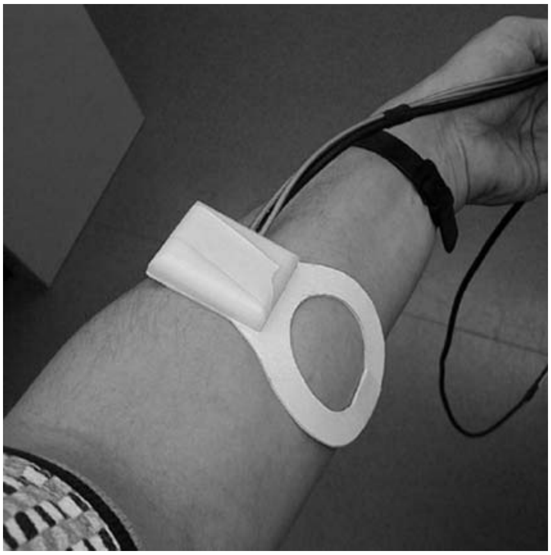

Fig. 1. Surface coil for 3 T MR system (National Research Council, Institute for Biodiagnostics, Winnipeg, Canada).

However, a single loop solenoidal probe, namely a surface coil (Figures 1 and 2), overcomes this obstacle. In addition, in MRS we are interested in small voxels to detect small abnormalities. Thus a volume coil is usually not required or even not welcome. A surface coil (Figure 2A) provides a very good SNR produces but also a very inhomogenous B_1 field (Figure 2B). Along the axis the B_1 field can be calculated, neglecting interaction of the tissue with the rf field, based on Bio-Savart law:

$$B_1(x) = \frac{\mu_0 I}{2} \frac{a^2}{\sqrt{(a^2 + x^2)^3}} \qquad (3)$$

where a is the radius of the coil, x is the axial distance from the center of the coil and I is the current flowing through the coil.

Surface Coil

So far we have concluded that the best solution from the point of view of the SNR is the application of the surface coil. Further improvement in SNR by up to $\sqrt{2}$ can be achieved by the application of the quadrature surface coil [4,5]. However, the perfect quadrature rf coil requires the creation of equal and orthogonal B_1 fields (Figure 3), which is difficult to achieve for a surface coil. The most common configuration for the quadrature surface coil [so-called circular polarized (CP) coil] is the use of a shaped butterfly coil and a standard surface coil to

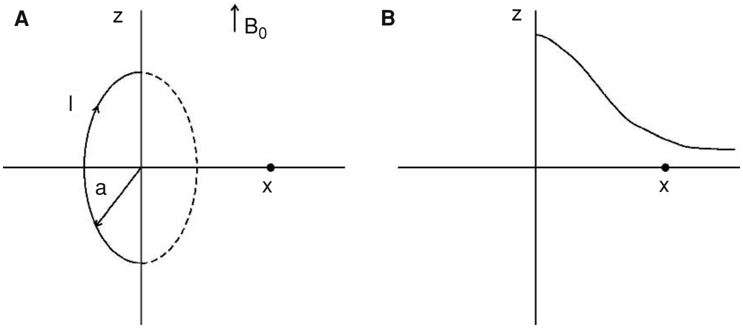

Fig. 2. (A) Geometrical model of the surface coil: A current I flows in the ring of a radius. (B) The B_1 field magnitude generated by the surface coil along the x-axis.

create two orthogonal or, more often—nearly orthogonal rf fields. While such a coil provides larger field of view (FOV) it gives only modest (less than $\sqrt{2}$) increase in SNR due to the lack of perfect perpendicularity or/and unequal amplitude of B_1 fields. The quadrature surface coil requires, however, less power when compared to the linear coil (LP coil). Let us now answer a question: what is the optimum diameter of the surface coil to maximize SNR within the specific VOI? In attempt to find the answer we will take a closer look at the sources of noise. Neglecting radiation losses, the noise picked up by the receiver (N) is proportional to the sum of the effective resistance of the sample (R_s) and the resistance of the coil itself (R_c):

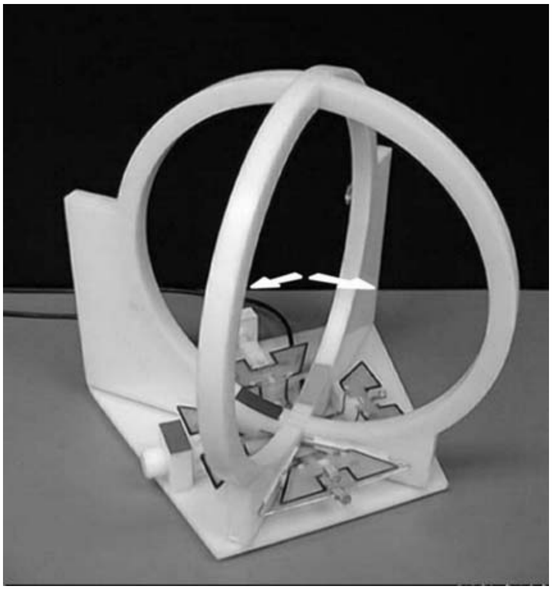

Fig. 3. Two surface coils assembled into the quadrature probe. The two perpendicular B_1 fields are marked with arrows (National Research Council, Institute for Biodiagnostics, Winnipeg).

$$N \propto \sqrt{R_s + R_c} \tag{4}$$

The resistance of the sample comes from two sources: dielectric losses (that can be minimized using distributed capacitance and proper capacitor shielding) and inevitable inductive losses associated with rf induced eddy currents within the sample. Hoult and Lauterbur [3] showed that

$$R_s \propto \omega_0^2 B_1 b^5 \tag{5}$$

where ω_0 is the Larmor frequency, B_1 is the rf field produce by unit current, b is the sample radius.

One can see that the sample losses increase with frequency and become predominant at a higher frequency. It can be shown [5,6] that in such a case SNR per unit volume depends on the surface coil radius a as:

$$SNR \propto 1/a \tag{6}$$

This equation, as explained in detail by Hayes and Axel [6] is exact only at the surface of the coil, however, it gives a good estimate of the dependence of the SNR of the coil radius. Thus, the smaller the coil the higher SNR hence surface coils which are so popular in MRS. The diameter of a surface coil may be chosen to give maximum SNR at a particular point within the sample. If sample loses are dominant (above 1T), maximum SNR can be obtained for $a = d/\sqrt{5}$ where a is the coil radius and d is the distance from the coil center [7,8]. When the coil losses are dominant [9] then the optimum SNR occurs for the coil radius $a = d\sqrt{2}$. The exact optimum diameter depends on the frequency and the sample. For example, at 3T and 1 cm^3 VOI placed at $d = 2.5$ cm from the coil the maximum SNR occurs, as found experimentally, when the coil diameter is 4.0 cm. This diameter lies between the coil loss dominant case (7.1 cm) and the sample loss dominant case (2.25 cm).

Superconducting rf Coils

The noise in NMR comes also from the coil and depends on the temperature:

$$R_c \propto \sqrt{\mu\mu_0\omega_0\rho(T_c)} \tag{7}$$

This equation could be used to decrease noise thus increase SNR by decreasing the coil resistance. The recent introduction of high-temperature superconductive materials [10] allowed new possibilities for this increase of SNR. This new technology, however, brings new technical challenges, such as cryocooling devices, high-temperature superconducting material, patient safety, etc., and has not yet found clinical applications. It is mostly used in micro-MRI research[10,11] and in chemistry MR labs.

Phased Array

The success of the surface coils in producing high SNR also, unfortunately, reduces FOV. To rectify this limitation a phased array technology was introduced to extend the FOV over the sample [12]. Each element of the array, coupled to an independent receiver channel, works as an independent surface coil maximizing SNR and increasing FOV (Figure 4). Recently, the so-called parallel imaging techniques using phased array have been introduced into MRI reducing the total acquisition time [13,14]. Despite the costs and complexity of the electronics 8, 16, or even 32-channel phased array coils are become a clinical standard. Because complexity of the MRS experiment (e.g. requirements of the phase control of rf pulses) the phased array technology is only slowly being introduced into MRS.

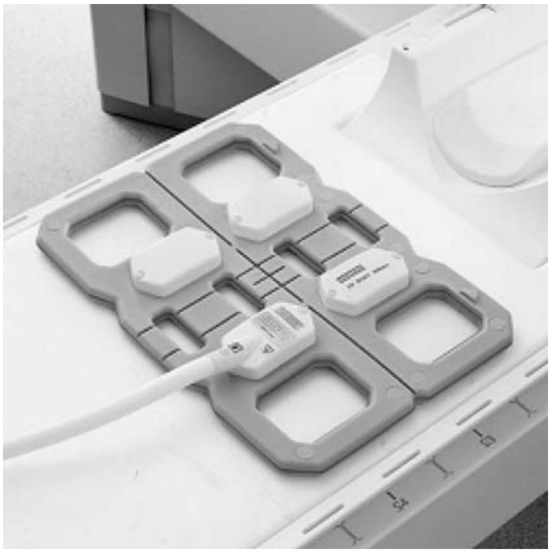

Fig. 4. Phased array (Siemens, Germany).

B_1 Homogeneity Vs. SNR

In quantitative MRS, metabolite concentration cannot be properly evaluated when the rf coil produces an inhomogenous B_1 field. Even excellent MRS techniques [15,16] require homogenous transmit and receive rf fields. The inhomogenous B_1 field causes a variety of inconveniences, such as imperfect spatial localization [17,18], poor water suppression [19], and contamination from outside the voxel of interest [20]. B_1 inhomogeneity also prevents the quantification of metabolites concentration as the spectra would then depend on the tissue–coil orientation. This would cause different spectra from the same tissue, which is of particular concern for heterogenous tissues such as tumors. Therefore, the application of rf coils producing spatially uniform B_1 field is preferred. This conclusion contradicts the previous one we recorded, i.e. that the best SNR is produced by a surface coil, which unfortunately produces a very inhomogenous rf field. Volume coils, such as the saddle coil, the solenoidal coil, the Adelman-Grant, the Helmholtz pair, and birdcage (Figure 5), etc. produce very homogenous field. Unfortunately, they suffer from low sensitivity and

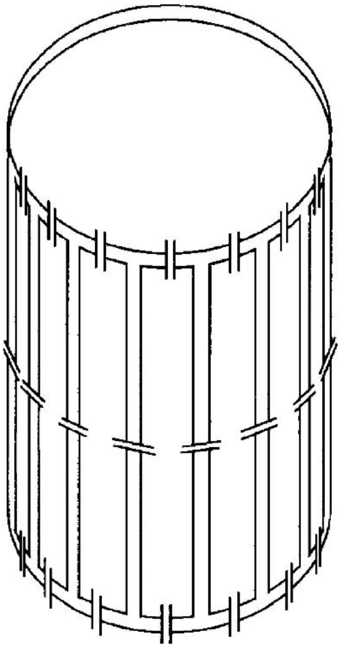

Fig. 5. Geometrical model of the 16-element birdcage rf coil.

high power requirements compared to the surface coil. Because the surface coil, as stated before, generates a very inhomogenous rf field, it provides spatially dependent flip angles, which is particularly inconvenient when more than one pulse is used—as is common in MRS.

There are few methods, none of these being perfect, that try to deal with this problem. One of them is the application of adiabatic rf pulses [21,22], that, however, are suitable only for a single-shot techniques. They also require high power [thus increased specific absorption ratio (SAR)], strong gradients, and they also limit echo time (TE). A very elegant solution was proposed by Bendall [23] who proposed the application of multiple inhomeogenous rf coils, that take advantage of the spatial dependence of flip angles to increase the localization and allow a larger FOV.

Transmit-Only and Receive-Only Coils

So far we have only considered coils that are transmit and receive (T_x/R_x). In this case the excitation and receive rf profiles are identical. However, in most clinical systems the standard configuration is volume coil—transmit-only (T_x), local coil—receive-only (R_x). This arrangement comes mostly from manufacturer convenience, since in this case the sample is excited always with the same, usually body rf coil and SAR is calculated for this one coil only. This configuration allows also easy attaching other receive coils dedicated for any particular body part. The set-up also avoids problems with inhomogenous excitation, yet reception remains non-uniform. Other difficulties with separate T_x and R_x coils are associated with SAR limits: the large body coil requires a lot of rf power (typically for 3 T clinical systems up to 30 kW) due to the unnecessary excitation of organs outside the VOI. The coupling between the coils [24–26] is yet another problem. All these challenges increase rapidly with the field strength.

Leaving aside SAR issues (which is particularly a pulse sequence issue) we will consider decoupling. The decoupling of the coils is needed to avoid any current being generated in the receive coil during the transmission. The problem here is that, during the transmission, mutual inductance between coils current is induced in the receiving coil, which generates an opposing B_1 field. During the receiving period the noise currents produced by the larger T_x coil are also induced in the receive coil. Both effects cause the degradation of the SNR and artifacts in MRI. To separate transmit and receive coils, crossed diodes (Figure 6) are used in series with the T_x coil as well as in parallel with the tuning capacitor of the receive coil. The solution as proposed by Bendall and Edelstein *et al.* [24] is to detune the receive coil during the power transmission and detune the T_x coil during the receiving period. The cross diodes in the T_x coil conduct during the transmit (high voltage) thus the coil is resonating at the Larmor frequency; during the receive period, when the current is small, the open diodes prevent the current from flowing in the T_x coil. An alternative to using active switching may also be used: the receive coil is actively decoupled using externally driven PIN diodes. The diodes are placed at a certain distance from the capacitance so the cable creates an inductance between the diodes and the capacitance. During the transmission the diodes are switched on and create a short-circuit. This way the R_x coil is not active. The same assembly could also be used without an external drive (passive mode): during transmission the small current, induced in the R_x coil by T_x coil turns the diodes on and such a circuit has a high impedance and prevents current flow in the R_x coil. During the reception the current is low the diodes are by-passed by the signal. In addition the T_x and $R_x$coils can be design to be electrically orthogonal each to other if the space allows.

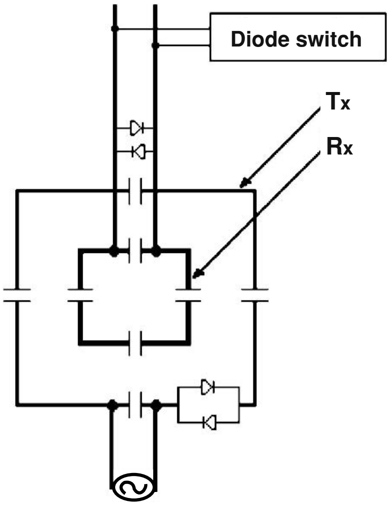

Fig. 6. Decoupling model of the transmit and receive coils. The cross diodes in the transmit coil conduct during the transmission while diodes in the receive coil are open during the receiving. The receive coil is actively decoupled using externally driven PIN diodes during the transmission.

At higher magnetic fields (>3T), when the rf wavelength within the sample becomes comparable with the sample size, and a body rf coil is used for the excitation, a new problem arises: the complex interaction between the body tissue and the rf field. This problem is discussed in detail by Hoult [27].

The other problem when using the separate transmit and receive coils is that the relative direction of B_1 field may be different for transmit and receive coils. This may also degrade the signal [28–30] as well efficacy of the shimming procedures [31,32].

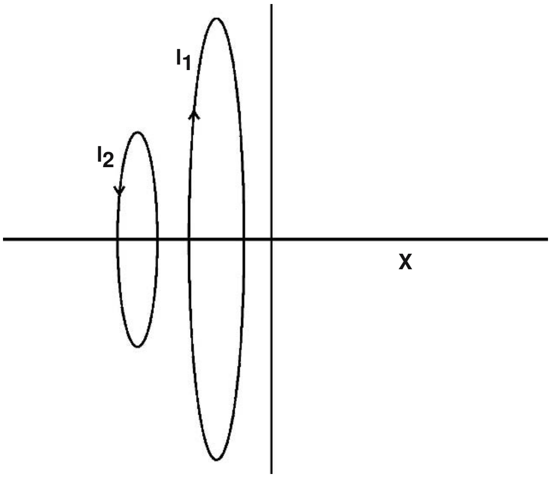

Fig. 7. Multi-ring surface coil assembly. Currents I_1, I_2 flow in opposite directions to compensate B_1 inhomogeneity of each separate surface coil.

Local rf Coils with Improved B_1 Homogeneity and SNR

An interesting solution [33,34] to generate identical fields for both excitation and receiving periods was proposed: the combination of surface coil sensitivity with volume coil homogeneity. This idea uses two or more inductively coupled rings of different diameter, carrying current in opposite directions (Figure 7). Such an assembly produces homogenous, identical excitation and receiving B_1 in the desired region of interest while providing SNR comparable with the surface coil. While this coil seems to be perfect for MRS its major disadvantage is fixed VOI, what in practice means that for each VOI another rf coil should be constructed. The possible applications of this coil include skin or thyroid MRS, where the VOI varies little between subjects.

Another solution to increase SNR is the application of rf shields [35]. This concept works particularly well for breast MR imaging and spectroscopy. If the B_1 field is perpendicular to the chest wall, a Helmholtz pair probe gives good field homogeneity over the breast and good chest penetration, but significant chest power dissipation with concomitant loss of SNR. Weak B_1 fields covering the large volume could generate substantially larger losses than bigger fields confined to a smaller volume. Thus, the combination of the Helmholtz pair with the rf shielding of the chest wall away from the breast brought a substantial improvement of up to a factor of two when compared with the standard breast rf coil.

Implanted rf Coils

For imaging of some small, deeper organs, for example, the spinal cord, the rf surface coils are used but due to their field drop with the distance from the coil, they bring even more challenges in the coil design. Because of that the SNR within the VOI is compromised due to the low and inhomogenous B_1 field. The noise source from the "disturbing" tissue (e.g. fat) between the coil and the VOI, where the B_1 is strong, is yet another source of noise. One of the possible ways of dealing with this problem is the application of implanted rf coils [36,37]. Briefly, the implanted coil consists of a loop of wire (the "actual" coil generating and receiving rf signal) tuned to the Larmor frequency, and a matching ring inductively coupled to the loop. Thus, no electrical connections between the implanted coil and the external matching network are required. Such an implanted rf coil provides better SNR than the surface coils, thanks to their close proximity to the VOI. It also brings some disadvantages: the procedure can no longer be considered non-invasive, and as such its application to human MRS becomes questionable. In addition, implanted coils are vulnerable to various failure modes including mechanical and electrical. The blood and body fluids can change the coil loading or even its position, thus SNR during the MRS experiment. In some cases matching also becomes difficult due to the restricted access of the matching coil and the loop.

Microcoils

When using ultra-high fields and ultra-low samples ($\sim$1 μl) new challenges arise such as susceptibility, low filling factors, increased coil noise, skin depth, etc. As shown [38,39] for the coils of diameter of order of millimeters or less the major source of the noise comes from the coil. Therefore, special attention must be placed to the resistance of the coil. A so-called single and multilayer rf microcoil, using metallic foil rather than wires was used to enable very high field *ex vivo* MRS [40].

The performance of the standard rf surface coil can also be surpassed by a microstrip rf surface coil for extremely high-field MRI as reported by Zhang *et al.* [41]. This design is based on the microstrip transmission line concept that does not require the use of lumped elements. The microstrip surface coil can be used up to 500 MHz. Such a coil gives about 20% better SNR when compared to the standard surface coil [41]. This concept can also be used with any other configurations such as quadrature volume or phase array rf coils. Such an assembly resonates at the frequency $f = c/2L\sqrt{\varepsilon_{\text{eff}}}$ where c is the speed of light, L length of the coil, ε_{eff} dielectric constant of the material. This concept has not yet found a clinical use but may be promising.

Dual Frequency rf Coils

Quantification of the tissue metabolites by heteronuclear MRS can be achieved using dual frequency rf coils. The dual frequency coils allow simultaneous measurement of two nuclei frequencies, without disruptions associated with exchanging coils for imaging and spectroscopy examinations. One is usually ^{1}H while the other is phosphorus (^{31}P), sodium (^{23}Na), or other nuclei (^{23}Na). The proton frequency is often used for high-resolution imaging that allows lesion localization while the other frequency is used for spectroscopic lesion analysis. The proton frequency also provides the sensitivity needed for shimming. Dual frequency coils have to deliver SNR of the single frequency rf coil as well as produce homogenous rf field over the sample volume. To achieve these needs double-tuned quadrature birdcage coils were developed. One example is a design based on two coaxial birdcage coils resonating at ^{31}P and ^{1}H frequencies each. Such a coil provides excellent ^{31}P performance although lower SNR for ^{1}H when compared to a single frequency ^{1}H coil. This design allows altering the ^{31}P coil length thus can provide better SNR sacrificing however B_1 [42]. Another solution is to use the same sized coils and tune every other leg of the coil to the desired frequency, using trap circuits and inductive matching to optimize the coil [43,44].

An elegant design based on transmission line resonators for a volume quadrature, double-tuned coil was also proposed by Vaughan [45]. In our work to even further increase SNR for two or more frequencies, a dual frequency surface coil was designed using frequency splitting circuitry [46]. This construction allows concurrent ^{1}H and ^{31}P MRS and provides the same B_1 homogeneity for both frequencies almost without reducing SNR when compared to the single frequency rf coils. Such a design was further improved by combining a multi-ring coil concept [47] with a splitting circuit. This coil provides better SNR than a volume coil within the specified VOI, but about 70% of the SNR of the single frequency surface coil, however, it creates homogenous and identical B_1 fields for both frequencies over the desired VOI. The dual frequency coils require dual frequency receive and transmit channels, which are still not standard in clinical MRI systems, hence their limited application.

Summary

This chapter describes the most common rf coils for MRS as well as possible methods of improving SNR and B_1 homogeneity. As concluded, there is no perfect rf coil for MRS. Compromises must be made among SNR, B_1 homogeneity, voxel size, total experiment time, size, and position of VOI. The choice of the coil depends on the application, field strength, available MRI system, and the patient position. The volume coil—transmit and surface or local coil receive-only seem to be the most effective, yet not perfect rf coil configuration.

Glossary of Terms

SNR	signal-to-noise ratio
B_1	rf field
M_0	magnetization
μ_0	permeability of free space
Q	quality factor of the coil
K	numerical factor depending on the coil geometry
η	filling factor
ω_0	Larmor frequency
V_c	volume of the coil
F	noise figure of the preamplifier
k	Boltzmann constant
T_c	probe temperature
Δf	bandwidth (in Hertz) of the receiver

Introduction

Acquisition of three-dimensional (3D) spatially localized, water-suppressed one-dimensional (1D) ^{1}H MR spectra has been optimized in human tissues over the last two decades [1–6]. Introduction of automated MRS a decade ago has enabled a 1–2 min pre-scan to calibrate the flip-angle using the transmitter power, to adjust the static field homogeneity (B_0) using the linear gradient shim coils, and to optimize water suppression, which used to be an at least 15 min operation, facilitating the integration of clinical MRS protocols into routine MRI examinations [7]. In ^{1}H MR spectroscopy of human brain, spectral resonances due to methyl, methylene, and methine protons of N-acetylaspartate (NAA), glutamate/glutamine (Glx), creatine (Cr), choline (Ch), *myo*-inositol (mI), GABA, aspartate (Asp), N-acetylaspartyl-glutamate (NAAG), and other metabolites have been identified in the region of 0–4.5 ppm [2–12].

One-dimensional MRS *in vivo* is hampered by the fact that it is difficult to resolve a multitude of peaks existing over a small spectral range of approximately 300 Hz at 1.5 T. Spectral overlap of macromolecules, GABA, and glutathione with the methyl resonances of NAA, Cr, NAAG, and methylene resonances of Glx has also been reported [8,14–15]. Attempts have been made to quantify Glx [16], glucose [17], and other metabolites with only minimal success due to the difficulty in extracting this information from a region with many overlapping resonances. Using spectral-editing techniques, it is possible to select a particular J-coupled metabolite [2,14,18–20]. However, one major drawback of editing techniques is that only one metabolite is optimized at a time assuming that the multiplets of the J-coupled metabolites are well separated. Using the LC-Model post-processing algorithm, quantification of several metabolites in human brain *in vivo* has been reported recently using a basis-set of 10–20 different metabolite spectra *in vitro* [21–23].

Unlike the spectral editing techniques, which target one metabolite at a time, two-dimensional (2D) MRS can unambiguously resolve many overlapping peaks nonselectively *in vitro* as shown by Ernst and co-workers two decades ago using the vertical bore NMR spectrometers [24–25]. 2D-MR spectroscopy enables converting a crowded overlapping 1D MR spectrum to a better-resolved 2D spectrum through the addition of a spectral dimension. Instead of a standard 1D spectrum plotting intensity vs. a single-axis (i.e. chemical shift), 2D MR spectroscopy techniques produce a 2D spectrum plotting intensity vs. two axes, the dimensions of which depend on the specific 2D MR technique [25]. Better dispersion of several metabolite peaks and improved spectral assignment make the proposed technique more attractive. It seems natural to explore the clinical potentials of 2D MRS techniques of human tissues *in vivo*.

There have been several attempts during the last 15 years in the implementation and evaluation of 2D NMR spectroscopy on *in vivo* MRI scanners and MR spectrometers [26–30]. The aim of this chapter is to discuss the recent progress on the implementation of selected localized 2D MRS sequences on the whole body 1.5 T and higher field MRI scanners. This includes a summary of 1D spectroscopy with and without chemical shift imaging (CSI), followed by single- and multi-voxel based 2D spectroscopy dealing with coherent interactions such as chemical shift and J-coupling. A brief overview of potential artefacts in 2D spectroscopy and simulation is also included.

Single- and Multi-voxel Based 1D ^{1}H MR Spectroscopy

Clinical 1D MR spectroscopy has some important differences and challenges compared to MR imaging. Often how the challenges are resolved define the particular technique of spectroscopy with its limitations and advantages. Some of these basic challenges are pertinent to water and lipid suppression, spatial localization of the volume of interest (VOI) including single vs. multiple volume elements (voxel) as shown in Figure 1.

Water and Lipid Suppression

What makes MR imaging quite sensitive is the large concentration of water in biological tissue. However, the dominance of water limits spectroscopy since the metabolites are tens of thousands of times lower in concentration than water. Thus, in order to obtain a visible signal from the metabolites, MRS techniques must incorporate ways of minimizing or eliminating the water signals. This water suppression can be extended from changes in hardware for data acquisition (digitizers), pulse sequences, to post-processing software. The primary contribution stems from an addition of three frequency selective (water as the target frequency) radio frequency (rf) pulses with arbitrary flip-angles followed by a dephasing gradient to the pulse sequence. These pulses are commonly called the chemical shift selective saturation (CHESS) pulses [5,31]. Instead of water saturation using CHESS, an inversion recovery scheme can also be employed with a 180° frequency selective pulse on water such that excitation of the metabolites can be prolonged until the crossing of the water signal at the null point with known T_1 values [32].

Quite often the lipid signals from either within the VOI or outside of the VOI hold a similar challenge like water. In order to suppress the lipids, the same two approaches utilized in water suppression in terms of pulse sequence modification can also be applied here [33]. The most common approach is the use of frequency selective (targeted at lipids) pulses in conjunction with spatial selection around the edges of the brain called the outer volume saturation or suppression (OVS) slabs. Of course, post-processing software can also contribute to elimination of lipid signals.

Spatial Localization of the Volume

There is a fundamental difference between the localization done in imaging and spectroscopy. Imaging relies on acquisition of the entire proton signal (primarily water and fat) and the differences in frequencies of the signal are attributed to the spatial shifts introduced *via* the application of the frequency encoding gradients during signal sampling to reproduce the selected slice within a plane or a data point in volumetric MRI. A frequency encoding gradient cannot be used in spectroscopy during sampling because the differences in frequencies of metabolites sought after are due to the small chemical shifts and a frequency encoding gradient would corrupt this basic information. However, the demand for volume definition remains, whether single voxel or multiple voxel spectroscopy is done since the metabolite concentration information is sought from a particular voxel and not the whole brain. The most common localization procedure is the use of slice selection and phase encoding gradients. These serve to demarcate the dimensions of the voxel and are operated for a very short duration. The spins then return to the influence of the external magnetic field.

Single Voxel Spectroscopy

The two most popular pulse sequences for defining a small (ranging from 1 cm^3 to 8 cm^3) volume within the anatomy are termed as STEAM and PRESS [3,9,34]. Both PRESS ($90°_{ss}-180°_{ss}-180°_{ss}$) and STEAM ($90°_{ss}-90°_{ss}-90°_{ss}$) use frequency selective RF pulses along with magnetic field gradients to isolate a single volume, called STEAMSV and PRESSSV; however, the timing and the sequence of the pulses has consequences on the sensitivity and the strength of the signal [35].

Multivoxel Spectroscopy or Chemical Shift Imaging

This technique known as spectroscopic imaging (SI) or CSI is challenged with distilling both chemical shift as well as spatial information from the acquired region of interest [36–37]. The data processing in this case requires both spatial and chemical shift dimensions. For CSI, the

PRESS and STEAM sequences described above can be used including the field gradients modified for spatial encoding (STEAMCSI and PRESSCSI). The phase encoding gradients are repeated several times between the remainder of the rf pulses each time repeating the entire sequence but with the phase encoding gradient amplitude changing slightly. This successive change is done in a stepwise fashion with the gradient amplitude changing; thus, several samples of a frequency are produced. The data can then be Fourier transformed to allocate signal intensities of different frequencies to appropriate voxels.

Single Volume Localized 2D ^{1}H MR Spectroscopy

For MR spectroscopy of a particular nucleus, namely hydrogen (^{1}H), one counts on the differences in internal spin interactions which are due to different inter- and intra-molecular environments. These differences in the molecular environment are of several types and are, hence, responsible for different features of a spectrum or an image. For example, the translational molecular motion is exploited in a diffusion weighted image. While the chemical shift expresses the local electronic environment and is predominantly an intra-molecular property, molecular motion also influences this shift significantly. A primary manifestation and measure of the chemical bonds between the nuclear spins, i.e. the indirect spin-spin coupling communicated through the covalent bonds, is the exclusively intra-molecular J-coupling, which is independent of the applied magnetic field. The motive for introducing the 2D MRS sequences to whole body MR spectroscopy is simple—the extraction of more information out of the MR spectrum to aid in the biochemical analysis of human tissue *in vivo*. 2D spectroscopy can do this by converting a crowded, overlapping 1D MR spectrum to a better-resolved 2D spectrum through the addition of a spectral dimension [24,25]. The problems due to the overlap in the 1D spectrum introduced by the multiplicity of various peaks due to J-coupling could be removed by separating the interactions due to chemical shift and indirect spin-spin coupling (J) along the two dimensions in 2D MR spectroscopy. Instead of a standard 1D spectrum plotting intensity vs. a single-axis (i.e. chemical shift), 2D NMR spectroscopy techniques produce a 2D spectrum plotting intensity vs. two axes, the dimensions of which depend on the specific 2D NMR technique.

The Nobel prizes were awarded to Prof. Richard Ernst in 1991 and Prof. Kurt Wuthrich in 2002 for their innovative contributions focused on coherent and incoherent intra- and inter-molecular interactions using multidimensional MR spectroscopy *in vitro* [38]. Exploitation of this interaction is the crucial link to the molecular chemistry of the metabolites in human tissues. Before applying these multidimensional MR techniques in human tissues, each sequence needs to be converted first into localizing a VOI using three orthogonal slice-localizing rf pulses. A second task is to minimize the number of rf pulses essential for creation of Hahn's spin-echo or coherence transfer echoes. Similar to the 1D MRS protocol, shown in Figure 2 are different compartments of 2D MRS protocol. In addition to repeated spectral acquisition for signal averaging, the sequence has to be repeated multiple times for encoding the second spectral dimension.

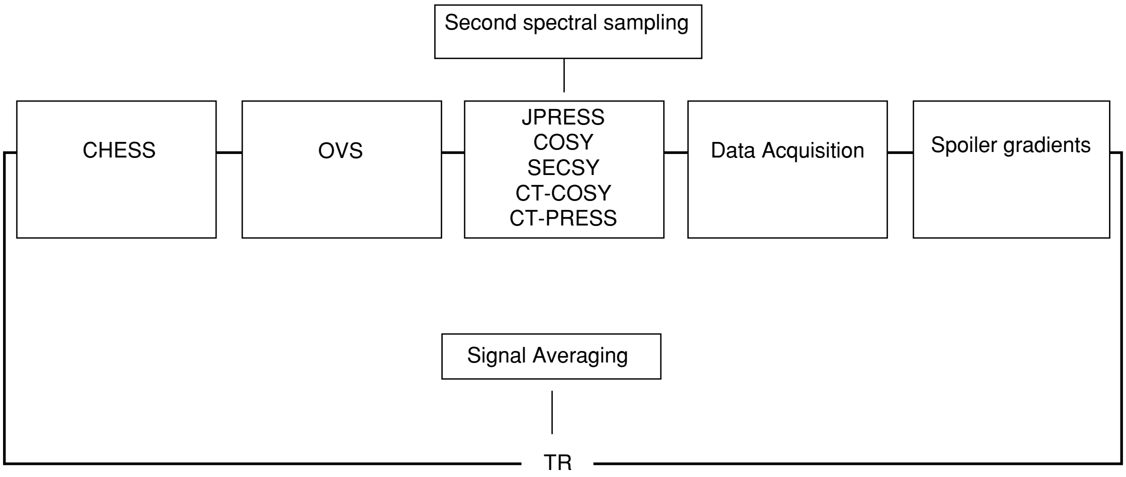

Fig. 2. Different modules of 2D MRS protocol.

2D J-Resolved MR Spectroscopy (JPRESS)

As discussed earlier, the conventional PRESS sequence uses three slice-selective rf pulses (90°, 180°, and 180°) along three orthogonal directions with the second spin-echo originating from a voxel at the intersection of three orthogonal slices. The original 2D J-resolved homonuclear MR spectroscopic sequence is a modified Hahn spin-echo sequence [90°-t_1/2-180°-t_1/2-acquire(t_2)], where signal is acquired during t_2 and the incremental period t_1 is the additional time domain to sample the second spectral dimension of a 2D MR spectrum [25]. In 1995, Ryner *et al.* coded the first 3D-localized 2D J-resolved sequence (JPRESS) by modifying the PRESS sequence to allow simultaneous incrementation of the two periods before and after the last 180° rf pulse [39,40] as shown in Figure 3. The localized 2D JPRESS sequence has been implemented on both GE and Siemens 1.5 and 3 T MRI scanners [39–46]. Shown in Figure 4 are 2D JPRESS spectra of a 100 mM Lac phantom using a Siemens 3T Trio MRI scanner before and after rotating the entire 2D dataset by 45°. A voxel size of 27 ml and a head transmit/receive coil were used. The time period Δ was kept to the minimum necessary to play out rf and gradient pulses. The evolution time (t_1) was incremented in 10-ms steps in order to achieve a spectral window of ±50 Hz that is well within the range of homonuclear (^{1}H–^{1}H) J-coupling. A digital resolution of 1024 complex points along t_2 over a sweep width of 2000 Hz and T_R of 2000 ms was used. The total duration was 4.3 min using two averages per t_1 and 64 increments. However, a longer acquisition time of 17 min will be necessary for signal averaging the metabolite signals at the physiological concentrations. Water suppression was achieved using CHESS. The refocusing of the chemical shift by the last 180° RF pulse resulted in only J-coupling information along the F_1 dimension. A 45° rotation of the 2D data matrix results in J-couplings and chemical shifts along orthogonal axes F_1 and F_2as shown in Figure 4B. As reported earlier [40,41], additional cross peaks due to strong coupling have been observed even at 3 T.

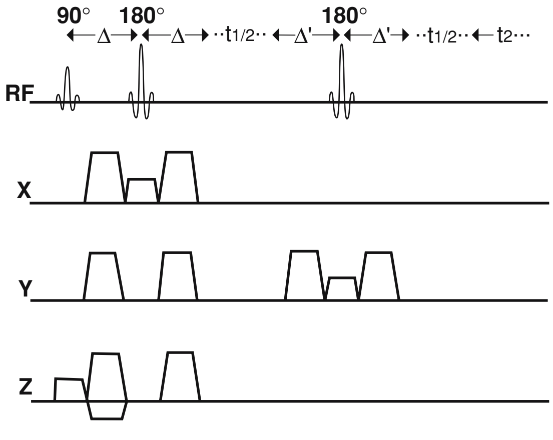

Fig. 3. Localized 2D J-resolved MRS sequence (JPRESS) consisting of three slice-selective rf (90°, 180°, 180°) pulses.

The peaks due to the non-coupled spins are also retained in the 2D J-resolved spectrum unlike the 1D edited spectra. Another advantage of this sequence is that 100% of the available magnetization is retained, neglecting losses caused by T_2 relaxation and spin diffusion. Hence, it is more advantageous than some of the filtered spectral editing techniques, in which 50% or more of the available magnetization is lost. The 2DJ-resolved pulse sequence is versatile such that it can be used for the acquisition of a standard 1D PRESS spectrum by simply removing the incrementation of the t_1-period. A homonuclear broadband decoupled ^{1}H spectrum can also be retrieved after projecting the 2D JPRESS cross peaks onto the F_2 dimension as demonstrated in Figure 4B. This technique has been further extended to human brain and prostate tumours recently to select certain metabolites [42–43]. An over-sampled 2D J-resolved sequence without any water suppression has also been demonstrated [44–46].

Chemical Shift Correlated MR Spectroscopy (L-COSY)

Figure 5 shows a localized 2D correlated spectroscopy (L-COSY) sequence [47]. Similar to JPRESS, the VOI was localized in ‘one-shot’ by a combination of three slice-selective rf pulses (90°-180°-90°), a new MRS volume localization sequence called CABINET (coherence transfer based spin-echo spectroscopy). The last slice-selective 90°RF pulse acts also as a coherence transfer pulse for the 2D spectrum

In addition to the slice-selective 180° rf pulse, there are B_0 gradient crusher pulses before and after the last 90° rf pulses. The incremental period for the second dimension can be inserted at two different locations: first, immediately after the formation of the Hahn spin-echo (t_1) and second, after the last gradient crusher column (k^*t_1), where k^*t_1 can be 4 μs or minimum allowed by the scanner hardware. The L-COSY sequence can be considered a single-shot technique in terms of simultaneous volume localization and coherence transfer. In contrast to PRESS, the CABINET sequence retains only 50% net signal from the localized volume due to a selection of only N-type echo, enabled by the B_0 gradient crusher pulses [47]. If a surface coil is used for both transmission/reception, one has to consider the influence of flip-angle errors due to the delivery of the inhomogeneous rf pulses delivered by a surface coil. In the CABINET sequence with the

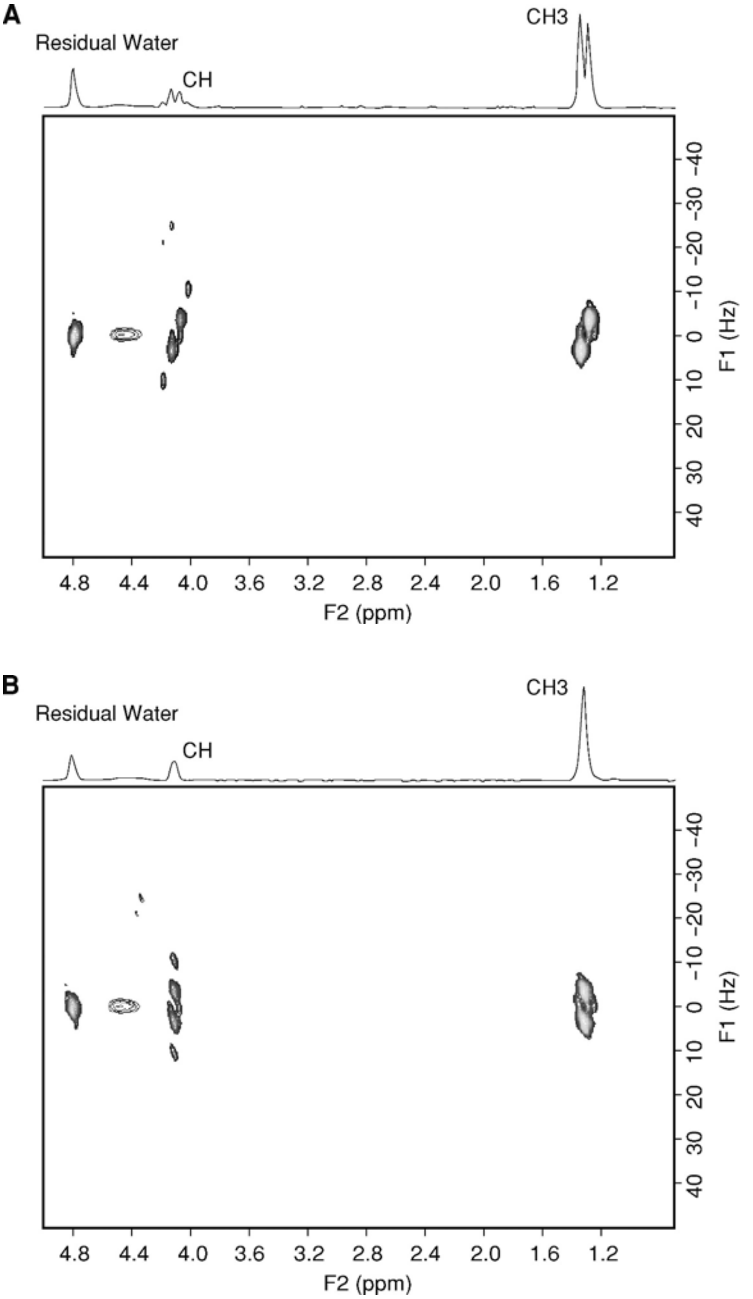

Fig. 4. Localized 2D JPRESS spectra of 100 mM Lac phantom. (A) before and (B) after 45° rotation of the 2D data matrix.

flip-angle distribution of (φ°, $2\varphi^\circ$, φ°), the total signal amplitude from the VOI will be scaled by a factor of $\sin 4\varphi$. The maximum attenuation coefficient for the PRESS sequence (φ°, $2\varphi^\circ$, $2\varphi^\circ$) will be $\sin 5\varphi$. The diagonal and cross peaks of an L-COSY spectrum have mixed phases along the F_1 axis. In contrast to the amplitude modulation in conventional COSY, the phase modulation in L-COSY is caused by the evolution during the B_0 gradient pulse before the last 90° rf pulse. Pure phase L-COSY spectra can be recorded using a quadrature detection method along the

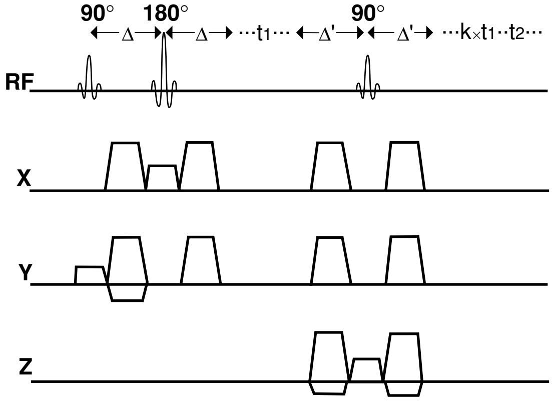

Fig. 5. The 2D L-COSY sequence consisting of three slice-selective rf (90°, 180°, 90°) pulses.

F_1 axis described by Doddrell and co-workers [48,49] that will require two separate P- and N- type spectral acquisition and recombination of the two datasets. Relaxation during the gradient pulses before the last 90° rf pulse will cause further losses in signal intensities.

Two-dimensional L-COSY has been implemented recently on GE and Siemens 1.5 and 3 T MRI scanners [41,47,50] and the test-retest reliability has been demonstrated *in vitro* as well as *in vivo* [41,51]. Shown in Figure 6 are the L-COSY spectra recorded in a) a grey matter brain phantom using a Siemens 3 T MRI scanner and b) the occipito-parietal white matter region of a 38-year-old healthy human subject using a GE 3 T MRI scanner. The brain phantom had the following metabolites at physiological concentrations: 8.9mM NAA, 0.7 mM GABA, 2.1 mM Asp, 0.9 mM Ch, 7 mM Cr, 1 mM Glc, 12.5 mM Glu, 2.5 mM Gln, 2 mM GSH, 4.4 mM mI, 0.4 mM Lac, 3.6 mM PCr, 0.6 mM PCh, 1.8 mM Tau, 0.3 mM Thr, 1 mM PE, and 1 mM DSS in a phosphate buffer solution to maintain pH of 7.2. 2D L-COSY spectra were recorded using the following parameters: 27 ml voxel, $T_E = 20–30$ ms, $T_R = 2$ s, total number of scans = 768 (96 Δt_1 increments and 8NEX/Δt_1). The total duration for each 2D scan with water suppression was approximately 24 min. Typical experimental parameters used for 2D L-COSY are listed in Table 1. Applications of this technique in brain and breast tumours, and brain disorders have also been reported recently [52–54]. Other researchers have also reported the implementation of different versions of 2D COSY [30,49,55–57]. A gradient enhanced COSY in combination with volume localized spectroscopy (VOSY) used the steam sequence for volume localization [49]. Due to additional signal losses, a human brain 2D COSY spectrum recorded in a gross occipital volume of $5 \times 6 \times 8$ cm^3 using a 2 T MRI scanner took a total sampling duration of 1 h and 42 min.

Simultaneous acquisition of COSY from multiple volumes of interest was proposed by Delmas and co-workers (55) and two-voxel localized COSY spectra of rat brain were recorded in a total duration of 42 min using a Bruker 4.7 T MRI scanner. A different pulse-sequence (ISIS-COSY) was also proposed by Welch *et al.* (57), where the volume was localized by outer-volume suppressed ISI (OSIRIS). Two major drawbacks of ISIS-COSY compared to L-COSY were: (1) eight shots are necessary to achieve the VOI and (2) five rf pulses are necessary to record the single voxel localized COSY leading to more dependence on the B_1-field inhomogeneity.

Spin-Echo Correlated MR Spectroscopy (SECSY)

A second variation of COSY, namely spin echo correlation spectroscopy (SECSY) was originally reported by Nagayama *et al.* [58]. Localized SECSY works the same way as L-COSY as shown in Figure 3 except the second incremental period (k^*t_1) should be kept the same as the first period with $k = 1$. Compared to L-COSY, the diagonal peaks of SECSY lie on ($F_2 = F_1 = 0$) and the J-cross peaks are symmetrically disposed above and below the diagonal. A localized SECSY spectrum recorded in the anterior cingulate of a 24-year-old healthy subject is shown in Figure 7. 1024 complex points along the t_2 dimension, 64 points along the t_1 dimensions, a 27 ml voxel and 16 averages per t_1 were acquired. The resultant 2D spectrum was displayed in the magnitude mode. Typical experimental parameters for 2D SECSY are included in Table 1. An advantage of SECSY over COSY is that a smaller sweep width is needed along F_1, however there is additional T_2^*-weighting during the second incremental period.

Constant-Time Based Point Resolved Spectroscopic Sequence (CT-PRESS)

Constant time (CT)-PRESS based on constant time (T_c) chemical shift encoding was recently implemented by Dreher*et al.* [59]. In addition to three rf pulses required for PRESS, an additional 180° rf pulse was used. 2D CT-PRESS spectra were recorded in rat brain with improved spectral resolution using a Bruker 4.7 T MRI scanner. Two different versions of modified CT-PRESS were recently implemented on a whole body 1.5 T MRI scanner including only three-slice selective (90° – 180° – 180°) rf pulses for volume localization and the CT chemical shift encoding as an integral part of volume localization [60]. In the first version, CT was inserted prior to the first spin-echo and in the second version, prior to the second spin-echo. A 2D CT-PRESS spectrum recorded in a phantom containing six metabolites, namely 12.5 mM NAA, 10 mM Cr, 3 mM Ch, 7.5 mM mI, 12.5 mM Glu and 5 mM Lac at pH = 7.3 using a GE 1.5 T MRI scanner is shown

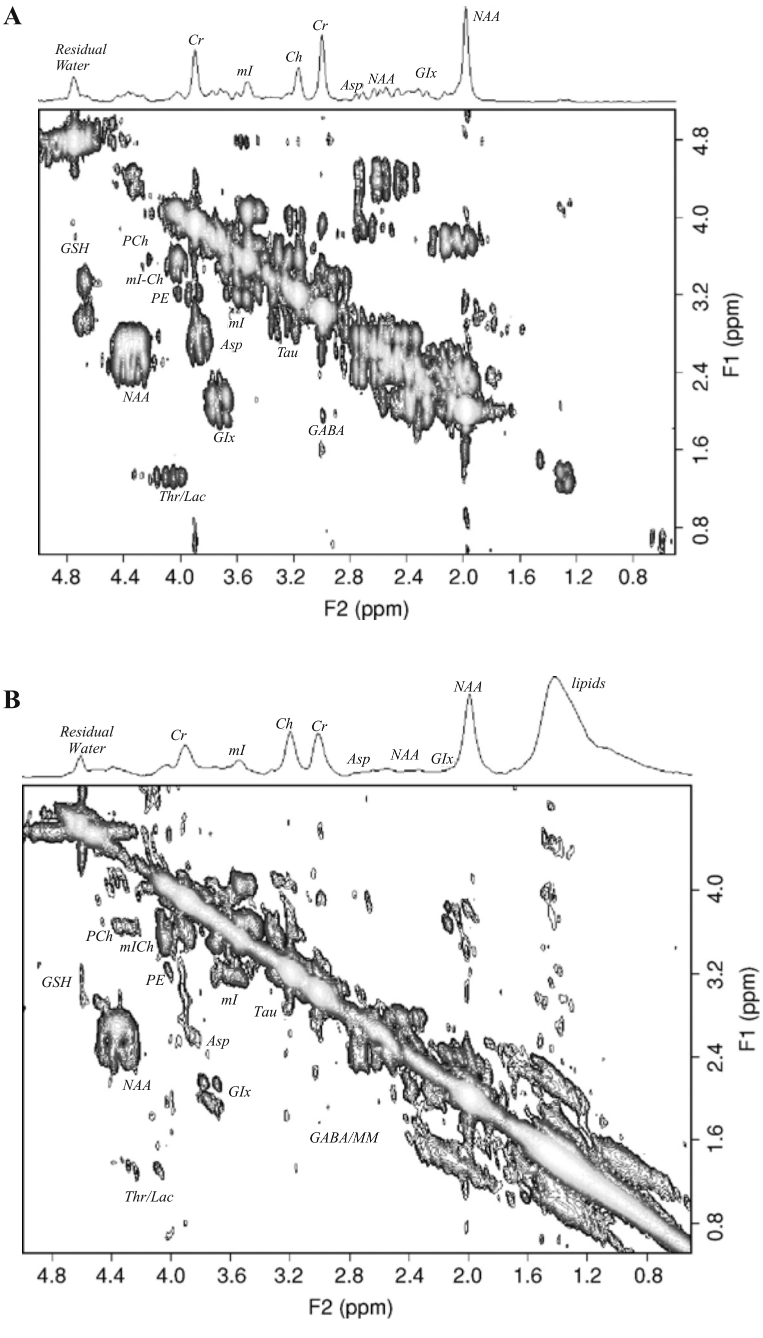

Fig. 6. 2D L-COSY spectra of (A) a grey-matter brain phantom (Siemens) and (B) occipito-parietal white matter region of a 38-year-old healthy human brain (GE) using 3 T MRI scanners.

Table 1: Experimental parameters for 2D MRS

T_R/T_E	2000/20–30 ms
Number of averages/Δt_1	8–16
Number of increments (Δt_1)	64–128
RF pulse widths (90°/180°)	3.2/5.2 ms
Digital resolution (t_2)	Complex 1024–2048
Voxel size	18–27 ml
Duration of crusher gradients	4–6 ms
Spectral width (F_2/F_1)	(2000–5000)/(625–1250) Hz

in Figure 8. Global water suppression was achieved using CHESS.

One major advantage of 2D CT-PRESS is that a homonuclear broadband-decoupled COSY-type spectrum along the F_1-dimension.can be recorded without a second rf-channel for decoupling. Also, compared to the basic localized COSY spectra, a further increase in SNR was obtained by CT-PRESS for coupled resonances since there was no coherence transfer of magnetization between the J-coupled protons leading to disappearance of cross-peaks. Two major drawbacks of the optimized 2D CT-PRESS are: 1) The signal amplitude in CT-PRESS depends on T_c. 2) The spectrum has to be acquired in the 2D mode, which requires long acquisition time.

Constant-time Based Correlated MR Spectroscopy (CT-COSY)

Constant time (CT)-COSY can be easily derived from CT-PRESS by converting the last 180° into 90° rf pulse [61]. Four versions of CT-COSY sequence with the following slice-selective (ss) rf pulses can be easily conceived as described below: (A) $90^\circ_{ss} - (T_c - \Delta t_1) - 180^\circ_{ss} - \Delta t_1 - 90^\circ_{ss}-$Acquire ($t_2$), (B) $90^\circ_{ss}-$ $(T_c + \Delta t_1)/2 - 180^\circ_{ss}-(T_c - \Delta t_1)/2 - 90^\circ_{ss} -$ Acquire(t_2), (C) $90^\circ_{ss} - \Delta t_1 - 180^\circ_{ss} - (T_c - \Delta t_1) - 90^\circ_{ss} -$ Acquire (t_2), and (D) $90^\circ_{ss} - (T_c - \Delta t_1)/2 - 180^\circ_{ss} - (T_c + \Delta t_1)/2 - 90^\circ_{ss} -$ Acquire (t_2), where T_c is defined as the constant time between the 90°_{ss} pulses.

Shown in Figure 9 is a localized 2D CT-COSY spectrum recorded in a phantom containing six metabolites, namely 12.5 mM NAA, 10 mM Cr, 3 mM Ch, 7.5 mM mI, 12.5 mM Glu, and 5 mM Lac at pH = 7.3. The following parameters were used: $T_R = 2$ s, $T_E = 132$ ms, $T_c = 125$ ms, $\Delta t_1 = 0.8$ ms, $\Delta t_2 = 0.8$ ms, spectral widths of 2500 Hz and 625 Hz along the two spectral axes (F_2 and F_1); 1024 complex points along t_2 and 128 points along t_1 dimensions; the number of excitations (NEX) per Δt_1between 8.

Compared to L-COSY, a fixed interval of T_c ($> t_1^{\max}$) separating the preparation and mixing periods is chosen to be of the order of ($1/2J$). The precession under J-coupling is not affected by the 180° rf pulse during T_c. Hence, a

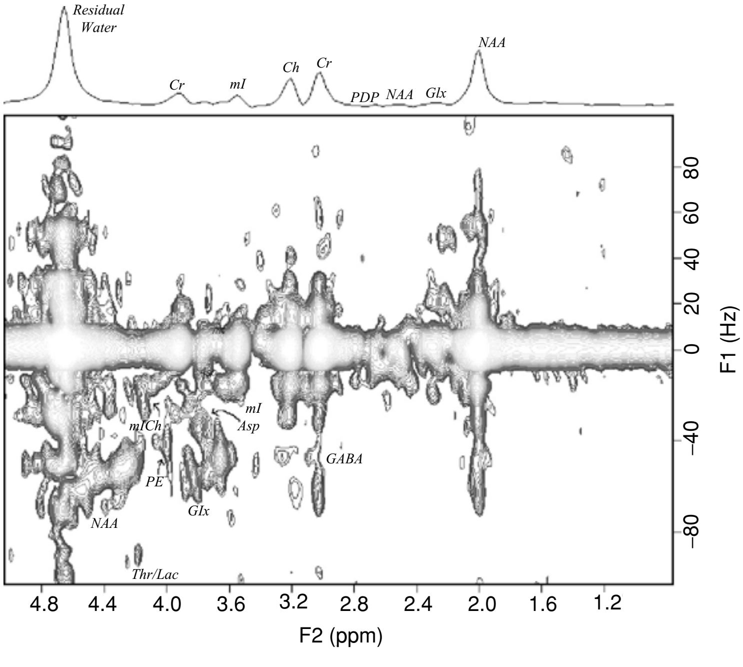

Fig. 7. 2D localized SECSY spectrum of recorded in the occipito-parietal grey matter region of a 24-year-old healthy volunteer using a 1.5 T GE MRI scanner.

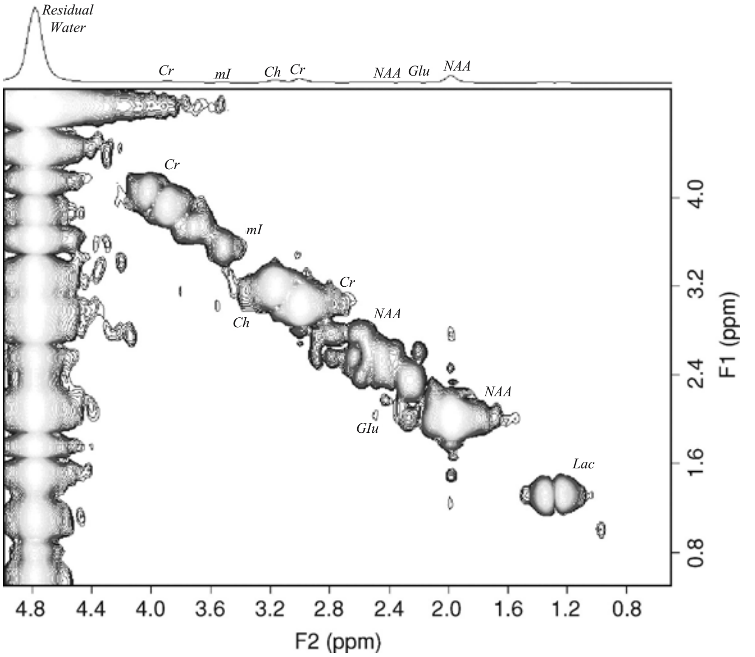

Fig. 8. A CT-PRESS spectrum of recorded in a phantom containing six metabolites using a 1.5 T GE MRI scanner.

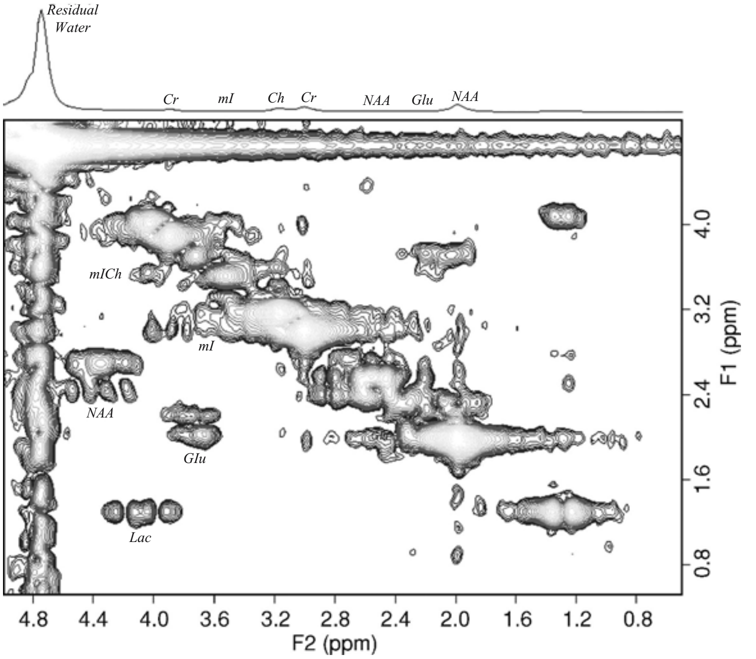

Fig. 9. A CT-COSY spectrum of recorded in a phantom containing six metabolites using a 1.5 T GE MRI scanner.

further increase in SNR was obtained by CT-PRESS for coupled resonances since there was no coherence transfer of magnetization between the J-coupled protons. Secondly, collapse of multiplets along the second dimension was evident without using a second rf channel to achieve broadband decoupling.

Artefacts in Localized 2D MRS and Simulation

In this section, a brief discussion of the commonly observed artefacts in localized 2D MR spectra in presented. First, the flip-angle errors such as an imperfect 180° rf pulse, can lead to ghost artefacts in 2D JPRESS. A four-step phase-cycling scheme, namely EXORCYCLE can eliminate such artefactual peaks [25]. Second, strong coupling effect also complicates 2D JPRESS as discussed by Ryner *et al.* [40]. These artefacts can also impact CT-PRESS and CT-COSY. Third, the asymmetric cross peaks of L-COSY/SECSY are disposed on both sides of the diagonal peaks. The asymmetry has been reported to be more severe with the upper cross peaks of NAA at ($F_2 =$ 2.5 ppm, $F_1 = 4.35$ ppm) above the diagonal [47].

A GAMMA (general approach to magnetic resonance mathematical analysis) software package can be used to simulate different metabolite spectra [62]. The GAMMA library [62] uses a density matrix description of the spin system and provides the simulation of MRS experiments. Density matrices can be calculated for each metabolite using the reported chemical shifts and J-coupling [10]. The GAMMA codes have been extended to simulate the JPRESS, L-COSY/SECSY, CT-COSY, and CT-PRESS spectra including water suppression. As shown in Figure 10, The first 90° rf pulse of the L-COSY pulse sequence is replaced by a binomial rf pulse ($1\,\bar{3}\,3\,\bar{1}$) to mimic the water suppression pulse sequence [63]; where the numerals give the relative pulse lengths, the bars indicate a 180° phase shifted pulse and equal delays τ between pulses. Thus $1\bar{3}\ 3\bar{1}$ corresponds to $11.25°(x)\text{-}\tau\text{-}33.75°(\text{-}x)\text{-}\tau\text{-}33.75°(x)\text{-}\tau\text{-}11.25°(-x)$, $\tau = 1/2\Delta f$, and Δf is the offset frequency [63]. The phase shift is optimized based on the target a null at the water frequency.

Shown in Figure 11 are (A) experimental 2D L-COSY spectrum of a phantom containing NAA, Cr, Ch, mI, Lac, and Glu and (B) simulated composite 2D COSY spectra of the same metabolites using GAMMA [64]. The parameters used for simulation were identical to that of experiments (T_E of 30 ms for L-COSY, 1024 complex points along $F_2$and 128 points along F_1). Another type of water-suppression artefact is due to the t_1-ridge running vertically at $F_2 = 4.8$ ppm as evident in the experimental COSY spectrum shown in Figure 11A. This is mainly due to the scanner hardware fluctuations during the acquisition of the 2D raw matrix [25]. Also, more artefacts can arise due to wrong choice of post-processing parameters and one needs to use caution in selecting optimal apodization filters along both F_2 and F_1 dimensions during post-processing the 2D data.

Multi-Voxel Based 2D ^{1}H MR Spectroscopy

Long data acquisition has been one of the major drawbacks of single-voxel localized 2D MRS. There will be a further increase of time when conventional SI is added to 2D MRS [36–37]. In contrast to reconstructing metabolite images from the 2D spatial and 1D spectral data, the metabolite images can be reconstructed from the 2D spatial and 2D spectral data projecting the cross peak volumes into the corresponding spatial images. This methodology was termed as "cross peak imaging" (CPI) by Metzler and co-workers [65–66]. An obvious drawback of CPI is extended total acquisition time. For example, a combination of 16 × 16 spatial, 64 spectroscopic encoding steps and T_R of 1 s will result in a total duration of 4.6 h [66]. Recently, implementation of circular sampling combined

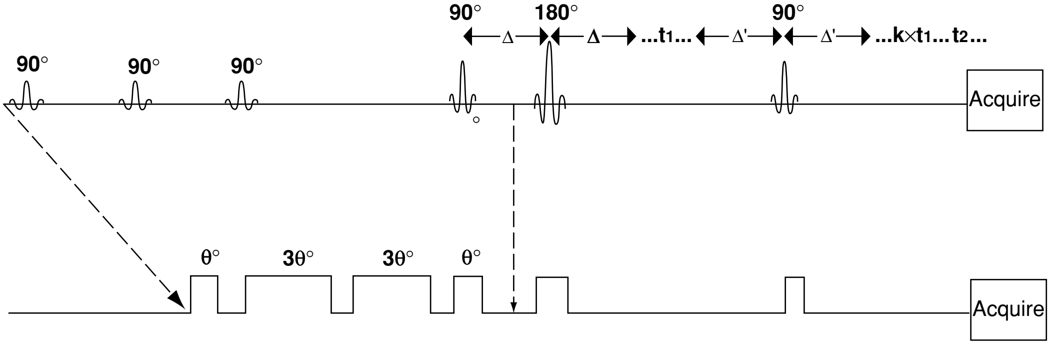

Fig. 10. A 2D COSY sequence used for simulation.

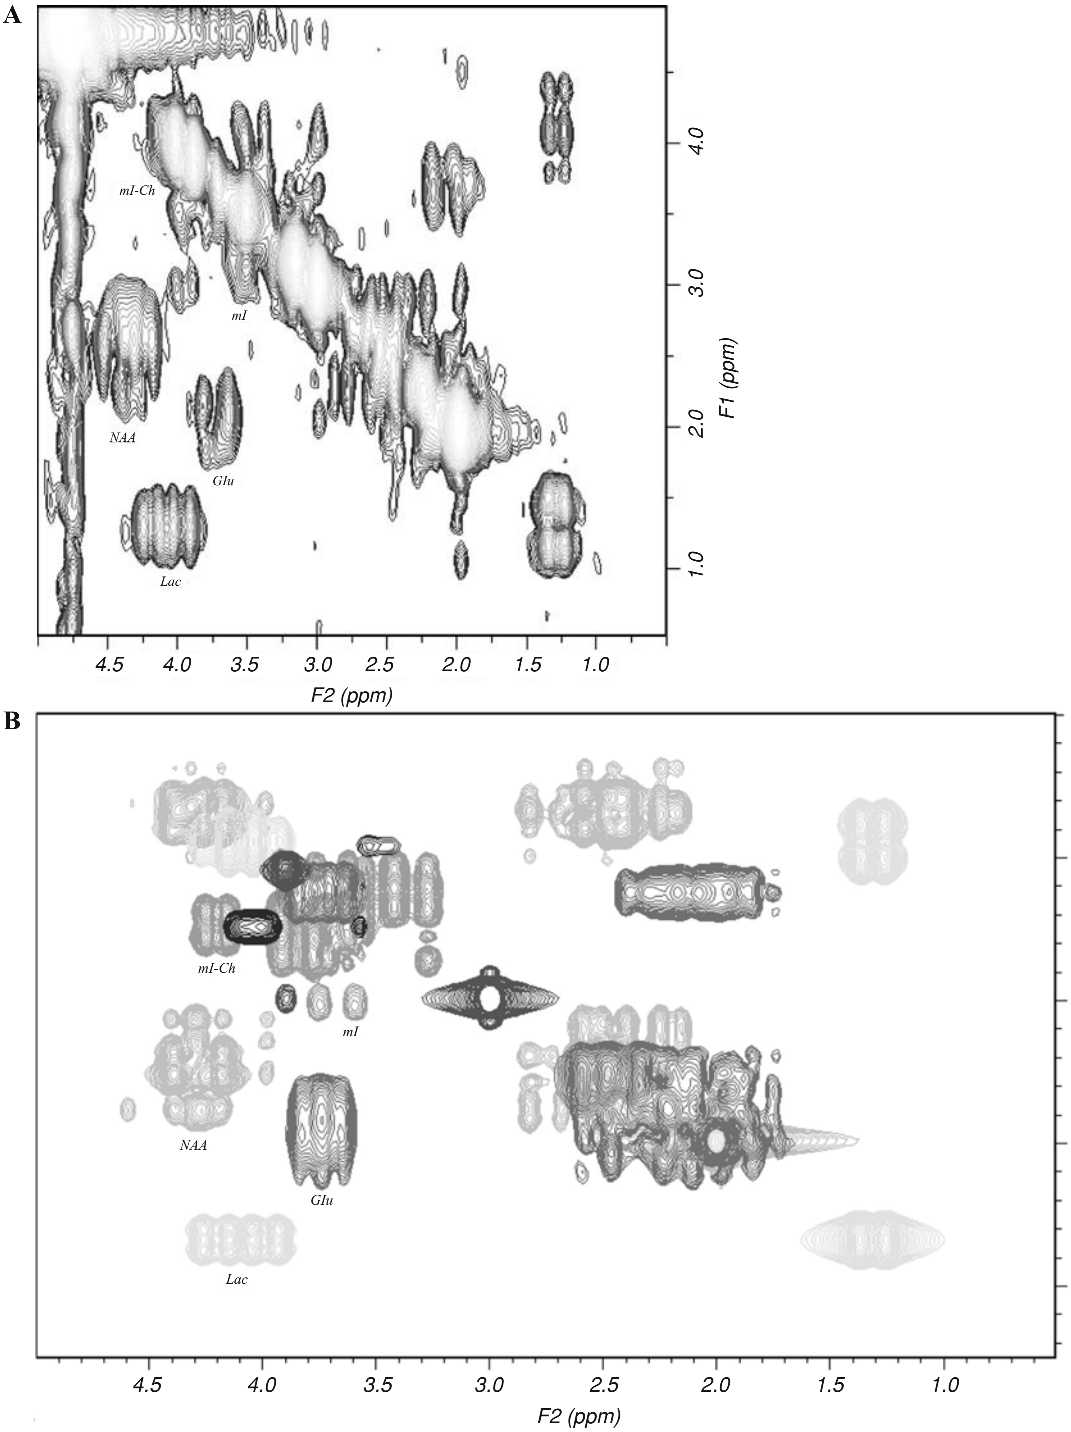

Fig. 11. 2D L-COSY spectra of (A) a brain phantom containing six metabolites and (B) simulated spectra for the same metabolites (Reproduced with permission from Banakar *et al.* [64]). (See also Plate 91 on page XVII in the Color Plate Section.)

with 2D J-resolved spectroscopy was demonstrated by Renshaw and co-workers using a 4 T whole body MRI scanner with a total duration of 2 h [67].

A drastic reduction of total duration has been proposed by two different multidimensional MRS sequences. First, Adalsteinsson and Spielman introduced the first application of time-varying gradients during the read-out time to acquire multi-voxel based 2D J-resolved spectral data in phantom solutions containing lactate and ethanol using a 1.5 T MRI scanner [68]. Spiral-based k-space trajectories were used in conjunction with a 2D J-resolved sequence. By preceding the spiral read-out with a 2D preparation scheme, 128 spectral encoding with T_R of 2 s resulted in a total duration of 17 min.

An asymmetric variant of echo-planar spectroscopic imaging (EPSI) consisting of a train of trapezoidal read-out gradients, each followed by short refocusing pulse was implemented by Meyer *et al.* [69]. A constant-time based COSY was used and the total acquisition was 34 min. Application of this technique was demonstrated in rat brain using a 4.7 T MRI scanner and the cross peak images of mI and Tau were recorded only. In an alternative approach, COSY was combined with spectroscopic ultra-fast low angle rapid acquisition with relaxation enhancement (U-FLARE) [70]. CT along the two spectral dimensions (evolution and detection) facilitated complete effective homonuclear decoupling. A spiral imaging combined CT-PRESS was also recently proposed [71].

Summary

Localized 2D MRS is still at its infancy and different techniques discussed earlier need further improvements in terms of voxel sizes, coil design, etc. Non-selective excitation of the J-coupled metabolites is facilitated by different 2D MRS techniques. 2D cross peaks of more than ten J-coupled metabolites have been observed using L-COSY recorded in the frontal and occipital regions of human brain [41,47,54]. In contrast to ISIS-COSY [57], the 2D techniques discussed in this chapter are one-shot based. Even though it has been shown recently that 1D MR spectra processed using the LC-Model algorithm [21], 2D L-COSY shows the unambiguous presence of 2D cross peaks originating from several J-coupled metabolites. However, further work is necessary in order to ascertain the superiority of 2D L-COSY over the other methodology. Due to the differential T_2^*-weighting during the incremental duration of 2D L-COSY, absolute quantitation of several metabolites is further complicated by lack of T_2 and T_1 values in the literature for different proton groups (methyl, methylene, methine, etc.) in any given metabolite. Regarding the application of these multidimensional MRS techniques in different pathologies, targeting a specific metabolite or selected metabolites in different pathologies may be more advantageous than non-selective excitation/detection of several metabolites. Another major concern is that the 2D spectra are complicated by artefacts contributed by strong coupling of various metabolite protons unavoidable at both 1.5 and 3 T MRI scanners. As discussed earlier, the artefacts in these multi-voxel based 2D MRS sequences need to be further evaluated. Further work is necessary to demonstrate the clinical potential of both single and multi-voxel based multidimensional MR SI methods.

Acknowledgment

This work was supported by the grants from the National Institute of Health (NIH) and the US Army Breast and Prostate Cancer Research Programs. Authors acknowledge the scientific support of Drs. Kenneth Yue and Lawrence Ryner in the earlier implementation of 2D MR sequences, and Ashwin Thomas and Tai Dou during the preparation of the chapter.

Part II, Section 2:
Applications in Pharmaceutical Science

Foreword to Applications in Pharmaceutical Science

NMR has a long history of applications in the pharmaceutical sciences. Initially it was almost exclusively used for the study of small molecules, i.e., drug leads or drugs themselves. As NMR technology developed and became amenable for the study of macromolecules and their complexes NMR has become an increasingly valuable as a tool in the drug discovery process. The 30 articles comprising this section of the Handbook of Modern Magnetic Resonance reflect the major contributions that NMR is making in this field. The articles cover the broad spectrum of activities that NMR encompasses, ranging from the early phases of drug discovery to lead optimization and even to the monitoring of drug effects within organisms in the newly emerging field of metabonomics.

The chapters are written by leading experts in their respective fields, who have highlighted specific applications with examples from their own laboratories. In keeping with the concept of a Handbook, most of the articles focus on a particular NMR technique. However several of the articles cover broad fields of application, as exemplified by the chapters on antimicrobial peptides and toxin structures. Both classes of molecules have obvious applications in the pharmaceutical sciences.

In the short space available in this introduction it is not possible to give a detailed overview of all of the articles. I would just like to highlight one area where I think NMR has shown particularly exciting potential and has had a major impact in the pharmaceutical sciences over the last few years. That area is NMR-based screening. There are now a number of complementary NMR approaches that can be used to discover new ligands by using NMR as the detector in screening assays. Reflecting the importance of this field four chapters that address various aspects of NMR screening are included in this Handbook and many of the other chapters also address the area.

Abstract

NMR spectroscopy has a wide range of applications in the pharmaceutical sciences. This chapter gives an overview of these applications and attempts to draw together information from the specialist articles on individual topics covered in this handbook of modern magnetic resonance.

Introduction

Since its inception NMR has been an important tool for the characterization of molecules that have relevance in the pharmaceutical sciences. Initial interest focused on small organic molecules that were either drugs themselves or were leads in the drug discovery process. As the technology developed over the last few decades molecules of increasing complexity have been examined and it is now possible to study not only small-molecule drugs, but also their macromolecular targets, including proteins and nucleic acids. NMR spectroscopy is now a powerful tool for the study of structure, dynamics, and interactions of biomolecules. In particular, the study of protein–ligand interactions forms the basis for the use of NMR spectroscopy in the process of drug design and discovery, ranging from the simple identification of whether a particular compound binds to a target protein on the one hand to the full determination of a protein–ligand complex's three-dimensional structure on the other.

An outline of the general process of structure-based drug design is given in Figure 1. The iterative cycle is generally started by determining the three-dimensional structure of a target protein or the structure of a complex between the target protein and a ligand, identified through screening a library of compounds. This structural information is then used to design new ligands, which are subsequently synthesized and screened for binding to the target protein and/or for biochemical activity. The structures of promising ligands are then determined in complex with the target protein and used to suggest improvements during further iterations of the design cycle. The cycle is repeated until suitable lead molecules with the desired affinity, specificity, activity, and pharmacokinetic properties have been identified.

NMR spectroscopy is ideally suited to provide critical information at several points of this iterative cycle. Together with X-ray crystallography it is the second major experimental technique used for determining the three-dimensional structures of proteins and protein–ligand complexes in atomic detail, thus providing accurate and detailed descriptions of the regions of a protein involved in ligand binding, the conformation of the bound ligand and the key interactions between the two molecules that determine binding affinity and specificity. By contrast with X-ray crystallography NMR is typically carried out in solution (for an overview on solid-state NMR spectroscopy applications see the related section of Handbook of Modern Magnetic Resonance), thus removing the need for suitable crystals. In addition, NMR spectroscopy is unique in providing crucial information about dynamics of the target protein as well as the bound ligand. Molecular motion is important in determining the kinetics of protein–ligand complex formation and dissociation. Upon binding of a ligand, the dynamics of the reactive site of the target protein is usually perturbed. In addition, the mobility of the active site also determines the range of ligands that can be bound and whether multiple conformations of the ligand can exist. Furthermore, NMR spectroscopy can be used to study solvent accessibility and study and identify

Fig. 1. Schematic outline of the process of structure-based drug design and discovery. In an iterative cycle the structures of protein targets and/or protein-ligand complexes are determined, ligands are designed using the structural information, screened for binding to the target and assayed for activity. The interactions of suitable ligands with the target proteins are structurally investigated and the information is used for improving the ligands in further iterations of this cycle until a suitable lead compound has been generated. NMR spectroscopy is involved in all aspects of this cycle: (1) Protein structure determination; (2) ligand screening; (3) structural analysis of protein ligand-complexes; (4) ligand design (as a conformational analysis tool); (5) ligand synthesis (as a structure verification tool); and (6) quality control of the pharmaceutic production process and metabonomic studies during clinical trials and after release of the drug.

bound water molecules. Finally, NMR spectroscopy can be used to determine binding constants and other thermodynamic data as well as ionization states of the protein and/or ligand.

In this overview article we will briefly discuss the applications of NMR spectroscopy techniques in drug design and discovery. More detailed discussions are presented in the individual chapters of this section of the Handbook of Modern Magnetic Resonance. A number of other review articles covering various aspects of the application of NMR spectroscopy in drug design and discovery have been published in recent years [1–8] and in addition to the specialist articles contained in this edition of Handbook of Modern Magnetic Resonance the reader is referred to these publications.

The review is divided into four sections. In the first section, we review the latest technical developments in NMR spectroscopy, ranging from hardware developments such as the use of cryoprobes and coupled techniques like LC-NMR to improvements in the acquisition and measurement of NMR spectra. The second section deals with the structural characterization of target molecules and ligands and discusses labeling strategies, NMR experiments suited for large molecules (TROSY) and the use of non-NOE-based NMR data such as residual dipolar couplings (RDC) and paramagnetic labels. The third section is dedicated to applications of NMR spectroscopy in the screening of ligands, and reviews target-based methods as well as ligand-based methods. While the first three sections focus on applications of NMR to obtain structural information, the fourth section focuses on NMR applications unique to pharmacy and pharmacology, from drug monitoring, quality control, and pharmacokinetics to the new field of metabonomics. The chapter finishes with a short section on future developments and directions.

Technical Developments

Several significant technical developments have been made in NMR in hardware, software, and experimental techniques in recent years. The most significant development in terms of NMR hardware is the introduction of cryoprobes. Cryoprobes reduce the thermal noise in the detection circuit by cooling the receiver coil and electronic parts of the probe (but not the sample) with liquid helium. Consequently, the sensitivity of a cryoprobe is two to four times higher than conventional room-temperature probes [9,10]. This sensitivity improvement benefits pharmaceutical applications in two ways: on one hand, the improved sensitivity can be utilized to investigate samples of much lower concentration than before, which is especially useful in natural product discovery or screening for low-concentration impurities in pharmaceutical samples during quality control, as reviewed in more detail in Chapter 2 by Martin [11]. On the other hand, the improved sensitivity can be utilized to acquire data of the same quality in a much shorter time—up to 16 times faster—which is especially useful in high-throughput screening applications.

Other developments on the hardware side include the integration of NMR spectroscopy with other analytical techniques such as liquid chromatography (LC) or mass spectrometry (MS) to yield techniques such as LC-NMR [12] or LC-NMR-MS [13,14]. In addition, developments such as direct-injection NMR (DI-NMR) [15] and flow-injection analysis NMR (FIA-NMR) [16] aim at utilizing NMR spectroscopy in support of pharmaceutical applications. DI-NMR has already become a routine technology in pharmaceutical laboratories and in other industrial applications [17–21]. These techniques are reviewed in Chapters 3–5 [22–24].

The most significant advance with respect to new experimental techniques is the development of transverse-relaxation optimized spectroscopy (TROSY) by Pervushin *et al.* [25], in which the line-broadening effects of transverse relaxation are eliminated by selecting specifically the line of a heteronuclear multiplet for which the effects of dipole–dipole relaxation and chemical shift anisotropy compensate each other, yielding improved spectral resolution and sensitivity. However, TROSY is applied only during evolution periods in NMR experiments, and transverse relaxation, which is still active during periods of magnetization transfer, becomes a limiting factor for molecular weights beyond 100 kDa when magnetization is transferred via spin-spin couplings with the insensitive nuclei enhanced by polarization transfer (INEPT) technique [26]. This limitation can be overcome by replacing INEPT steps with cross relaxation-enhanced polarization transfer (CRINEPT) [27], which combines INEPT with cross-correlated relaxation-induced polarization transfer [28], a highly effective transfer mechanism for molecules with a molecular weight above 200 kDa. Thus, TROSY and CRINEPT represent complementary techniques that have revolutionized NMR spectroscopy within a short period of time by making it applicable to proteins larger than the "traditional" 30 kDa limit [29]—reports of NMR data on a 900 kDa complex have been widely cited [30]. In addition, modifications of the TROSY experiment, like solvent-exposed amides with TROSY (SEA-TROSY), have been developed [31] that are specifically geared towards screening studies as part of structure-based drug design approaches. Techniques for improving the study of large proteins and protein complexes with NMR spectroscopy are reviewed in more detail in Chapter 19 [32].

Other developments with respect to experimental NMR techniques focus on modifying and speeding up data acquisition. In general, they involve replacing the uniform sampling of time-space with other sampling schedules and consequently replacement of the discrete Fourier-transformation (DFT) with other transformations. One approach is multiplexing, by encoding more than one resonance frequency in one dimension, as realized in G-matrix FT (GFT) [33,34] or Hadamard encoding [35,36]. Other approaches are projection-reconstruction NMR (PR-NMR) [37] and maximum entropy reconstruction (ME) [38]. These techniques are discussed in more detail in Chapters 6, 14, 15 [39–41].

Structure-based Design

As already outlined, the first step in the cycle of structure-based drug design is the structural characterization of the target receptor molecule. Table 1 shows a collection of

Table 1: NMR technologies used for structural characterization of receptors, ligands, and ligand–receptor complexes

Target	Technique	Information
Receptor	2-4D NMR	3D structure
	RDC	3D structure
	Relaxation	Macromolecular dynamics
Ligand	1D/2D NMR	Solution conformation
	RDC	Solution conformation
	Chemical shift	Charge/tautomeric state
	Lineshape/relaxation analysis	Solution dynamics
	Transfer NOE	Bound conformation
Receptor–ligand complex	3D/4D NMR	3D structure of complex
	RDC	Ligand orientation in complex
	Shift perturbation (HSQC)	Mapping of binding site, Stoichiometry of complex, K_D
	Line width	Binding kinetics
	Relaxation	Dynamics of complex

NMR techniques that can be employed for this purpose as well as for the structure determination of protein–ligand complexes.

Isotopic labeling is essential for the structure determination of target proteins that are not small in NMR terms (i.e. larger than 10 kDa). Labeling is also a prerequisite to harvest the benefits of the TROSY effect. The stable isotopes most commonly used for labeling are ^{15}N, ^{13}C, and ^{2}H (deuterium), and they can be employed in different labeling schemes [42,43]. Uniform labeling with ^{15}N and ^{13}C allows for sequential assignment and structure determination of the target protein with multidimensional triple resonance experiments [44]. For larger proteins, additional substitution of non-exchangeable protons with deuterium ameliorates relaxation effects. In this case, TROSY experiments are usually employed to obtain spectral information. In large multidomain proteins individual domains can be labeled by segmental labeling thereby simplifying the information in the NMR spectrum [45]. Another method of simplifying spectral information, which is especially useful for screening studies with large proteins, is the selective labeling of individual amino acids or of amino acid types [46,47]. The former approach can also be achieved with amino-acid specific pulse sequences [48,49].

After NMR spectra have been recorded, and all resonances have been assigned, the three-dimensional structure of the target protein is determined mostly from information based on NOE connectivities and dihedral restraints [50]. Recently, additional sources of structural information have been made accessible, most important among them RDCs [51] and shift and relaxation changes associated with paramagnetic nuclei [52,53]. Both methods have the distinct advantage of providing long-range constraints, which is a useful complementation for the short-range information derived from NOEs and dihedral restraints. Furthermore, they are able to provide structural information in the case of large proteins that have been extensively labeled with deuterium and thus have a reduced number of observable proton-proton NOEs. Labeling, RDC and paramagnetic methods are discussed in more detail in Chapters 8, 9, 11, 12, and 19 [32,54–57].

Similar methods can be employed to determine the three-dimensional structures of ligand molecules. Although ligand molecules are easier to examine because of their small size and can generally be studied by standard homonuclear NMR methods, the use of more advanced techniques such as RDCs has been demonstrated to be beneficial e.g. for obtaining structural information on sugars and small organic molecules as reviewed in Chapter 11 [56]. Other examples of the application of NMR spectroscopy for structure determination of small organic molecules are antimicrobial peptides and scorpion toxins as discussed in Chapters 16 and 17 [58,59].

A major milestone in structure-based drug design is a detailed determination of the three-dimensional structure of a ligand-target protein complex. If the structure of the target protein has been solved, but the ligand binding site is unknown then a quick determination of the binding site can be obtained by chemical shift mapping: a labeled sample of the target protein is titrated with the ligand, and due to the change in chemical environment associated with ligand binding amide proton resonances at, or close to, the binding site change their position in a HSQC spectrum. Mapping of the shift perturbations on the structure of the target protein reveals the ligand binding site. Similarly, in the case of a small ligand protein binding to a large receptor the binding face of the ligand can be determined by titrating labeled ligand with unlabeled receptor and chemical shift mapping.

To determine the detailed nature of protein–ligand interactions the observation of intermolecular NOEs between target protein and ligand is crucial. The aforementioned combination of labeled protein and unlabeled ligand (or vice versa) is helpful here, and for example, “filtered” experiments can be used to selectively observe NOE signals either within the protein, within the ligand, or most importantly the desired intramolecular signals between protein and ligand [60].

RDCs offer an alternative approach for determining the orientation of ligands within the target protein’s binding site. Upon binding, the ligand adopts the alignment tensor of the target protein, and thus a comparison of ligand RDCs in the free and bound state makes it possible to determine the conformation of the ligand in the bound state in the complete absence of ligand-protein or ligand–ligand NOEs [61–63]. A further discussion of techniques for determining the structures of protein–ligand complexes, including some case examples, is given in Chapters 13, 18, 19, and 20 [32,64–66]. Transferred NOE and cross-correlated relaxation methods are also particularly important for determining the conformation of bound ligands, provided certain kinetic conditions are met. These approaches are described in Chapters 7 and 21 [67,68].

One of the distinct advantages of NMR spectroscopy is the possibility of obtaining information about the dynamics of a protein or a protein–ligand complex. The dynamics of the binding site is of fundamental importance in determining affinities and binding kinetics. In addition, it is a not an uncommon observation that the binding site of a protein exhibits considerable flexibility, but becomes more rigid upon binding of the ligand [69,70]. Phenomena like this can be readily investigated with NMR relaxation experiments, which can determine molecular motions on a nanosecond up to millisecond timescale [71]. In addition, lineshape analysis offers an avenue into further determining events on the millisecond timescale like chemical exchange, including the measurement of rate constants of the exchange process [72]. Finally, NMR titrations can be used to determine dissociation constants of a protein–ligand complex. These topics are further reviewed in Chapters 18, 21, 22, and 23 [66,68,73,74].

NMR Screening

The screening of libraries of compounds is becoming an increasingly useful adjunct to structure-based drug design. Table 2 gives an overview of the different screening strategies that can be employed. In general, screening techniques can either be target-based—i.e. changes in the macromolecular target protein upon ligand binding are observed, or ligand-based—i.e. changes in NMR properties of the ligand upon binding are observed.

In general target-based screening techniques are based on monitoring chemical shifts with a HSQC spectrum. For large target proteins specific labeling strategies and TROSY experiments are employed, but the principle stays the same. A recent modification of the TROSY experiment specifically geared for application in screening programs with large target proteins is the SEA-TROSY experiment [31]. The experiment is based on the concept that only groups on the solvent-exposed surface of the protein are likely to be involved in ligand binding, while residues in the protein interior are unlikely to be in contact with the ligand. SEA-TROSY observes by magnetization transfer from the bulk water only solvent-exposed amide protons in fully deuterated and ^{15}N-labeled proteins that are dissolved in water. Thus the SEA-TROSY spectrum contains significantly fewer signals than conventional spectra, alleviating the problem of spectral overlap for large target proteins.

Table 2: NMR technologies used for high-throughput screening of ligand–receptor complexes

Target	Technique	Reference
Receptor-based	SAR by NMR	[75]
	SEA-TROSY	[31]
	NMR-SOLVE	[47]
Ligand-based, Direct	Relaxation	[78,79]
	Diffusion coefficients	[78]
	STD	[83]
	ILOE	[65,85]
	Transfer NOE	[68,80]
	NOE pumping	[81,82]
	Water-LOGSY	[84]
	SHAPES	[87]
Ligand-based, Indirect	FAXS	[86]
	3-FABS	[96]
	STD with spy-molecule	[86]

The by now “classic” strategy employed in NMR target-based screening is structure–activity relationships (SAR) by NMR [75]. It aims at the identification of two ligands with moderate binding affinities that bind to two different but adjacent binding sites on the target protein. Crosslinking of the two ligands via chemical synthesis then produces a first-generation lead molecule with substantially improved binding affinity. It has been responsible for the development of numerous novel drug leads, as outlined in the article by Hajduk in this Handbook [76].

NMR-Structurally orientated library valency engineering (NMR-SOLVE) is a new target-based screening approach that has been developed specifically for the postgenomic era to provide guidance for the construction of libraries against multiple related target proteins [47]. One key element of NMR-SOLVE is to use highly selective isotopic labeling (e.g. ^{13}C-^{1}H labeled CH_3 groups in otherwise uniformly deuterated proteins) to observe only a small number of key resonances in a binding site, thus yielding information in the absence of complete assignments. The NMR-SOLVE strategy is based on the fact that several enzyme families have multiple binding sites—one that is common for all family members, and one that is specific for each protein. In a first-step NMR-SOLVE uses a known reference ligand that binds to the common binding site to map and identify the specifically labeled groups that are around this binding site. In the next steps mimics of the reference ligand that could bind to the common binding site of most family members of the protein family are investigated. Finally, in an act of core-expansion structural information is used to design a linker that could connect the core of ligand-mimetic fragments binding in the common binding site with additional ligand fragments that would bind to the secondary binding sites, unique to each protein. Thus, a library of bivalent ligands is obtained that is specifically geared towards a given protein family. The NMR-SOLVE strategy has been demonstrated with target proteins as large as 170 kDa [47]. Further discussion on target-based screening approaches can be found in Chapters 27 and 29 [76,77].

A plethora of ligand-based screening methods has been developed targeting a wide variety of observable NMR parameters, as indicated in Table 2. Parameters that have been utilized include longitudinal, transverse, and double-quantum relaxation [78,79], diffusion coefficients [78], and intramolecular and intermolecular transfer of magnetization, such as transfer NOE [68,80], NOE pumping, and reverse NOE pumping [81,82], saturation transfer experiments [83], Water-ligand observed via gradient spectroscopy (water-LOGSY) [84] and inter-ligand NOEs (ILOE) [65,85]. Individual techniques are discussed in detail in Chapters 21, 26, and 29 [68,77,86] and are reviewed here only briefly.

The main advantage of monitoring the small ligands is that there is no need for isotopic labeling of the target protein, and thus limitations of protein yields in minimal media or molecular size of the target protein do not apply. Furthermore, the identity of a binding ligand in a mixture can be readily established, and screening methods based on 1D-NMR experiments are generally faster than a 2D-HSQC spectrum. However, ligand-based methods provide no direct information about ligand binding sites, and generally require the ligand to be in fast or medium exchange with the target protein.

Ligand-based screening methods can be divided in two classes: direct methods, in which the NMR signals of the ligand are observed directly, and indirect methods, where signals of a "reporter" or "spy" molecule that binds weakly to the target protein are observed. The indirect methods are especially suitable for the investigation of strongly binding ligands that are not in fast exchange with the target protein. As the ligand binds competitively to the protein, it replaces the reporter molecule, and the changes in the NMR signal of the reporter molecule are observed.

A broadly applicable approach that utilizes ligand-based screening is SHAPES [87]. This drug design strategy is based on a diverse library of small organic fragment molecules, whose molecular shapes represent those most commonly found in the structures of established drugs. Unlabeled target proteins are screened against this library of weakly binding water-soluble library, and hits are used to construct more complex, high-binding lead compounds. The strategy is discussed in more detail in Chapter 28 [88].

Studies of Drug Effects

NMR spectroscopy has not only applications within the iterative cycle of structure-based drug design, as outlined in the previous section, but can also be applied in later stages once a lead molecule has been identified. One obvious example is the use of NMR spectroscopy as a routine analytic technique for the quality control during synthesis and production. This includes the profiling of drug impurities or the analysis of drug stability. Another application is pharmacokinetics and the screening for drug metabolites in biological fluids or extracts. The use of coupled analytical techniques such as LC-NMR and new technical developments such as cryoprobes have already been mentioned and are reviewed in more detail in Chapters 2, 3, and 4 [11,22,23].

A most exciting development in this respect is the application of NMR spectroscopy in metabonomics [89]. Metabonomics is formally defined as the quantitative measurement of the dynamic multiparametric metabolic response of living systems to pathophysiological stimuli or genetic modification [90]. In other words, in metabonomics biofluids and tissues are monitored with various analytical techniques, chiefly among them 1D-NMR spectroscopy, for changes in the levels of metabolites. These changes can occur as a consequence of disease (vs. healthy state) or after administering of a drug. The immense value of metabonomics in all stages of drug development from first assessments of pharmacology, through clinical trials and later on for monitoring of patients and epidemiological studies is becoming increasingly apparent. NMR-based metabonomic techniques and applications are discussed in detail in Chapter 24 [90].

Future Directions

A remaining frontier for both NMR spectroscopy and X-ray cystallography is the structure elucidation of membrane proteins. Membrane proteins are often involved in signal transduction and consequently many targets of pharmaceutical interest involve membrane-bound or membrane-associated proteins. Recent developments in the field of solid-state NMR have made it possible to study the structure of membrane proteins [91,92]. Similar progress has been made in solution NMR spectroscopy with the development of phospholipid bicelle systems that mimic the environment of the cell membrane and are mobile enough to allow the study of drug-membrane or protein-membrane interactions with solution NMR. These developments are further detailed in Chapter 10 [93].

Another challenge/opportunity for NMR spectroscopy in the pharmaceutical sciences comes from structural genomics programs. In the postgenomic era it is becoming increasingly important to obtain information about ligand-target protein interactions not just for one target protein, but for whole classes of related proteins. More often than not, full assignments of the target protein(s) are not available or cannot be obtained within the constraints of time. Thus the development of techniques, such as NMR-SOLVE [47], that can provide information about ligand–protein interactions without full NMR characterization of the target protein is very important. A discussion of NMR applications in structural genomics is provided in Chapter 30 [94]. One of the interesting features that is emerging from such programs is that the average size and amino acid composition of genomically encoded proteins is substantially different from folded proteins in the PDB. There are many proteins now being discovered that are intrinsically unfolded and hence unsuitable for structure determination. Chapter 25 [95] describes NMR approaches to the study of such proteins and to the related issue of protein misfolding in disease.

Instrumentation

Applications of Cryogenic NMR Probe Technology for the Identification of Low-Level Impurities in Pharmaceuticals

Gary E. Martin
Pfizer Global Research & Development, Michigan Structure Elucidation Group, Kalamazoo, MI 49001-0199

Abstract

Following the detection of low-level impurities in pharmaceuticals, structural characterization of these components represents a continuing challenge. Irrespective of whether the impurity in question arises from side reactions of the chemical processes being employed for the synthetic elaboration of the active pharmaceutical, through degradation chemistry processes, or through accidental contamination, the identification of low-level impurities is a mandatory component of the preparation and marketing of pharmaceuticals. The development of cryogenic NMR probes and the corresponding increases in sensitivity that they provide has significantly impacted this phase of pharmaceutical development. The role of cryogenic NMR probe technology in the characterization of low-level impurities from pharmaceuticals is discussed.

Introduction

Multiple creative approaches have been utilized in the quest for improved NMR sensitivity. NMR spectroscopy, despite the wealth of chemical structure information that it can provide, has always had an Achilles' heel in the form of the low inherent sensitivity of the technique. Approaches that have been used to improve sensitivity have included the development of new pulse sequences, such as the proton- or "inverse"-detected heteronuclear 1D-, 2D-, and 3D-NMR experiments that are now in wide use. Another approach that has been heavily exploited has been that of "shrinking" the size of NMR probes and hence the required sample [1,2]. Although small volume probes have been known for a considerable period of time, contemporary small volume probe development effectively began in 1991 with the first reports of 3 mm NMR probe applications, followed shrinking of probe diameters to 1.7 mm, then 1 mm, and finally μ-coil probes with sample volumes as small as a few μl. This area was the subject of a recent review and the interested reader is referred there for more details [3]. Cooling the rf coils of an NMR probe to cryogenic temperatures to reduce noise, thereby improving sensitivity, is also a well-established approach to enhancing NMR performance [4–7].

Unlike conventional NMR probe developments, which were commercially realized after prototype design and testing, the commercial manufacture of cryogenic NMR probes proved to be a more daunting task requiring a number of years for even the first prototypes to be delivered to customer laboratories. In part this was due to design considerations necessary to cool the internal components to temperatures for the rf coil in the range of 10–25 K and preamps housed in the probe body to temperatures near 50 K without destroying those components during thermal cycling that the probe must occasionally be subjected to. Nevertheless, numerous commercial cryogenic NMR probes have been delivered and have begun to have a significant impact on the way in which various disciplines perform NMR-based chemical structure investigations.

Cryogenic NMR Probes

Commercial examples of cryogenic NMR probes have been developed in a limited number of configurations. Typically, they have been 3 or 5 mm diameter probes and most commonly, inverse-detection triple resonance gradient designs, although a cryogenic probe for direct carbon detection has also been developed. Cryogenic NMR probes have also been developed for flow applications. Perhaps one of the most interesting of these is the interchangeable flow cell (IFC) design by Varian, which allows the user to change between NMR tubes and a flow cell without having to remove the cryoprobe from the magnet. Although some early cryogenic probes were developed and tested using an open configuration of a liquid helium dewar, to the best of the author's knowledge, all commercial examples use a closed loop system to deliver the helium refrigerant to the probe at temperatures in the vicinity of 8–10 K. The helium refrigerant is used to cool the rf coils to their operating temperature as well as the associated electronic circuitry housed in the probe body such as preamps, after which the helium refrigerant is cycled back and re-chilled. Typically,

Graham A. Webb (ed.), Modern Magnetic Resonance, 1205–1212.
© 2008 *Springer.*

the rf coil temperature for cryogenic probe installations is 25 K although in the author's laboratory 500 and 600 MHz cryogenic gradient triple resonance inverse probes are both operated at 20 K to provide improved sensitivity. From a serviceability standpoint, the closed loop helium chillers perform reliably for intervals ranging from 10 to 14 months in the author's experience before requiring a rebuild. This type of required "annual" maintenance, and the associated expense, should be taken into consideration when any NMR laboratory weighs the sensitivity advantages of a cryogenic NMR probe installation vs. a high sensitivity small volume conventional NMR probe.

Sample Preparation

In the author's experience, one factor that has a considerable impact on cryogenic NMR probe performance is the uniformity of sample preparation. While conventional NMR probes are very forgiving in terms of sample-to-sample variation in column height, etc. the same cannot be said for cryogenic NMR probes. Figure 1 shows an example of the variability of performance that can be seen simply by varying column height in a conventional NMR tube over the range from 35 to 20 mm. Given that the utilization of cryogenic NMR probes will generally be in those cases where time or sample are scarce, the impact of sample preparation on the quality of the data generated should receive adequate attention.

Another less obvious factor associated with sample preparation when using a cryogenic NMR probe is the selection of tube size. While it would seem to make sense to use a 5 mm NMR tube for samples to be run in a 5 mm cryogenic NMR probe, thereby avoiding filling factor losses, reality is quite the opposite. Almost counterintuitively, substantially better performance can be obtained with extremely scarce samples by preparing them carefully in a 3 mm NMR tube. An illustration of attainable s/n ratios for a limited quantity of the simple antibiotic clindamycin in 3, 4, and 5 mm NMR tubes is presented in Figure 2. These results can be explained when the noise sources in a cryogenic NMR probe are considered. In reality, the sample is the single largest source of noise in a cryoprobe NMR experiment. Hence, as the diameter of the NMR sample itself is decreased in going from 5 to 4 and then 3 mm sample tubes, the noise contributed to the experiment correspondingly diminishes as the isolation of the rf coil from the noise source improves with smaller diameter NMR tubes [8]. Thus, despite potential filling factor losses associated with smaller diameter NMR tubes run coaxially in a 5 mm probe, performance still improves since the impact of the sample noise is larger than filling factor losses.

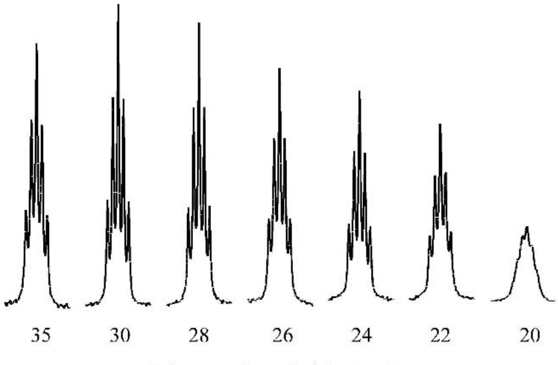

Fig. 1. The effect of solvent column height on lineshape and s/n characteristics for a 4 mm NMR tube with a sample of d_4-methanol. The spectra of the solvent multiplet were acquired in a Varian 5 mm 500 MHz triple resonance gradient-inverse detection Cold Probe^{TM}. Each column height was first gradient and then manually shimmed to afford the best possible lineshape and sensitivity.

Identification of Degradants

To illustrate what would be a typical pharmaceutical industry application of cryogenic NMR probe sensitivity, a sample of a complex alkaloid studied more than a decade ago that was kept in a sealed 5 mm NMR tube was used as a model system. The sample consisted of 2.5 mg of the complex spiro nonacyclic indoloquindoline alkaloid cryptospirolepine (**1**) that was stored in DMSO-d_6 (Scheme 1). During the life of the sample, the color changed from an initial red-orange to a dark brown. When the sample tube was cut open and the sample subjected to HPLC analysis, the chromatogram shown in Figure 3 was obtained. By LC/MS methods, there was no trace of the starting alkaloid left in the sample among the 26 degradant peaks observed in the chromatogram. An investigator dealing with a typical pharmaceutical would not be faced with total degradation. Instead, most of the drug would be intact and impurity peaks ranging from a few tenths of a percent to a few percent would be observed in the chromatogram. Nevertheless, this still affords a useful example of the capabilities engendered in cryogenic NMR probe technology.

The two largest chromatographic peaks in the HPLC of the degraded sample of **1** were identified as cryptolepinone (**2**) and cryptoquindolinone (**3**). Cryptolepinone (**2**) is a simple molecule and was readily identified from just a COSY and ^{1}H–^{13}C GHSQC spectra. Cryptoquindolinone (**3**) is a more complex molecule and required considerably more effort to characterize. Approximately 100 μg of **3** was isolated chromatographically and, using a 600 MHz spectrometer with a state-of-the-art 3 mm triple resonance gradient inverse-detection NMR probe afforded a good ^{1}H–^{13}C HSQC spectrum overnight (18 h). Given the relative differences in sensitivity of the HSQC

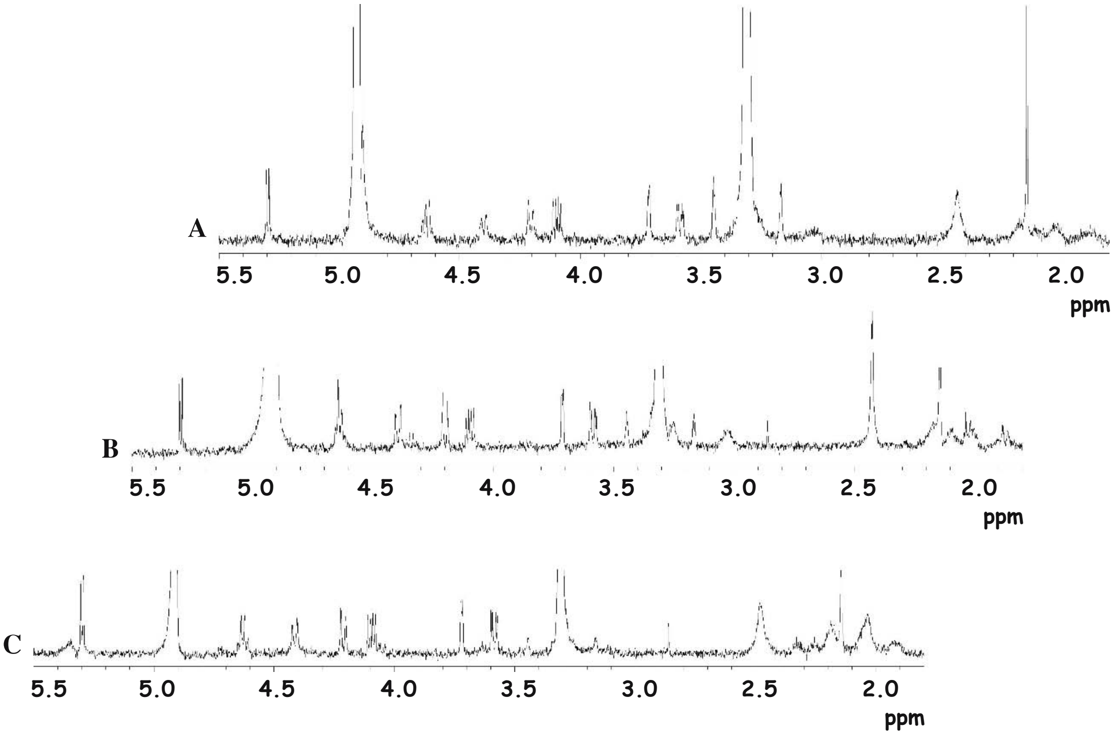

Fig. 2. Comparison spectra of 11.6 μg samples (0.0027 μmoles) of the simple antibiotic clindamycin prepared: (A) 500 μl solve in a 5 mm NMR tube; (B) 292 μl solvent in a 4 mm NMR tube; or (C) 163 μl of solvent in a 3 mm NMR tube (identical column heights of 30 mm). Each sample was gradient and then hand shimmed to afford optimum lineshape and performance, after which a spectra was recorded using 8 transients. The s/n ratio was then measured using the anomeric proton of the sugar with a 200 Hz standard "noise" window downfield of the lowfield anomeric proton doublet. The measured s/n for three samples in this limited sample scenario was: (A) 14.4:1 s/n; (B) 20.8:1; and (C) 21.5:1.

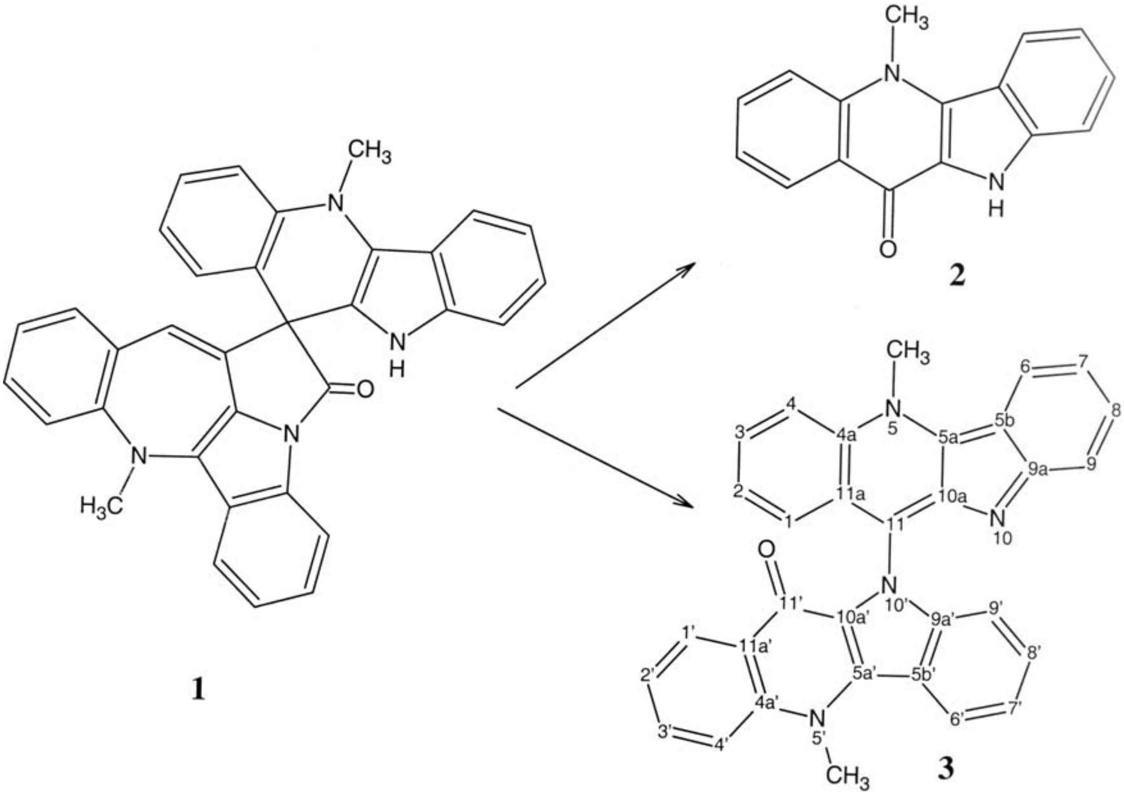
and HMBC experiments, a long-range ^{1}H–^{13}C spectrum was anticipated to require from 3 to 4 days. In contrast, using the available sample, the 6 Hz optimized HMBC [9] shown in Figure 4 was acquired overnight at 500 MHz using a 5 mm triple resonance gradient inverse-detection cryogenic NMR probe. These data were necessary to assemble the structure of the degraded molecule. Using the same sample, it was also possible over a weekend to acquire a 3–6 Hz optimized long-range ^{1}H–^{15}N CIGAR-HMBC spectrum of **3** in which correlations to three of the four nitrogens in the structure were observed, including a correlation to the N10 resonance at 230 ppm, which confirmed the presence of the C=N double bond as shown in Scheme 1. Without where indicated access to a cryogenic NMR probe, long-range ^{1}H–^{15}N data for a sample of this size would consume a week or more of spectrometer time, precluding the acquisition of these data in most laboratories.

The example just described is typical of many encountered within the pharmaceutical industry. While it is certainly possible to isolate larger samples and solve impurity and degradant structures using conventional NMR probe technology there are several disadvantages to doing so. First the chromatography required to isolate larger samples generates large volumes of chromatographic mobile phase that must be disposed of or recycled. Second, the time required to isolate larger samples for conventional spectroscopy is proportionally longer and undesirable whenever tight timelines are imposed on a pharmaceutical development effort for whatever reason.

Applications of Cryogenic NMR Probe Technology

There are several possible ways to break down applications of cryogenic NMR probe technology that have appeared in the literature thus far. One logical subdivision would be to separate applications on the basis of the type



Scheme 1.

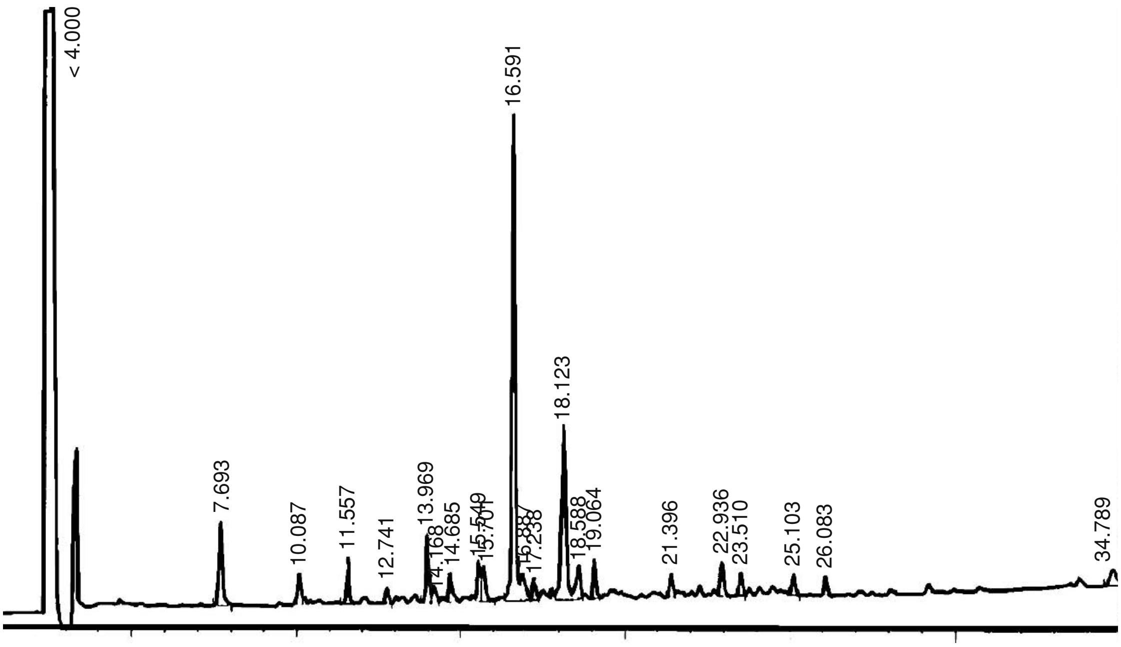


Fig. 3. HPLC chromatograph showing the result obtained after chromatographing a 2.5 mg sample of cryptospirolepine (**2**) stored in DMSO-d_6 for more than 10 years. Based on LC/MS measurements, none of the starting alkaloid remained in the sample.

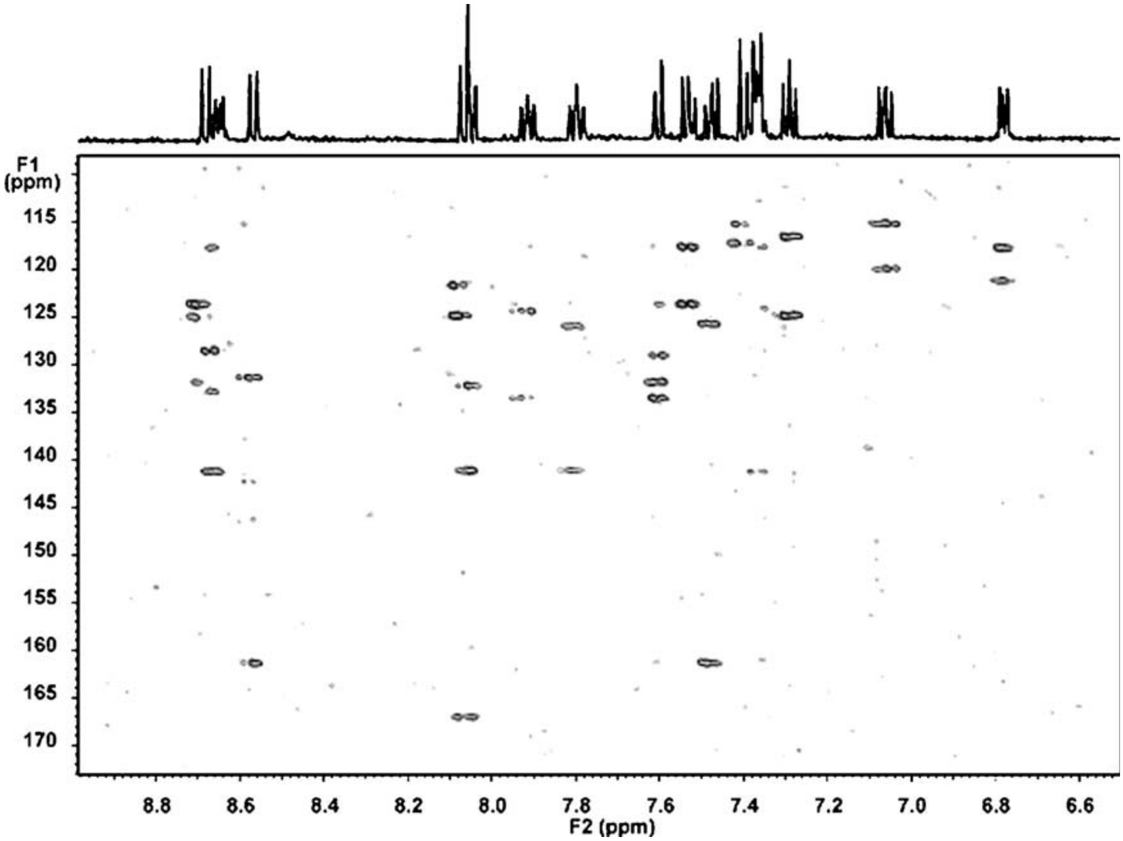

Fig. 4. Phase-sensitive 6 Hz optimized non-gradient HMBC spectrum of a sample of ∼100 μg of cryptoquindolinone (**4**) dissolved in 150 μl DMSO-d_6 in a 3 mm NMR acquired overnight using a Varian 500 MHz 5 mm triple resonance gradient inverse-detection cryogenic NMR probe.

of cryoprobe employed. However, the vast majority of applications utilize inverse-detection cryogenic probes so subdivision on the basis of probe type is not particularly informative. A more logical way of sorting applications is on the basis of the type of study reported. It is this basis that will be used for this final segment of this contribution. Reports that have appeared in the literature will be subgrouped into small molecule applications, which include both natural products and pharmaceuticals; metabolic and metabonomic studies; and finally protein and biochemical applications, in which NMR screening is included.

Small Molecule Applications

Among the earliest of the small molecule applications reported in the literature was a report by Logan and co-workers in 1999 that demonstrated the results that could be obtained with a 5 mm ^{1}H cryogenic probe in the acquisition of NOE difference spectra on small samples of the natural product taxol [10]. In 2000, the author and co-workers reported a comparative study using conventional and cryogenic 3 mm gradient inverse NMR probes using a 40 μg sample of the indole alkaloid strychnine [11]. This comparison demonstrated an improvement in performance for the cryogenic probe relative to the conventional 3 mm probe by approximately a factor of 3.5X. Liu and co-workers presented the results of their application of cryogenic NMR probe capabilities in the study of several mass-limited pharmaceutical samples [12]. With samples ranging from 10 to 80 μg this group of authors was able to record data that allowed the characterization of the samples. In an example that utilized a ^{13}C detection cryogenic NMR probe, Bringmann and co-workers [13] reported the results of a study of the biosynthetic pathway leading to acetogenic isoquinoline alkaloids. The ^{13}C-^{13}C INADEQUATE experiments employed to study the incorporation of [$^{13}C_2$] acetate were greatly facilitated by the enhanced sensitivity provided by the cryoprobe.

The significant performance advantage of cryogenic NMR probes for the acquisition of long-range ^1H–^{15}N correlation data was demonstrated using the small oxazolidinone antibiotic eperezolid by the author and co-workers in 2001 [14]. Using a 2 mg sealed sample, data were acquired in both a conventional 3 mm gradient inverse triple-resonance probe and a 5 mm cryogenic probe. Data with a s/n ratio of ~100:1 were acquired in less than 30 min using the cryogenic NMR probe while it took ~4 h to achieve only half that s/n ratio in the conventional 3 mm probe.

In 2002, Gustafson and co-workers reported the elucidation of the complex polyketide-derived macrolactam pecillastrin A from a deep water Caribbean sponge [15]. It was necessary for these authors to resort to a 500 MHz gradient inverse triple resonance cryogenic probe to acquire the necessary long-range correlation data on the 800 μg sample of the C_{82} natural product to complete the structure elucidation. Later in 2002, the author and co-workers [16] reported the utilization of a 500 MHz gradient triple resonance cryoprobe in the acquisition of long-range ^1H–^{13}C and ^1H–^{15}N correlation data in the characterization of one of the isolated degradants, **3**, shown in Scheme 1. Cook and co-workers put the sensitivity enhancement of cryogenic NMR probe technology to excellent use in their study of the Boreal forest fulvinic acid [17]. This group of authors acquired both ^1H–^{13}C HSQC and HMBC on this complex mixture, which gave >300 direct correlation responses in the HSQC spectrum. In a study that represents an interesting potential technique for natural products characterization, Griesinger and co-workers reported the measurement of long-range ^1H–^{13}C coupling constants of natural products at natural abundance using orienting media [18]. Sandvoss and co-workers, exploited the sensitivity of a cryoprobe to facilitate the acquisition of HSQC-TOCSY data for limited samples of two complex new asterosaponins from the starfish *Asterias rubens* [19]. Cryogenic NMR probe capabilities were also of importance in the acquisition of HSQC-TOCSY and ^1H–^{15}N long-range data acquired during the characterization of the complex indoloquinoline dimeric alkaloid quindolinocryptotackieine, which relied on Computer-Assisted Structure Elucidation (CASE) methods because of the extensive overlap in both the proton and carbon frequency domains [20]. Another example of the use of cryogenic NMR probe capabilities for small molecules is found in the work of Exarchou and co-workers [21] who used a combination of solid phase extraction (SPE) and cryoprobe technology for the identification of constituents present in Greek oregano. Further applications are surveyed in a recently published review [8].

Metabolic and Metabonomic Applications

In the first application of cryogenic NMR probe technology of which the author is aware, Pease and co-workers reported the results obtained with a 2.5 mm cryoprobe in the characterization of several metabolites [22]. Using a spectrometer equipped with a ^{13}C detection cryogenic NMR probe, Keun and co-workers investigated the applicability of ^{13}C spectral data as a compliment to routinely utilized ^1H data for metabonomic studies [23]. Griffin [24] reported an overview of ongoing metabonomic studies of xenobiotic toxicity and disease states that relied on cryoprobe data. Corcoran and co-workers [25] characterized the sensitivity advantages afforded by cryogenic NMR flow probes in LC-NMR-MS applications in a study of acetaominophen metabolites in urine. Stöckigt and co-workers [26] described the results of an interesting study in which alkaloid metabolism in hybrid *Rauwolfia* plant cell cultures was followed using a 500 MHz cryogenic NMR probe. The authors contrast the cryoprobe results with conventional 800 MHz NMR data on the same samples. Cryogenic NMR probe capabilities were also utilized by Bertini and co-workers [27] to study the degradation of aromatic compounds by *Pseudomonas putida*. More recent applications are surveyed in a recent review [8].

Protein and Biochemical Applications

In an early application in the field of protein NMR, Dötsch and co-workers [28] reported the development of several new ^{13}C detected protein NMR experiments designed to exploit the sensitivity of a ^{13}C detection cryoprobe. Wand and co-workers [29] described their efforts in the optimization of the application of cryogenic NMR probe technology in the study of proteins. In one of the early applications of cryoprobe technology involving proteins used in NMR-based screening of pharmaceuticals, Fesik and co-workers [30] compared the results obtained in NMR screening studies using specifically ^{13}C labeled amino acids in proteins with the more traditionally employed ^1H–^{15}N HSQC NMR screening methods. The authors demonstrated that with cryogenic NMR probes, this approach gave ~3X the sensitivity of the more traditional proton-nitrogen based screening approach.

After the initial flurry of cryoprobe applications in the field of protein NMR, there was somewhat of a gap before papers again began to appear. This interval corresponds to initial vendor-investigator collaborations during the early development of cryogenic NMR probes and when they began to appear in the laboratories of the investigators. Cowburn and co-workers [31] communicated the results that they obtained for triple resonance NMR experiments of proteins using a cryogenic NMR probe in 3–4 h that would typically require 1–2 days using conventional NMR probe technology. Bertini and co-workers [32] employed ^{13}C direct detection cryoprobe capabilities to facilitate a study of broad lines in paramagnetic metalloproteins in late 2003. Another application of the use of a ^{13}C detection cryogenic probe was the early 2004 report by Bertini and colleagues [33] in the acquisition of ^{13}C–^{13}C NOESY spectra of large macromolecules. In a departure from most other cryogenic NMR probe applications, Shu and Frieden [34] described the application of a ^{19}F cryogenic NMR probe in a study of the urea-dependent unfolding of murine adenosine deaminase by measuring sequential destabilization of ^{19}F NMR. Petros and co-workers [35] employed a 500 MHz cryogenic NMR probe in a study to define the p53 DNA-binding domain/Bcl-X_L binding interface. The cryoprobe data were used to monitor perturbations in the ^{13}C shifts of labeled substrate to the unlabeled p53 DNA-binding domain. Germann and co-workers [36] used the sensitivity of a 500 MHz cryoprobe to acquire F_2-coupled ^{1}H–^{13}C HSQC spectra of a DNA duplex containing an α-anomeric adenosine as a part of a study to explore substrate recognition by endonuclease IV. Further examples are again found in a recent review [8]. Armengod and co-workers [37] utilized a 500 MHz cryoprobe to facilitate multinuclear NMR assignments for the 18.7 kDa GTPase domain of *E. coli* MnmE protein. The enhanced sensitivity of the cryoprobe was necessary to provide adequate signal-to-noise for the assignments of the low solubility and unstable protein sample.

Conclusions

Cryogenic NMR probes are continuing to go through what will probably be a long series of iterative design improvements that should move sensitivity incrementally higher. At present, cryogenic probes offer a very significant gain in sensitivity over conventional NMR probes, typically threefold or higher at observation frequencies ranging from 500 to 900 MHz. The pharmaceutical industry is already heavily invested in cryogenic NMR probes, which have significant reduced sample isolate requirements for the characterization of impurities and degradants of pharmaceuticals in the possessive author's—laboratories. Similar advantage has been gained in laboratories devoted to the characterization of metabolites of pharmaceuticals. As investigator access to cryogenic NMR probe-equipped spectrometers continues to improve, there will undoubtedly be many new applications reported in the literature in the fields of natural product characterization, biosynthesis, forensic sample identification, and many other disciplines.

Flow NMR Techniques in the Pharmaceutical Sciences

Paul A. Keifer
University of Nebraska Medical Center, Eppley Institute, 986805 Nebraska Medical Center, Omaha, NE 68198-6805, USA

Introduction

Flow NMR [1,2] is a rapidly growing subset of solution-state NMR, which itself is commonly used in the pharmaceutical sciences. Flow NMR is defined here as any solution-state NMR technique in which the sample is introduced into the NMR probe as a flowing stream. The sample may—or may not—be flowing during the time of actual data acquisition. In contrast, conventional solution-state NMR uses static samples contained in glass tubes.

All known flow NMR techniques can be separated into two categories, depending upon the primary purpose of the flow. The first category uses a separation technique, such as chromatography or electrophoresis, prior to the NMR analysis (Figure 1A). The standard examples are LC-NMR and LC-NMR-MS [3]. The second category uses the liquid flow primarily as a means of transport; as a way to conveniently move solution-state samples in and out of the NMR analysis coil (Figure 1C and 1D). The standard examples of this category are direct-injection NMR (DI-NMR) [4] and flow-injection NMR (FIA-NMR) [5].

Flow NMR has both advantages and disadvantages when compared to non-flow NMR techniques. As such, although flow NMR complements non-flow NMR, it will never replace it. One advantage of flow NMR is that it allows samples to be moved quickly and easily in and out of the flow cell in the NMR probe. One disadvantage is that some flow hardware can be prone to contamination (or even clogging), because the NMR probe's flow cell is often used for hundreds of different samples.

LC-NMR

Complex mixtures are normally analyzed by fractionation, followed by an examination of the individual components one at a time. The traditional method of doing this consists of running a chromatographic separation off-line, collecting the individual fractions, evaporating them to dryness (to remove the mobile phase), and re-dissolving them in deuterated solvents. This is followed by examination with conventional NMR methods (using specialized microprobes, submicroprobes, Nanoprobes, or microcells, as needed) [6].

LC-NMR is an alternative to this method. It combines the separation and analysis steps, and because the analysis immediately follows the separation, it is especially useful if the solutes are volatile, unstable, or air-sensitive [7].

LC-NMR was first developed in 1978 [8], but during the 1980s it was more of an academic curiosity than a robust analytical tool. It became more popular during the mid-1990s as high-sensitivity flow probes became more readily available, better solvent-suppression techniques were developed [9], and the overall robustness increased. LC-NMR is now considered to be an almost routine technique [3].

The hardware for LC-NMR, including the NMR flow probe, is shown in Figure 1A. LC-NMR experiments can be run either in an on-flow mode, in which the mobile phase moves continuously during acquisition, or in a stopped-flow mode, in which the peaks of interest are stopped in the NMR flow probe for as long as is needed for NMR data acquisition. On-flow data are more useful for preliminary or survey-mode analyses, while stopped-flow data are more useful for careful examinations of individual components, using either 1D or 2D NMR techniques.

There are at least four ways to acquire stopped-flow data. First, the chromatographic peaks of interest can be stopped in the flow probe (directly as they elute from the chromatography column) and analyzed one at a time, for as long as necessary. Second, the LC pump may be programmed to "time slice" through a chromatographic peak, stopping every few seconds to acquire a new spectrum (or pumping very slowly). This is useful both for resolving multiple components (by NMR) from within a peak that is not fully resolved chromatographically, or for verifying the purity of a chromatographic peak. A third method involves collecting the chromatographic peaks of interest into loops of tubing (off-line) and then flushing the intact fractions into the NMR flow probe (one at a time) as needed. A fourth method involves trapping the eluted peaks onto another chromatographic column and then re-eluting them with a stronger solvent into the flow probe. This method (called SPE-NMR; Figure 1B) is discussed below.

Fig. 1. Flow NMR fluid paths for: (A) LC-NMR and LC-NMR-MS, (B) SPE-NMR, (C) FIA-NMR, and (D) DI-NMR. Boxes show highly significant differences of each technique. The fluid pumps in LC-NMR and SPE-NMR are typically piston pumps capable of producing solvent gradients. The pumps in DI-NMR are typically syringe pumps. The pumps in FIA-NMR can be either (solvent gradients are not typically used nor required). The optional detectors in LC-NMR, SPE-NMR, and FIA-NMR may be any type of single (or multiple) in-line non-destructive chromatography detectors (i.e., UV, RI, radiochemical, ELSD, fluorescence). In LC-NMR, SPE-NMR, and FIA-NMR, the fluid flow is always uni-directional through the probe. In DI-NMR the flow of sample fluid is usually bi-directional (unless the flow cells are made of only uniform capillary tubing), but the additional rinsing steps may be either bi-directional or uni-directional.

The acquisition of LC-NMR data can be difficult for several reasons. First, the mobile phases in LC-NMR are solvent mixtures, and because the solvents are often non-deuterated there are usually one or more solvent resonances that need to be suppressed. Second, the resonances of the organic solvents within the mobile phase contain ^{13}C satellites, which complicate the NMR spectrum and also need to be suppressed. Third, the pulse sequences of many solvent suppression schemes (like presaturation) do not work well on samples that are flowing through the probe. Fourth, during the commonly used gradient elution, the solvent resonances that need to be suppressed are constantly changing frequency (because the solvent composition changes during the experiment). In reversed-phase LC-NMR (which uses water), the chemical shift of water can move up to 3 ppm during a gradient run. Fifth, if the mobile phase is fully protonated (non-deuterated) there will be no ^{2}H lock to keep the frequencies constant. All of these problems are solved by using WET solvent suppression combined with the SCOUT-scan technique [9]. WET uses a combination of shaped-pulse selective excitation, multi-frequency SLP pulses, PFG, and indirect-detection-style ^{13}C decoupling during the shaped pulses to properly suppress multiple solvent resonances using only a two-channel spectrometer. The FIA-NMR and DI-NMR techniques (discussed below) also benefit from using SCOUT and WET [4,5].

LC-NMR-MS

Although LC-NMR is a powerful analytical tool, it can be made even more powerful by adding mass spectrometry to create on-line LC-NMR-MS [10]. This is usually done by splitting off a fraction of the chromatographic effluent (prior to the NMR flow cell) and sending it to a mass spectrometer. Numerous papers and reviews have shown how LC-NMR-MS runs one-step analyses on problems that were either sample limited or that proved to be tough structural problems [3,11,12]. LC-NMR-MS has now been fully adopted for pharmaceutical problems that are both urgent and important. Both LC-NMR and LC-NMR-MS are now commercially available (Bruker—www.bruker.com, Varian—www.varianinc.com, and JEOL—www.jeol.com).

One advantage of incorporating a mass spectrometer into the detector chain is that the mass spectrometer output provides a selective and sensitive signal that can be used to stop the fluid flow to allow NMR signal averaging (to increase the NMR signal-to-noise). This is especially useful for drug-metabolism studies where mass information about the parent compound is already known [13].

Other Detectors in LC-NMR

In LC-NMR, although the NMR serves as one detector, additional in-line detectors (connected in series) can also be used. One or more additional detectors—such as UV, fluorescence, radiochemical, refractive index, or evaporative light scattering detectors—are commonly added (Figure 1), either to get more data or to trigger the HPLC pump to stop the flow on a specific chromatographic peak (for NMR signal averaging).

Other Chromatography in LC-NMR

Other types of chromatography (besides reversed-phase HPLC) were coupled to NMR flow probes starting around 1994. Examples include capillary electrophoresis NMR (CE-NMR), capillary electrochromatography NMR (CEC-NMR), capillary HPLC (CapLC-NMR or CHPLC-NMR), supercritical fluid chromatography (SFC-NMR), and supercritical fluid extraction NMR (SFE-NMR) [3,14–16]. Additionally, size-exclusion chromatography NMR (SEC-NMR) is used to analyze polymers [17–19], and ion-exchange chromatography NMR is used to analyze both protein mixtures [20] and polar metabolites [21].

Other Plumbing Schemes: Loop-Collection LC-NMR and Solid-Phase Extraction NMR (SPE-NMR)

As mentioned above, chromatographic peaks are sometimes collected in loops (i.e. in loops of capillary tubing controlled by a loop-collection system) prior to NMR analysis. The contents of each loop can then be individually flushed into the NMR probe as needed.

A variation upon loop collection is SPE-NMR (solid phase extraction LC-NMR), which attempts to increase solute concentration (to increase NMR sensitivity) by reversing the sample dilution that inevitably occurs during loop collection and analysis [22,23]. In SPE-NMR, the HPLC peaks that elute from the column are individually diverted to in-line solid-phase extraction cartridges (Figure 1B). Water is added to the mobile phase so that the solutes are retained on this small cartridge. Once the column trapping is complete, the solutes are eluted with a stronger solvent (which can be deuterated to ease the NMR analysis) into a concentrated plug that is pumped directly into the NMR flow cell. SPE-NMR has been used for the analysis of microsomal incubate metabolites [24] and natural products [25].

Applications of LC-NMR

LC-NMR has been readily embraced by numerous fields in pharmaceutical research, as evidenced by hundreds of research publications. LC-NMR and LC-NMR-MS are now essentially routine techniques for groups studying drug metabolism [26,27]. They are proving useful for drug-manufacturing and quality-control groups [28], for the analysis of drug impurities [29], for the analysis of drug stability [30], for identifying unstable compounds [31–33] or volatile compounds [34], for metabonomics [35,36], and for evaluating the environmental fate of pharmaceuticals [37]. LC-NMR is being used for natural product drug discovery [38–41] as well as for determining the chirality of natural products [42]. LC-NMR was also evaluated for monitoring reactions within production facilities [43] and has proven useful in evaluating compounds that do not contain UV chromophores [44]. Numerous reviews of the applications of LC-NMR and LC-NMR-MS are in the literature [3,11].

Limitations of LC-NMR

Although LC-NMR and LC-NMR-MS techniques are very powerful analytically, they tend to be slow (1–24 h) compared to LC-MS [45] or other high-throughput analysis methods (2–5 min) because of two limitations. First, NMR is less sensitive than many other techniques (i.e., mass spectrometry) and the need for signal averaging consumes time. Second, although LC-NMR can handle solvent gradients, samples for NMR need to have a “uniform magnetic susceptibility,” which means that LC-NMR is not easily adaptable to ultra-fast “turbo” solvent gradients that ramp from 0 to 100% in just a few minutes. These two limitations, combined with the higher cost of an LC-NMR system (as compared to LC-MS), mean that LC-NMR and LC-NMR-MS are best suited to solving the toughest problems on the most expensive samples that cannot be solved in other ways.

Flow-Injection Analysis NMR (FIA-NMR)

The second category of flow NMR methods uses the liquid flow primarily as a means of transport to and from the NMR probe, and does not use any separation technique. This category consists of two basic techniques that differ in the type of fluid flow used: flow-injection analysis NMR (FIA-NMR) [5] and direct-injection NMR (DI-NMR) [4].

Like classical flow injection analysis [46], classical FIA-NMR [5] injects the sample as a plug into an unbroken stream of fluid (an "isocratic mobile phase"), and the resulting sample plug is pushed into the NMR detector coil (and then stopped) by the controlled motion of the fluid (Figure 1C). The fluid serves three purposes. First, it serves as a conveyer belt to carry the sample into the NMR probe. Second, it rinses out the flow cell at the end of the analysis. Third, it allows samples smaller than the volume of the flow cell to be analyzed. (The intact liquid stream reduces the NMR line broadenings caused by the magnetic-susceptibility distortions that would arise from air bubbles in a non-filled NMR flow cell, although this also causes sample dilution when small sample volumes are injected. Unlike other variants of FIA, conventional FIA does not use any air bubbles (or other devices) as separators in the liquid stream [46].)

As in all other flow NMR techniques, once the sample is placed within the NMR flow cell, the NMR acquisition itself can be readily automated. This can consist of PFG gradient shimming (if desired), automated receiver gain adjustment (if desired), and SCOUT scans (to find the solvent frequencies and create the appropriate WET-shaped pulse), followed by the acquisition of 1D or 2D NMR spectra using WET solvent suppression. The whole process (injection and acquisition), for entire queues of samples, is normally controlled by automation software running on the NMR spectrometer.

The first hyphenation of FIA and NMR was published in 1997 [47,48], where it was called "column-less LC-NMR." More recent papers have since demonstrated its viability as an analytical method [5,49,50], and it has been the subject of several reviews [6,51]. Note that there are entire books [46] and journals [52] dedicated to the technique of FIA.

Direct Injection NMR (DI-NMR)

In contrast to FIA-NMR, DI-NMR [4] injects the sample solution directly into an empty flow cell in the NMR probe (Figure 1D). The sample is not injected into a stream of liquid (because no "mobile phase" is present), which generates the maximum NMR sensitivity (because there is no sample dilution) and allows the sample to be recovered intact if desired. Sample recovery is normally accomplished by pulling the analyzed samples back out the way they went in (Figure 1D). The flow cell is then rinsed by pushing clean solvent in and out as many times as is needed to remove traces of solute. Residual rinse solvents can be a source of sample dilution, although the flow cell is emptied each time, so the dilution is usually minimal. Although samples could instead be recovered by pushing them on through the detector coil, this is usually inefficient and requires additional inefficient rinsing steps, unless the NMR flow cell has a capillary (non-standard) geometry.

Although the solvents used in LC-NMR are usually simple mixtures of water and either acetonitrile or methanol, DI-NMR has been run with a wider range of solvents and solvent mixtures, including $CHCl_3$, dimethylsulfoxide (DMSO), tetrahydrofuran (THF), biofluids, and water, as well as HPLC mobile phases. NMR software has evolved so much that it is now relatively easy to automatically acquire NMR data on samples dissolved in even complex solvent mixtures when using WET solvent suppression and the SCOUT-scan technique [9].

One disadvantage of DI-NMR is that the volume of the injected samples must be bigger than the volume of the NMR flow cell or the NMR resonances will be broadened (due to magnetic-susceptibility distortions arising from the air pockets within the flow cell). The other disadvantage of DI-NMR is that the sample cell can become contaminated from repeated contact with "raw" samples, or the connecting capillary tubing can become plugged. Both of these issues can be addressed in FIA-NMR, although FIA-NMR does not readily allow sample recovery, and does not generate the maximum possible NMR sensitivity. Note that FIA-NMR and DI-NMR are complementary, in that their advantages and disadvantages are the opposite of each other.

The injection in DI-NMR is typically performed using a robotic liquid handler controlled by the NMR spectrometer. The normal liquid handlers used for DI-NMR allow samples to be stored in a wide range of containers, including disposable vials or microtiter plates (vs. the precision glass sample tubes required in conventional solution-state NMR). DI-NMR is now commercially available [as systems called VAST (from Varian—www.varianinc.com) and BEST (from Bruker—www.bruker.com)]. These systems are normally capable of analyzing samples ranging in size from 150 to 350 ml (or more), with concentrations ranging from 1–50 mM, and stored in multiple 96-well microtiter plates. A typical analysis time may range from 2 to 7 min, depending upon the viscosity of the solvent, the concentration and volume of the sample, and the amount of rinsing desired. A complete description of DI-NMR was published in 2000 [4], which included a description of the use of DI-NMR in the analysis of combinatorial chemistry libraries, and numerous examples of different data-presentation formats.

The technique of DI-NMR was first published in 1997 [47,48], followed quickly by publications describing its use for analyzing chemical libraries [4,53–58], for analyzing biological fluids (including the commercial analysis of human plasma) [59,60], and for the screening of ligand binding with proteins and other biomolecules [36,61–63]. DI-NMR has spurred further developments in flow probes

[64], NMR pulse sequences [65], and reference standards [66,67]. The development of DI-NMR has also been the subject of several reviews [2,6,36,47,48,51,63].

Complementary Technologies

Numerous developments in other fields of NMR are proving useful to flow NMR. One important area is in probe development. "Normal" flow probes have active volumes of 30–60 ml. (Conventional flow cells require sample volumes of at least twice the active volume to obtain reasonable NMR lineshapes.) Some applications may require probes that have different volumes, to analyze either smaller-volume or lower-concentration samples. For the latter application, a larger volume (120-ml) flow probe was optimized for "SAR-by-NMR" (NMR-screening) assays that use DI-NMR to acquire ^{15}N HSQC data [64].

Microcoils

Even more interest is being generated by the work on smaller-volume "microcoil" flow probes [3,15,68–71]. The RF coils of microcoil probes are wound around capillary tubing and this produces probes with active volumes of typically 1–5 ml. These probes are usually filled using a flow technique, but not always [72,73]. There are dozens of articles now describing the use of microcoil flow probes to analyze effluents from on-line capillary HPLC, capillary electrophoresis (CE), and capillary isotachophoresis (cITP-NMR) [74–79]. As evidence of their sensitivity, a microcoil was used to analyze the 540 pmol of compound cleaved from a single 160-micron-diameter solid-phase resin bead [80]. A microcoil flow probe was also used to identify members of a natural products library using 5–50 micrograms of compound dissolved in 3 microliters of solvent [57]. Microcoil probes have now been interfaced with automated capillary liquid handlers, and are commercially available (from the MRM division of Protasis; www.protasis.com).

Interchangeable Flow Cells

Another limitation of flow NMR, particularly DI-NMR, is that repetitive injections of "raw" samples can eventually contaminate (or clog) the NMR flow cell. (LC-NMR samples have been "filtered" through the HPLC column, and FIA-NMR can incorporate in-line filters, but DI-NMR cannot easily do so.) This limitation has been addressed with the development of user-changeable flow cells to form the interchangeable flow cell (IFC) probe, which has been discussed in the literature [6,51]. User-changeable flow cells are designed to minimize instrument downtime.

Cold Probes

NMR users always need better spectral signal-to-noise. The conventional solution is to increase the signal intensity, but another way is to decrease the noise. This has been accomplished by cooling the electronics of the NMR probe (but not the sample) so as to reduce thermal noise. The resulting probe, called a cold probe, a cryogenic probe, or a cryoprobe, is usually operated at a temperature of 25 K, which provides a signal-to-noise improvement of about fourfold [81]. This technology has since been incorporated into flow probes [11,82,83].

Parallel NMR: Multiplex NMR

The goal for any high-throughput technique is to run the analyses in parallel. NMR has historically been only a serial technique, but this is changing, as ways are being developed to acquire NMR data in parallel—by placing multiple sample chambers, each with their own dedicated detection (RF) coil, all within one NMR probe (within one magnet) [84,85]. The multiple coils are usually designed so they can analyze one sample while other samples are being loaded into different coils (to reduce the percentage of analysis time lost to shuttling samples into the NMR magnet) [86,87]. Other functions of multiple-coil (multiplex) probes are to measure rapid-reaction kinetics (by placing multiple coils at different points along a flowing sample) [88], to acquire capillary electrophoresis data using solenoidal microcoils [89], or to acquire the difference spectrum between two samples in a "difference probe" [90,91].

Alternative Ways to Acquire nD-NMR Data

The filter diagonalization method (FDM) [92] is a way to rapidly acquire nD-NMR data rapidly, and store the resulting data in a much smaller space. Although the development of FDM is still in its infancy, if it can rapidly acquire 2D ^{1}H{^{13}C} or ^{1}H{^{15}N} heteronuclear correlation (HSQC) data, this could help DI-NMR either to characterize combinatorial chemistry libraries or to screen proteins for ligand binding. It may also benefit LC-NMR.

Frydman *et al.* have developed another method for rapidly acquiring nD-NMR data [93]. They have proposed using this technique in combination with LC-NMR [94]. Although its sensitivity limitations make it currently impractical for LC-NMR, it may prove useful in the DI-NMR analyses of compound libraries.

DOSY: A Possible Alternative to LC-NMR

Diffusion-ordered spectroscopy (DOSY) [95] can separate the 1D NMR spectrum of a mixture into individual 1D sub-spectra based upon the diffusion rates of the individual components. DOSY is already being used now for NMR screening (determining which compounds bind to large-molecule receptors) [96], although not in a flow mode. (It easily could be because other kinds of NMR screening are being performed using flow NMR.) DOSY has also been proposed as a possible alternative to LC-NMR [97]. The *combined* use of DOSY on LC-NMR fractions is interesting, but it is unlikely to be a practical technique due to the typically low NMR signal-to-noise in LC-NMR. DOSY should prove useful within DI-NMR, however, to verify compound purity in a chemical library.

Conclusions

A variety of different flow NMR techniques are currently being used in the pharmaceutical sciences, each with their own unique advantages and disadvantages. LC-NMR techniques offer separation capabilities, and are powerful, but are often slow. FIA-NMR is well suited to fast, repetitive, destructive analyses that do not need chromatographic separations, where carryover must be minimized, and which do not require much NMR time-averaging. DI-NMR is best suited to repetitive, non-destructive analyses that do not need chromatographic separations, where the sample needs to be recovered, where slight carryover is not a problem, and which may need time-averaging of the NMR data.

Developments in NMR Hyphenation for Pharmaceutical Industry

Manfred Spraul

Bruker BioSpin GmbH, Silberstreifen, D-76287 Rheinstettan, Germany

Introduction

First introduced in 1978 [1], LC-NMR since the early 1990s has grown into a standard analytical method in pharmaceutical industry with an increasing number of publications every year [2–24].

This has been enabled by improved magnet design, dedicated NMR flow probes, automatic multiple solvent suppression, and full automation. The typical application areas for LC-NMR in the pharmaceutical industry are:

- screening for drug metabolites in biofluids or extracts;
- drug impurity profiling;
- drug stability profiling;
- detection of new biomarkers of toxicity or disease;
- combinatorial chemistry and parallel synthesis to investigate product mixtures;
- natural product screening.

The following operation modes have evolved and can be executed in an automated fashion on a modern hyphenated system which will be explained in more detail later and include:

- on-flow LC-NMR;
- direct stop-flow;
- loop collection [17];
- post-column solid phase extraction (SPE) [14,23];
- time slicing.

To be able to perform the stop-flow, loop collection, or post-column SPE, a non-NMR detector is needed to locate LC peaks of interest for the NMR transfer. UV detection was used exclusively in early LC-NMR experiments. Currently, DAD and MS are used for LC peak detection in most cases. Refractive index detectors are less suitable for LC-NMR due to the gradient LC methods that are required to keep the eluting peaks as sharp as possible to preserve the NMR sensitivity.

In the following sections, the operation modes mentioned above will be explained and the required hardware discussed.

On-Flow LC-NMR

In this mode, the flow from the chromatographic column is guided through a flow cell in a dedicated NMR flow probe. Repeated NMR measurements are performed in a pseudo-two-dimensional (2D) acquisition mode; however in contrast to real 2D experiments, there is no incremented evolution time and timing stays constant over the whole experiment. The time for one measurement is defined by the flow rate of the chromatographic separation and typically lies between 8 and 20 s for standard analytical columns. The flow cells used in the NMR probe head typically have an active volume of 120 or 60 μl, with the active volume defined by the detection coil dimensions. The total volume of such a flow cell is about 200 or 100 μl, respectively.

The possible accumulation time in one experiment of an on-flow run is defined not only by the flow rate, but also by the steepness of the LC gradient. Normally in reversed phase separations, water is replaced by D_2O for locking purposes. In addition to the locking advantage, the need for solvent suppression on two signals is also reduced. If water is used, the signal can be very broad, especially when methanol is used as the cosolvent through exchange with the methanol-OH. The suppression power required for such a system would be large and would also reduce desired signals in the vicinity of the water resonance. When D_2O is used, non-deuterated methanol or acetonitrile are added for the LC gradient. The dynamic range of the NMR detection system is limited by the large concentration difference between the compounds of interest and the organic solvent signal, which is orders of magnitude larger. Suppression of the solvent signals therefore is mandatory in order to achieve the optimized detection of the weak solute signals of interest.

A further complication arises through the fact that the chemical shifts of the NMR signals are strongly dependent on the composition of the solvent mixture and the pH. This means in an LC-gradient run, the relative position of the organic solvent signal to the water frequency constantly moves. If one has to suppress the solvent, one has to follow this change in frequency constantly. Within one experiment the suppression frequencies can be defined

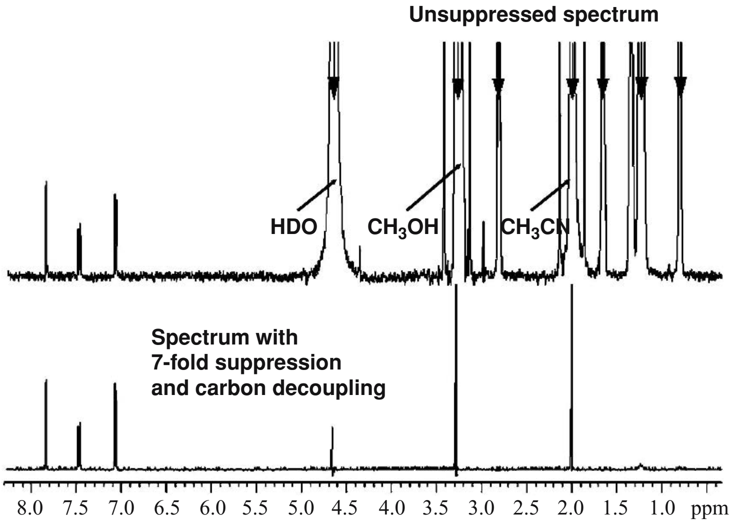

Fig. 1. The effect of automatic solvent suppression in LC-NMR on a solvent system containing acetonitrile, methanol, water, and ion-pair reagent, the signals marked with an arrow are selected for suppression automatically.

automatically by a short preparation experiment, which only takes a few seconds and delivers the correct frequencies that are then loaded for the experiment with suppression. In order not to lose suppression quality, the length of one accumulation is restricted due to the steepness of the LC gradient. Solvent signals like acetonitrile or methanol show a single resonance line, which is easy to suppress. However, at the 0.5% level of this signal, a doublet is visible. This is due to the fact that 1% of the carbon atoms are not carbon-12, but carbon-13, which are NMR active and cause the splitting of the resonance line to a doublet. These carbon satellite lines, as they are called, are still large compared to the solute signals and also increase the disturbed area in the spectrum. Therefore it is advantageous to remove the doublet by also irradiating the carbon frequencies at the same time; by this action the doublet collapses into the singlet line of the C12-based solvent, which is already suppressed. The automation control of a modern NMR spectrometer allows the suppression of as many solvent lines as needed, by using phase-shifted-shaped radio frequency pulses and carbon decoupling. However, it is obvious that the observable region in a spectrum can be diminished seriously when suppressing too many solvent or buffer lines.

Figure 1 shows the typical effect solvent suppression, comparing the non-suppressed spectrum with the result of the automatic solvent suppressed spectra. In this case, an ion-pair reagent separation was performed and the signals of acetonitrile, methanol, residual water, and octane-1-sulfonic acid were suppressed.

The lines to be suppressed are indicated by arrows in the upper spectrum. The solute in this case was 5-hydroxysalicylic acid.

A typical on-flow experiment is shown in Figure 2, along the horizontal axis the proton-NMR chemical shift is shown, along the vertical axis the retention time of the chromatogram is increasing from bottom to top. The lines at 2 and 4.7 ppm are due to the suppressed acetonitrile and water signals. A 100 µl of urine, obtained 4 h after ingestion of 500 mg of paracetamol (male adult) was injected onto a 150 × 4.6 mm RP-18 column using a flow rate of 0.8 ml/min and a time resolution on the NMR detection of 16 s. The acetonitrile signal shows the change in frequency due to the LC gradient, it moves to higher ppm values with increasing amount of acetonitrile. Some paracetamol metabolites can be identified through the aromatic signals between 6.8 and 7.3 ppm. The anomeric protons of the glucuronides show resonances at $\sim$5.2 ppm.

Taking a horizontal row out of the on-flow spectrum generates the ^{1}H-spectrum at a given retention time.

Due to the short residence time in the flow cell and by this the limited number of scans per row, sensitivity in this operation mode of LC-NMR is limited to the microgram range of detection. Therefore the need for stopped flow measurements emerged, especially for pharmaceutical applications, where often impurities or low concentration metabolites have to be identified.

Direct Stop-Flow

To be able to stop the flow exactly when the maximum of an LC peak of interest has reached the center of the flow cell, fast detection of the LC peaks is needed. NMR is too slow and not sensitive enough, therefore other analytical tools are needed. UV detection is most often used as a

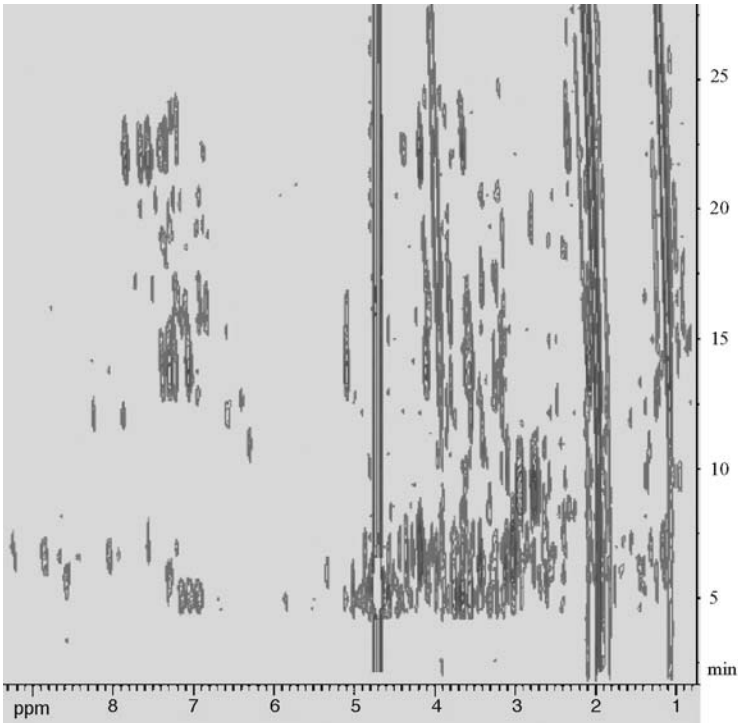

Fig. 2. On-Flow LC-NMR spectrum of a reversed phase separation after injection of a human urine obtained 4 h after ingestion of 500 mg of paracetamol (150 × 4.6 mm RP-18 column using a flow rate of 0.8 ml/min). (See also Plate 92 on page XVIII in the Color Plate Section.)

chromatographic detector and it is much more sensitive compared to NMR. Therefore a UV cell has to be positioned between the LC column outlet and the NMR flow cell. An additional valve is needed to switch the NMR flow cell off-line when an LC peak has reached the flow cell. Knowing the capillary length and diameter, as well as the flow rate, the time for an LC peak to the NMR flow cell can be calculated. In order to perform automatic stop-flow, software is needed that monitors the UV signal and stops the pump at the correct time. Since the pump flow is not stopped immediately, the valve mentioned, will turn on the stop command, to isolate the NMR flow path and prevent all movement of the LC peak inside the NMR flow cell.

In this mode of operation, long-term NMR acquisitions can be executed, also allowing fully quantitative measurements, impossible in the on-flow mode. This is also the mode to execute 2D experiments to get further structural information.

The direct stop-flow mode has limitations, if multiple stops are needed to look to all LC peaks of interest. All peaks still residing in the column or on the way to the NMR when a stop occurs will undergo diffusion. The longer the stop, the more diffusion will lead to LC peak broadening by this degrading the chromatographic resolution. After a restart, the peaks still on the column will be partly refocused; however, an effect is clearly visible. Broadening of LC peaks leads to loss of NMR sensitivity due to a smaller fraction of the peak fitting into the flow cells active region. Pump control also has to assure, that after a restart, the gradient ratio is the same as when the flow stopped.

Figure 3 shows a comparison of a chromatographic separation on an RP-18 column at 1 ml/min flow with injection of a mixture of four *p*-hydroxy benzoic acid esters. The left side shows the run with stop-flow on every peak, and the right side shows the on-flow result. The degradation of the chromatographic separation is clearly visible; even so only four short stops to acquire a one-dimensional (1D) NMR spectrum were done. The problem of the multiple stop-flow degradation can be overcome by the use of a loop collection system, which is explained in the next section.

An extension of the direct stop-flow experiment is the so-called time slicing, in this case the flow is stopped for example every 30 s, independent of LC peak positions. This allows a pseudo on-flow experiment to be obtained with reduced time resolution along the chromatographic axis and improved NMR sensitivity due to the longer acquisition time. It is also possible to do the time slicing

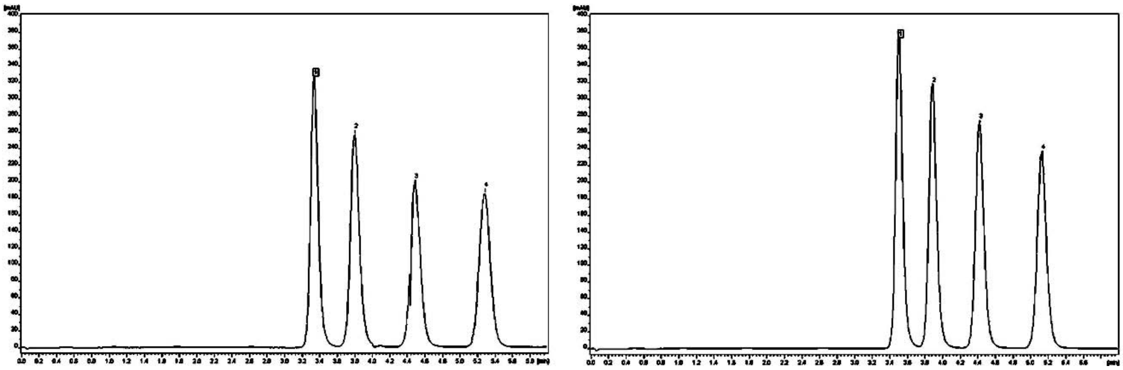

Fig. 3. Visualization of the effect of multiple stop-flow on the separation quality of a reversed phase separation after injection of a mixture of four *p*-hydroxy benzoic acid esters (methyl- to *n*-butyl-ester, 5 μg each on column) 150 × 4.6 mm RP 18 column, flow rate 0.8 ml/min).

into loops (see "Loop Collection" section) or solid phase extraction cartridges (see "Post-Column Solid Phase Extraction" section).

Loop Collection

If LC peaks are cut out of the running separation into small capillaries, where the LC peak shape is retained, the separation quality does not suffer. In order to achieve this, another valve system is needed, that allows the connection multiple capillaries allowing the collection of multiple LC peaks into the loop capillaries. In this mode, the flow is uninterrupted, only valves are turned to redirect the individual peaks into the capillaries. The first model introduced had 12 fixed loops. The next generation of loop collection systems had 36 loops housed in a removable cartridge, which is placed in a temperature-controlled environment, allowing the loop contents to be cooled, to further reduce diffusion inside the capillaries. Such a loop collection system allows the collection of LC peaks outside the NMR laboratory by transferring the cartridge after collection. To allow clear identification of the loop contents, such cartridges are equipped with an on board memory, carrying all of the information about the LC peaks in the capillaries. By using capillaries with small internal diameter (i.d.), the LC peak shape is maintained and can be transferred to the NMR flow cell to retain the sensitivity.

During a separation, multiple LC peaks can be collected and after the separation, the peaks are sequentially transferred to the NMR flow cell. This procedure also guarantees minimized back mixing between LC peaks close in retention time, which is a problem with direct stop-flow due to the stopping and restarting of the pump.

Using high-pressure valves in the loop collection device allows operation with small capillary i.d., e.g. 0.15 mm. The NMR sensitivity of the system can be improved by blowing the transfer pathway and the NMR flow cell dry using nitrogen gas before the transfer. In this operation mode, there is no dilution of the LC peak by preceding solvent.

Figure 4 shows an exchangeable loop cartridge with 36 capillaries with the top cover removed. The individual loop positions are connected to the flow path by turning the cartridge.

Since the NMR flow cells are restricted in size, typically 60 or 120 μl active volume, it is essentially impossible to place a complete LC peak inside the NMR flow cell and sensitivity is lost. In a typical analytical LC column (e.g. 150 × 4.6 mm) peaks eluting after 15–20 min, for example, would show an eluting volume above 200 μl. This problem applies to direct stop-flow and loop collection. It does not apply to on-flow operation, as there the peak is flowing through the cell completely. A way to reduce the sensitivity loss is described in the following section.

Post-Column Solid Phase Extraction

SPE is a well-known technology in LC and LC-MS to concentrate or pre-clean the sample before injection. If the SPE device is placed after the LC column, several advantages are obtained for LC-NMR operation. In this case, the SPE operates like the loop collection system, sitting after the LC peak detection (UV cell) and a valve to direct the flow into the SPE cartridges. To be able to trap LC peaks in reversed phase mode also at high organic solvent ratios, addition of water is needed before the trap cartridges. This also allows the trapping of peaks multiple times, by repeated injection and trapping of the same peaks to the same trap cartridge.

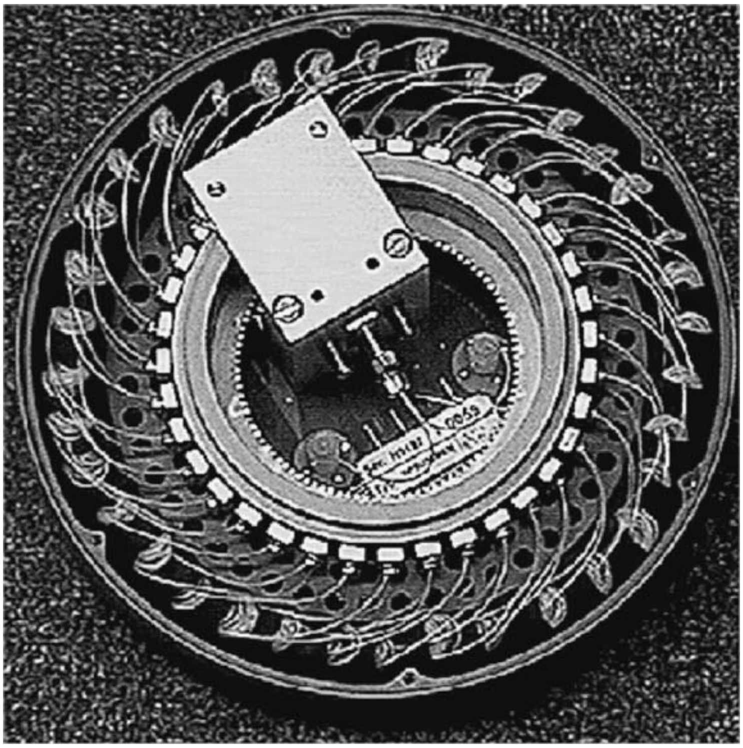

Fig. 4. Loop collection cartridge with 36 loops for LC peak collection in LC-NMR. (See also Plate 93 on page XVIII in the Color Plate Section.)

The advantages obtained are as follows:

- Higher NMR sensitivity (up to a factor four for single SPE) by up-concentration of the LC peaks.
- Use of non-deuterated solvents in the trapping process reduces cost and does not lead to deuterium exchange as is observed with MS detection when using D_2O.
- Free choice of solvents and buffers independent of their NMR signals as solvents are removed before the NMR measurement by drying with nitrogen.
- Elution of the peaks trapped with pure deuterated solvent, typically only 200 μl of solvent are needed, which is less than half compared to the solvent amount in a 5 mm NMR tube.
- Multiple trapping allows a linear increase of the NMR S/N until the trap cartridge holding capacity is reached.

To control break through of a peak from the trap cartridge, it is advisable to place a second UV detection device in the outflow after the trap cartridge. The amount of trap cartridges needed depends on the automation possibilities. With an autosampler, multiple samples can be injected, and for each sample multiple peaks can be trapped. It is also possible to run time slicing experiments. In this case, the flow would be guided through a trap cartridge for a certain time period (e.g. 30 s), before the next cartridge is switched in line. In this mode, the goal is to work toward a total analysis of a sample. A typical example would be in urine analysis. To allow a large number of SPE cartridges, a system has been introduced, placing trap cartridges in 2 well plates of 96 cartridges each. A gripper transfers the cartridges from the well plate to the flow lines. Since it must be possible to trap LC peaks close to each other in retention time, two flow lines are used. So when one cartridge is exchanged, trapping occurs on a second cartridge. Such an SPE device consists of a high-pressure double dilutor, nitrogen gas supply, two well plates with trap cartridges, two flow lines, and a gripper to transfer the trap cartridges.

Trap cartridges can have an inner diameter of either 1 or 2 mm and are 10 mm long. The eluting volume of an LC peak is approximately 10 or 25 μl respectively. To preserve the sensitivity gain from using trap cartridges, an NMR probe head with 30 μl active volume is best suited.

SPE operation under reversed phase conditions will not allow the trapping of very polar compounds, therefore the optimal LC-NMR system is equipped with the SPE device and a loop collection system and allows the switching of targets during a chromatographic run: polar compounds are collected into the loops, later eluting peaks are trapped on the SPE cartridges.

A further possibility to increase NMR sensitivity, namely the use of cryogenic probes is described in "Cryogenic Probes for LC-NMR" section. SPE allows 2D experiments or even carbon direct detection to be obtained, whereas under standard LC-NMR conditions, only proton 1D spectra can be measured in reasonable time frame.

Cryogenic Probes for LC-NMR [24]

Cryogenic probes use the noise reduction afforded by low coil temperature to enhance the NMR sensitivity by up to a factor of 4 compared to a conventional room temperature probe. A rapidly growing number of such probes can be found in NMR laboratories. While the first probes of this type were for tube applications only, dedicated cryoflow probes were introduced in 2002 and have been optimized for the LC-SPE application, with active volumes of 30 μl. Since a cryogenic probe is not as readily changed as the room temperature equivalent, probes were introduced that allow rapid conversion of a tube cryoprobe into a flow probe without compromising on signal to noise. A further improvement of sensitivity could also be obtained by cooling the pre-amplifier system.

Combining a single SPE step with cryoprobe detection allows the enhancement of LC-NMR sensitivity by more than a factor of 20 compared to conventional LC-NMR.

Figure 5 shows a comparison of NMR sensitivity obtained with the injection of 5 μg of *p*-hydroxy benzoic acid esters onto a reversed phase column (100 × 2 mm). Doing standard LC-NMR detection at 500 MHz with 24 scans, an S/N of about 9:1 is achieved for the aromatic protons. Doing post-column SPE allows an S/N of about 23:1 with a room temperature flow probe. Adding a cryoflow device brings up the sensitivity to 170:1 as shown in the figure. Doing fourfold trapping increases the S/N to 660:1. In this example, the S/N gain of going from LC-NMR to SPE was not a factor of 4, as an example was used where the peak of interest had a retention time less than 4 min. Higher S/N gain can be obtained for later eluting LC peaks, where the eluting volume is substantially increased and the concentration factor is higher.

Using flow inserts into tube-based cryoprobes allows compensation for another disadvantage of a dedicated flow probe: the flow cell size can be adjusted to the eluting peak volume. While the 30 μl flow cell is optimized for 2 mm SPE cartridges, a 10 μl cell is better suited for SPE with 1 mm cartridges, where the eluting volume is further reduced. Larger flow cells are needed for conventional LC-NMR with 4.6 or 2 mm LC columns. In this case, the eluting peak volume is substantially larger and the small detection volume of the probe would reduce sensitivity of the NMR experiment in direct stop-flow or loop collection mode.

If the cell volume of a flow cell is changed, it also changes the inner diameter of the connection capillaries. Doing SPE with 1 mm cartridges produces an eluting peak of around 10 μl. Having standard LC-NMR capillaries with an i.d. of 0.25 mm would broaden the peak eluting from the SPE cartridge considerably. Normal LC-NMR with analytical columns, however, needs this inner diameter to allow standard flow rates.

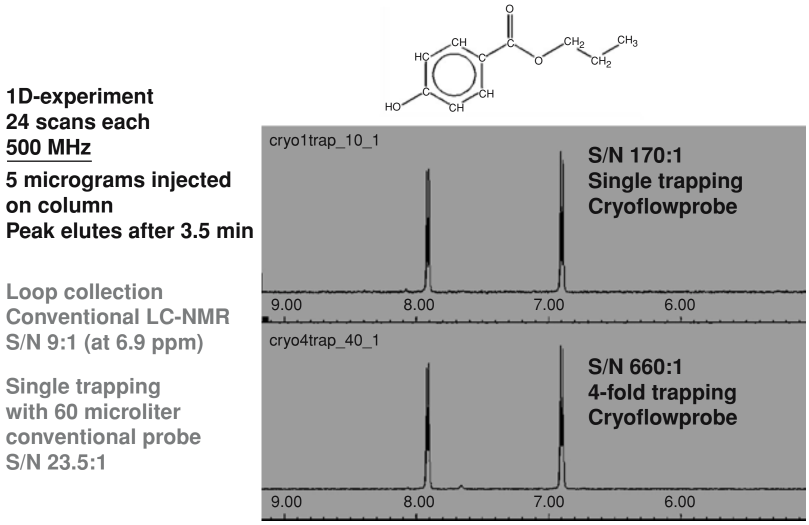

Fig. 5. Result of LC-SPE-NMR signal to noise using a cryogenic probe with single trapping of *p*-hydroxy-benzoic acid-*n*-propyl ester after an injection of 5 μg and fourfold trapping.

Improvements in the LC Peak Detection by Integrating Mass Spectroscopy into the LC-NMR Setup [13,25–36]

LC peak detection as described so far has mostly used UV detection. UV is a sensitive detector, but lacks structural specificity and cannot detect compounds without chromophores. A typical situation is the search for drug metabolites in biofluids. Such compounds often have aromatic rings and will of course give rise to UV signals; however in biofluids there are also many naturally occurring compounds giving UV signal, therefore it is difficult to find out which are the drug metabolite peaks. This leads to the situation that all peaks giving UV signals have to be measured by NMR. Doing this, peaks of no interest will also be acquired and expensive NMR time is lost. This situation can be improved, using mass spectroscopic detection, especially if high resolution MS can be used in conjunction with LC-NMR. In many cases, possible metabolite structures can be predicted, and their masses can be specifically sought out. Combining UV and MS detection provides a safety net to prevent LC peaks of interest being overlooked. The simplest way to do LC-NMR/MS is to implement a splitter into the flow path after the column and the UV detector. Obviously, only a small fraction of the flow has to be guided to the mass spectrometer, due to its much higher intrinsic sensitivity. Typically split ratios of 20:1 or higher are used. Since the MS information has to be searched for peaks of interest, the transfer to the MS electrospray interface must be completed before the NMR fraction reaches the valve. The position of the valve determines the fate of the peak fraction for the NMR, whether it goes to the flow cell directly, to a loop, to SPE, or to waste. Due to the lower NMR sensitivity, much larger sample amounts are typically injected than needed for MS detection, even considering the split ratio. This can lead to contamination of the detector if appropriate measures not are taken.

Keeping this in mind, a dedicated LC-NMR/MS interface was developed (as shown in Figure 6) that consists of a splitter, a T-piece, a double dilutor, and valve with a delay loop allows the length of transfer to the MS interface to be changed.

Having a double dilutor and a T-piece allows dilution of the flow to the MS further, to readjust the polarity of the solvent system as needed for ionization, or to add ionization helping agents that are not wanted in the NMR component of the LC peak fraction. The valve with the delay loop allows the transfer timing into the electrospray interface of the MS to be changed. This is used if a peak that went into loop collection is transferred from the loop system into the NMR. During the transfer, the NMR/MS interface is passed again and MS spectra can be run. This valve position guides the MS fraction through the delay loop, which enhances the transfer pathway in such a way, that after the NMR fraction is positioned in the flow cell, the MS fraction is still in the delay loop. When the NMR fraction reaches the flow cell, the main pump stops. The double dilutor in the NMR/MS interface can then be used to transfer the MS peak fraction in the delay loop slowly into the electrospray interface of the mass spectrometer. In doing so, a time frame of several minutes can be obtained, where MS spectra can be measured from this peak. Having minutes for measurement allows time for experiments such as multiple fragmentation, switching from positive to negative ionization, or the acquisition of high-resolution MS spectra. Such information can be obtained to help in structure identification. Together with 1D and 2D NMR spectra, an unknown structure can be solved. Therefore the NMR/MS interface allows the enhancement of the LC peak selection for the NMR and the attainment of important structural information.

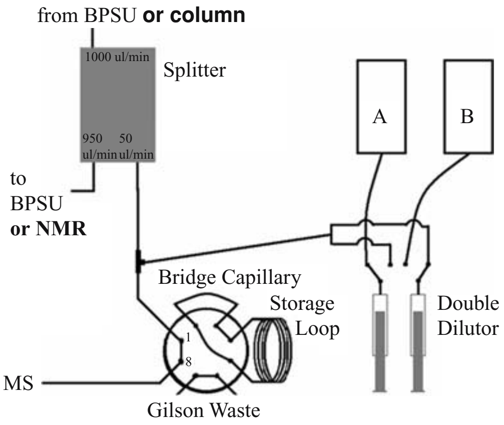

Fig. 6. Dedicated LC-NMR/MS interface, consisting of a flow splitter, a T-piece connected to a double dilutor and a valve with delay loops. The unit is positioned after the LC column or can be switched in line after a loop collection unit (BPSU).

To allow even more selectivity in the decision of which peaks proceed to the NMR, multiple decision-making channels can be defined that use UV or other analogue information together with various MS decision-making channels. MS decisions are possible based on total ion current, selected ions, an ion range, and/or MS/MS information, if the mass spectrometer used allows this.

Conclusion and Outlook

Over the last few years, the performance of LC-NMR has been improved substantially by the addition of tools that allow an increase in the NMR sensitivity by up to two orders of magnitude using post-column SPE, cryogenic probes and shielded magnets with improved homogeneity. Adding mass spectroscopy as an integral part of the process has allowed an increase in the selectivity of the LC peak selection and at the same time obtaining more information for structure elucidation. In the years to come, downscaling will play an important role in further improving the performance of LC-NMR. This is true for the columns used, the SPE cartridges and as a consequence of those, the active volume of the NMR flow cell will have to shrink. This means that the detection coils will have to shrink equally in order not to lose filling factor. With further reduction in the size of the NMR probes, techniques such as CE or CEC will be interfaced with the NMR successfully and such open the area to new applications.

LC-NMR in Dereplication and Structure Elucidation of Herbal Drugs

Gloria Karagianis and Peter G. Waterman
Centre for Phytochemistry and Pharmacology, Southern Cross University, PO Box 157,
Lismore, NSW 2480, Australia

Abstract

The direct on-line ^{1}H NMR analysis of HPLC eluates from plant extracts using a flow probe offers the opportunity to gather structural information on individual plant metabolites without the often time-consuming preliminary purification of each metabolite. Two examples are discussed. Firstly, resolution of the major flavonoid constituents in "skullcap herb" in the absence of "standard compounds" can be achieved by a single pass experiment and interpretation of 1D ^{1}H spectra. Secondly, the potential of the technique to allow a full structure elucidation of an unknown compound using a full range of 1D and homo- and inverse detected heteronuclear 2D experiments will be examined using extracts of *Aloe* species from South Africa.

Introduction

The coupling of high performance liquid chromatography with nuclear magnetic resonance (LC-NMR) spectroscopy represents a powerful analytical technique for detailed on-line structure and composition analysis of plant extracts. It has been more than 25 years since the first paper on LC-NMR was published [1]. Since then the technique has rapidly advanced, particularly over the last decade, with the introduction of higher field magnets, pulse field gradients, and efficient solvent suppression techniques, which are now standard in modern NMR instruments. For a detailed account on the historical development of LC-NMR, the reader is referred to the recent review by Elipe [2].

In principle, LC-NMR is based on the separation of organic mixtures by reversed-phase HPLC, followed by direct on-line NMR analysis of each eluting peak. In a typical LC-NMR setup, the HPLC instrument is connected to a UV detector and the chromatographic outlet passes through a special interface, comprised of switching valves, which connects to the LC-NMR flow probe via PEEK capillary. The HPLC system must be located ca. 2–3 m away from a conventional spectrometer in order to avoid interferences to its operation from the stray magnetic field produced by the cryomagnet. However, with shielded cryomagnets, this distance is reduced to less than 0.5 m.

There are basically three different modes of operation available in LC-NMR: (1) on-flow; (2) stop-flow; and (3) loop-collection. The simplest of these is on-flow as the HPLC and NMR systems can operate independently and no HPLC detector is required. Proton NMR spectra are acquired continuously while the eluate is flowing through the detection cell of the NMR flow probe. While this mode has the advantage of maintaining good HPLC resolution, it suffers in having the lowest sensitivity because of the very short dwell time in the NMR flow cell (3.6 s at 1 ml/min flow rate for a flow cell with 60 μl detection volume). Therefore, its application is limited to 1D proton acquisitions on mixtures containing major components.

The stop-flow mode is the most versatile and is significantly more sensitive than the on-flow mode and allows the measurement of 2D NMR correlation experiments, which are important techniques in the structure determination of unknown compounds. In this mode, the user sets predefined HPLC peak thresholds and UV detector parameters so that the LC pump stops on each chromatographic peak that meets these criteria, and the NMR collects the required data. This operation requires dedicated chromatographic software to control the synchronization between the HPLC and NMR systems. The chromatographic separation is triggered to stop on the peak after a calibrated time delay, which is the time required for the peak to travel from the UV detector to the NMR flow cell, and is determined during installation procedures. Once the peak is positioned in the NMR, the sample remains static in the flow cell and the conditions remain stable during the course of the NMR acquisition. This allows precise adjustments to the field homogeneity and solvent suppression parameters to be made so as to give optimized NMR measurements. In our laboratory, we routinely use the stop-flow mode for the analysis

Graham A. Webb (ed.), Modern Magnetic Resonance, 1229–1235.
© 2008 *Springer.*

of plant extracts that give good chromatographic separation. We have found this mode to be highly efficient, particularly in situations where the plant metabolites are present at relatively high levels, as rapid structural information can be obtained from a single chromatographic run.

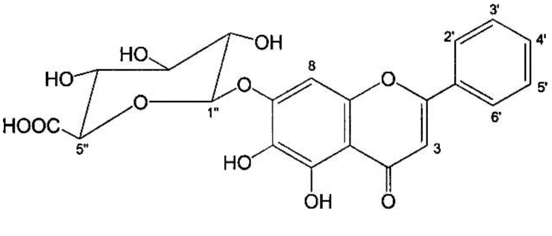
In the third mode, loop collection, the eluting chromatographic peaks are first captured into separate capillary loops and later transferred to the NMR for analysis. This mode is useful for the analysis of complex extracts that contain closely eluting peaks, and where large differences in metabolite concentrations are observed. Another useful aspect of this technique is that the chromatographic separations are performed independently of the NMR measurements, which means the NMR spectrometer can be used for other purposes during the preparation of the LC-NMR samples.

For LC-NMR analysis, the choice of mobile phase solvents is limited typically to mixtures of deuterium oxide:methanol or deuterium oxide:acetonitrile with 0.1% deuterated trifluoroacetic acid commonly added to the aqueous phase to help improve the resolution of the chromatographic peaks. As the NMR signals arising from the HPLC solvents are much larger than those of the analyte, they need to be suppressed. Solvent suppression techniques, such as the presaturation or WET pulse sequences, are therefore required for acquisition of LC-NMR spectra. One drawback to the use of solvent suppression is that any analyte signals residing underneath those of the solvent will also be suppressed, causing a loss in structural information. This can be a major disadvantage when dealing with mixtures containing unknown compounds. However, this problem may be overcome by carrying out the LC-NMR analysis in two independent solvent systems as exemplified in the study by Ndjoko *et al.* [3] on pyrrolizidine alkaloids.

In theory, LC-NMR should be of great value in natural products chemistry where one is often dealing with mixtures of structurally allied compounds that can be resolved by HPLC. This has been confirmed in a number of studies [4–7], but the technique has not become popular for a number of reasons including cost and the amount of instrument time required for a comprehensive NMR investigation. In this paper, we demonstrate both the very rapid use of LC-NMR to confirm the major flavone glycoside present in a plant extract and a comprehensive 1D and 2D homo- and hetero-nuclear study for structure elucidation of an unknown compound.

Dereplication of Skullcap Herb

Problems can arise with the identification of herbal drugs and their constituents, most notably in cases such as skullcap (*Scutellaria* species), where a number of different species are being used with similar, but different suites of compounds. A traditional phytochemical approach involving isolation, purification, and structure elucidation was initially used to establish that the flavone glucuronide baicalin (**1**) rather than its congener scutellarin (**2**) was the major flavonoid in samples of *Scutellaria lateriflora* (Figure 1). This is expensive and time consuming and we were able to overcome the need for isolation through use of LC-NMR.



1 Baicalin
2 Scutellarin = 4'-OH
3 Ikonnikoside = 2'-OH

Fig. 1. Chemical structure of flavonoids from *Scutellaria lateriflora*.

Figure 2A shows a typical C_{18} reversed-phase chromatogram for *S. lateriflora* exhibiting five peaks attributable to major flavonoid components. For each of the five flavonoids 1D ^{1}H NMR spectra were obtained, the total time required for this exercise being about 2 h. Figure 2B shows the spectrum for the major flavone glycoside. From an analysis of the signals for each proton, making the presumption that the compound under analysis is a flavone, it is possible to identify two singlets attributable to H-3 and a single A-ring proton (H-8 in this case). The presence of glucuronic acid is established by the two doublets that can be attributed to H-1″ and H-5″ with coupling constants that require both protons to be axial. The remaining aromatic signals integrate for five protons and are made up of a doublet (2H) and two triplets (1H and 2H—shown in expanded form in Figure 2C), which are typical for an unsubstituted flavonoid B-ring. All these features are supportive of the structure of baicalin, and establish that the major constituent in this extract is baicalin. Figure 2D shows the spectrum for the first small peak that eluted from the extract (R_t 8.07 min, Figure 2A). While the resolution is not as good as for baicalin, proton resonances are clearly defined. Once again H-3, H-8 of the flavone, and H-1″ and H-5″ of

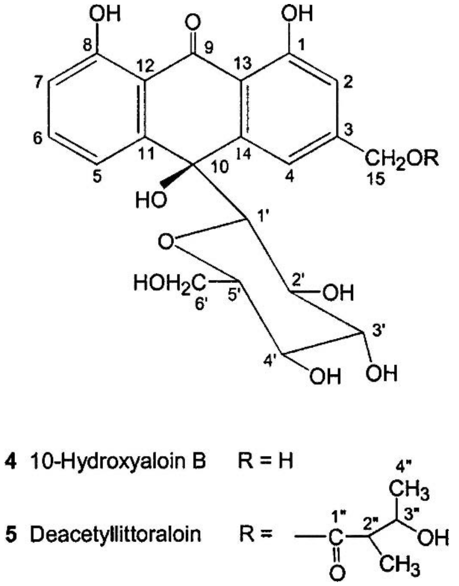

Fig. 3. Chemical structure of oxanthrones from *Aloe littoralis*.

the glucuronide can be identified. But in this case, the signals attributable to the B-ring have changed. The pattern has simplified to two doublets (2H each) which requires a *para* di-substituted aromatic ring. This, coupled with the 16-mass unit increase in molecular weight in comparison with baicalin identified the minor component as scutellarin.

In the same manner, it was possible to identify the other three components such as ikonnikoside (**3**, R_t 9.19 min as shown in Figure 2A; with the four B-ring protons now in an ABCD splitting pattern), a methyl ether of ikonnikoside (R_t 15.94 min), and 2,3-dihydrobaicalin (R_t 16.62 min).

Structure Elucidation of *Aloe* Metabolites

The genus *Aloe* contains numerous species with very localized distributions and populations that can comprise fewer than 100 individuals. The pioneering work undertaken on using LC-NMR to identify compounds from small amounts of exudates [8] has established that we can determine the identity of individual *Aloe* secondary metabolites on weights of as little as 40 μg. Using the crude leaf exudate of *Aloe littoralis*, we were able to obtain 1D proton, 2D homonuclear (COSY, TOCSY) and 2D heteronuclear (HSQC, HMBC) NMR data on the two major metabolites, 10-hydroxyaloin B (**4**), and deacetyllittoraloin (**5**) (Figure 3).

Figure 4 shows the 2D COSY spectrum of **4** and 2D TOCSY spectrum of **5.** The coupling pattern observed in these two experiments, along with the 1D proton NMR data, indicate that the two metabolites are structurally similar. Both show connectivities consistent with an aromatic ABC spin-system and a hexose moiety, which can be identified as glucopyranose. In addition, the resonance and large coupling constant of the shielded doublet corresponding to the anomeric proton H-1′ in each metabolite, indicate a C-linkage and β-configuration for the sugar group.

Figure 5 shows the 2D HSQC and 2D HMBC spectra of **4**. All C-H connectivities are clearly visible in the 2D HSQC. From an analysis of the long-range couplings observed in the 2D HMBC, the position of the hydroxymethyl group and the C-glucopyranosyl group on the oxanthrone ring system could be determined. These long-range couplings are illustrated in Figure 6. The combined data from these two inverse ^{1}H, ^{13}C correlation experiments allowed the unambiguous assignment of the ^{13}C resonances of 20 of the 21 carbons in **4**. Similarly, the 2D HSQC and 2D HMBC data obtained on **5** allowed the unambiguous assignment of the ^{13}C resonances of 25 of the 26 carbons present. The HMBC long range couplings observed for **5** were similar in pattern to those shown by **4**, and confirmed the presence of a 10-hydroxyaloin skeleton in **5** (Figure 6). Additional long-range correlations observed for **5**, in particular from the oxymethylene protons (H-15) to the ester carbonyl at C-1″, confirmed along with 2D COSY and 2D TOCSY data the assignment of the nilate (3-hydroxy-2-methylbutanaote) moiety at position C-15. The only carbon resonance that could not be assigned in both metabolites was that of the ketone group at position C-9. This carbon is situated more than $^3J_{HC}$ from the nearest proton, making its detection out of the scope of a conventional HMBC experiment.

This last example clearly indicates the considerable capacity of LC-NMR as a direct tool for structure elucidation. Unfortunately with current technology the cost, in terms of instrument time, remains prohibitive. However, with new probe technology and improved sample handling in the LC phase this should change over the next few years. At that point LC-NMR, we believe, will be used widely to ascertain novelty prior to large-scale natural product isolation studies being undertaken. Among other advantages this will allow us to undertake analysis of the increasing number of species that are critically endangered without the need for destructive harvesting.

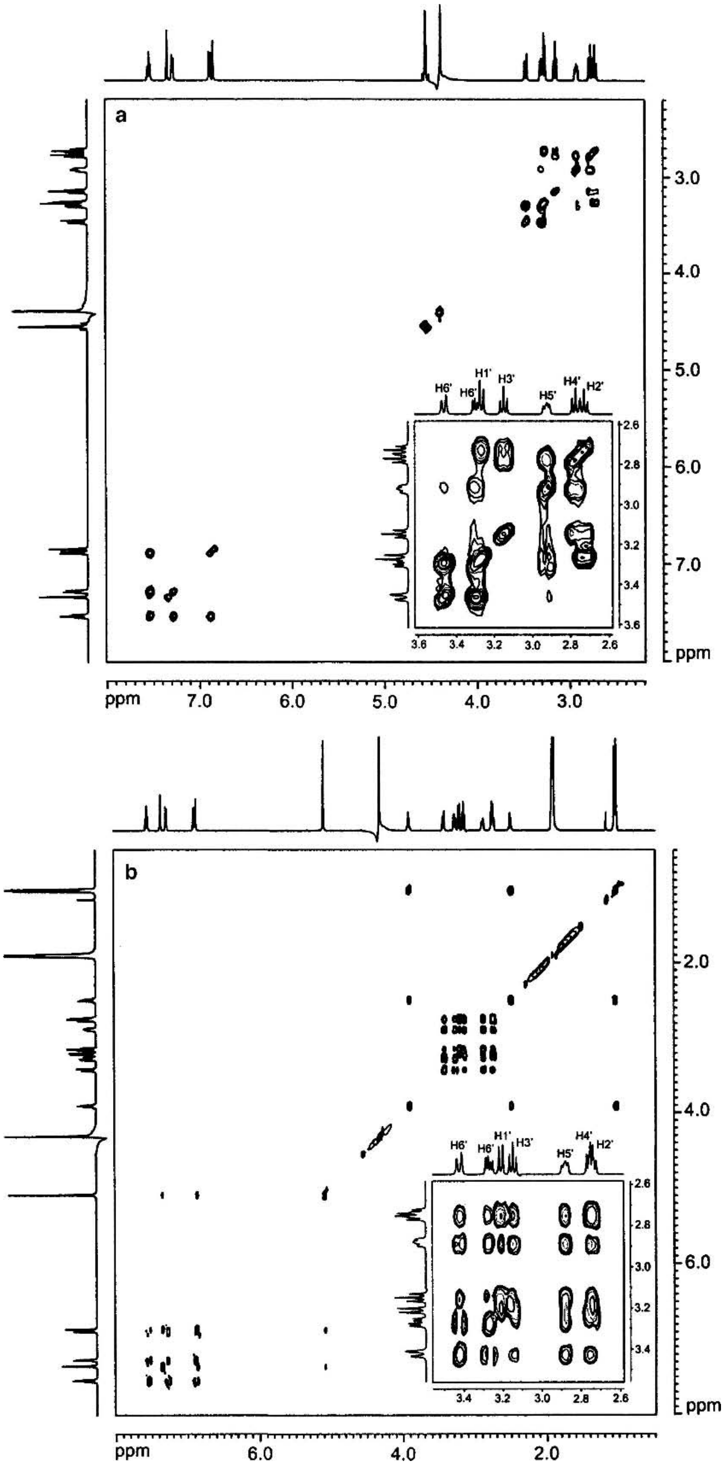

Fig. 4. (a) Stop-flow 2D LC-COSY spectrum of 10-hydroxyaloin B (**4**); (b) stop-flow 2D LC-TOCSY spectrum of deacetyllittoraloin (**5**) with a mixing time of 65 ms. Expansion of the region containing cross-peaks from the glucose moiety is shown in both spectra.

New Approaches to NMR Data Acquisition, Assignment and Protein Structure Determination: Potential Impact in Drug Discovery

Antonio Pineda-Lucena
Associate Principal Scientist, Protein NMR Laboratory, AstraZeneca Pharmaceuticals, Macclesfield Cheshire England

Introduction

The majority of drugs available today were discovered either from chance observations or from the screening of synthetic or natural product libraries. The chemical modification of lead compounds, on a trial-and-error basis, typically led to compounds with improved potency, selectivity, bioavailability, and reduced toxicity. However, this approach is labor- and time-intensive, and researchers in the pharmaceutical industry are constantly developing methods with a view to increasing the efficiency of the drug discovery process. One of these relatively new approaches is the so-called rational drug design that relies heavily in the determination, either by X-ray crystallography or nuclear magnetic resonance (NMR) spesctroscopy, of the three-dimensional structures of the targets and the ligand-target complexes.

NMR spectroscopy is a biophysical technique with wide applicability in drug discovery research, particularly for the detection and characterization of molecular interactions. NMR can also be used as a tool for the determination of structure and dynamics of proteins, and protein-ligand complexes. In drug design, NMR can be used to validate or invalidate hits from high-throughput-screening (HTS) and can also generate lead compounds by a fragment-based approach. Thus, NMR is not only a technique for structure-guided drug design, but can also be integrated with HTS and combinatorial chemistry. Being so versatile, NMR can be applied to all phases of a drug discovery program, including target selection, lead generation, and lead optimization [1].

To most pharmaceutical companies structural information is an important contributor to drug discovery programs, and this information is sought and utilized whenever a target appears structurally feasible. For structure determination of large proteins, or the complex of a large protein with a tightly bound inhibitor, structure determination by X-ray crystallography is generally faster. On the contrary, smaller proteins sometimes do not readily crystallize and can be more rapidly solved by NMR. Furthermore, NMR can be applied to the structure determination of weakly bound ligands. The two methods are complementary, and each has its own strengths and weaknesses.

From a practical point of view, the main challenges NMR faces in the pharmaceutical world are the costs associated with the production of large amounts of labeled material for screening and structural studies, and, more importantly, the speed with which data are generated. Only when these issues are resolved, will NMR be able to fully exploit its potential in the drug discovery field. This chapter will review some of the methodologies recently developed to increase the efficiency of strategies for data acquisition, analysis, and protein structure calculation by NMR.

Fast Multidimensional NMR Spectroscopy

Data acquisition for multidimensional NMR spectra is not optimal in terms of speed. Systematic exploration of the indirect evolution dimensions one step at a time has the advantage that no signal frequencies are overlooked, but this is not the fastest mode of data acquisition for relatively sparse spectra. In a traditional three-dimensional NMR experiment, the evolution of the signal is followed as a function of t_1, t_2, and t_3 independently. On the contrary, a variety of methods [2] introduced in the last few years seek to simplify this process by cutting down the number of individual measurements, either in the time domain or in the frequency domain. Two of the most promising approaches are described below.

In GFT-NMR, the speed problem of multidimensional NMR is tackled by incrementing several evolution periods jointly, either exactly in step with one another or with suitable scaling factors between them. In a three-dimensional case where the evolution rates are all equal, this is equivalent to exploring the body diagonal of a cube representing the time-domain data space. This is clearly much quicker than incrementing these time dimensions independently. The chemical shifts appear in the experimental time-domain data set as linear combinations, but if several scans are carried out with the radiofrequency

Graham A. Webb (ed.), Modern Magnetic Resonance, 1239–1246.
© 2008 *Springer.*

mixing pulses systematically phase-shifted in 90° steps, a separation can be achieved by a procedure based on a G-matrix [3].

The reduction in measurement time improves exponentially as the number of locked dimensions increases, despite the increase in mandatory scans. However, the technique sacrifices sensitivity for each stage of dimensionality reduction, and higher-dimensional experiments necessarily incur increased signal loss through relaxation. Eventually a point is reached where the sensitivity, rather than the duration, becomes the limiting factor. Thus, the strength of the GFT method lies in the possibility of reducing the dimensionality of high-dimensional spectra, and the limitations of the GFT method might be expected to become evident in cases of severe overlap and in situations where sensitivity is a problem.

Another strategy aims to use projection-reconstruction (PR) techniques to recreate the full three-dimensional NMR experiments. This approach is related to that used in the X-ray tomography field [4] where it is employed to study complex systems. PR-NMR [5,6] reduces the time required to perform a three-dimensional experiment by an order of magnitude, and four-dimensional spectra by two orders of magnitude, by replacing the slow exploration of the evolution dimensions one-by-one by the acquisition of a relatively small number of plane projections.

If F_1 and F_2 are the evolution dimensions and F_3 the direct acquisition dimension of a three-dimensional NMR experiment, then the projections onto the orthogonal F_1F_3 and F_2F_3 are readily recorded by setting $t_2 = 0$ and $t_1 = 0$, respectively. These are the first planes of the three-dimensional spectrum and can be measured quite quickly. In an ideal situation where not too many peaks contribute to the intensity of a single response in the projection, and where the measured NMR intensities in both projections are reliable, the entire three-dimensional spectrum can be extracted from information on these two planes. In actual practice, ambiguities are to be expected and must be resolved if the three-dimensional spectrum is to be recovered. One solution is to measure a skew projection intermediate between the F_1F_3 and F_2F_3 planes by incrementing t_1 and t_2 jointly, with a suitable scaling factor. Skew projections are obtained by replacing the normal evolution time increments, t_1 and t_2, with $t_1\cos\alpha$ and $t_2\sin\alpha$, where α is the desired projection angle (Figure 1). The projection method relies on a Fourier transform theorem [7,8] which states that a section through the origin of a two-dimensional time domain signal $S(t_1, t_2)$, subtending an angle α with respect to the t_1 axis, transforms as the projection onto a line through the origin of the two-dimensional frequency-domain signal $S(F_1,F_2)$, subtending the same angle α with respect to the F_1 axis. By extension, a three-dimensional NMR experiment where the evolution parameters t_1 and t_2 are incremented simultaneously in the ratio $\Delta t_2/\Delta t_1 = \tan\alpha$, projects the three-dimensional NMR spectrum onto a plane tilted through an angle α with respect to the F_1F_3 plane. With the usual hypercomplex Fourier transformation, where real and imaginary signal components are acquired in both evolution dimensions [9] and suitably combined [10], projections are obtained for both $+\alpha$ and $-\alpha$, providing two independent views of the three-dimensional array of NMR peaks.

Although the sensitivity per unit time is the same as that of the conventional mode, it is reduced overall in proportion to the square root of the experimental time. Consequently, PR can realize its full theoretical speed advantage only if the inherent sensitivity of the sample is already adequate. Fortunately, modern high-field NMR spectrometers have improved in sensitivity, particularly those equipped with a cryoprobe receiver coil. As opposed to other methods of simultaneous incrementation of two evolution parameters [3,9,11], PR-NMR uses a simple and transparent method for data processing, providing a direct comparison with the traditional three-dimensional spectrum.

The inverse Radon transform can be used to reconstruct a three-dimensional NMR spectrum from a small number of different plane projections [12,13]. The Radon procedure calculates multiple line integrals of the absorption along parallel paths through the sample, and repeats the process for a set of different angles of incidence arranged around a circle. The Radon transform converts these line integrals into a related set of projections at right angles to the original beams. In practice, it is the inverse Radon transform that is of particular interest.

The reconstruction treatment aims to use the unique multidimensional array of NMR peaks compatible with all the measured plane projections. Projections involve the integration of the absorbed intensity along a series of parallel beams through the sample, and the Radon transform calculates these line integrals. The actual approach followed to find a density function compatible with all the measured projections depends on the quality of the NMR spectra. Thus, spectra with good sensitivity favor a processing scheme based on only a few projections. In this case, a three-dimensional array $S(F_1, F_2, F_3)$ is reconstructed by processing one F_1F_2 plane at a time. In a typical F_1F_2 plane, the raw experiment data for $\alpha = 0°$ and $\alpha = 90°$ are one-dimensional absorption spectra, representing the projections of NMR intensity onto the F_1 and F_2 axes, and a provisional map defining all the possible cross-peak coordinates can be derived easily. This provisional map is obtained by a two-dimensional convolution of the one-dimensional F_1 and F_2 traces. Some of these locations correspond to actual peaks, and others will later, after acquisition of additional projections at $\pm\alpha$, turn out to be unoccupied. Once all F_1F_2 planes have been processed, the three-dimensional spectrum is complete and can be displayed in any of the usual formats.

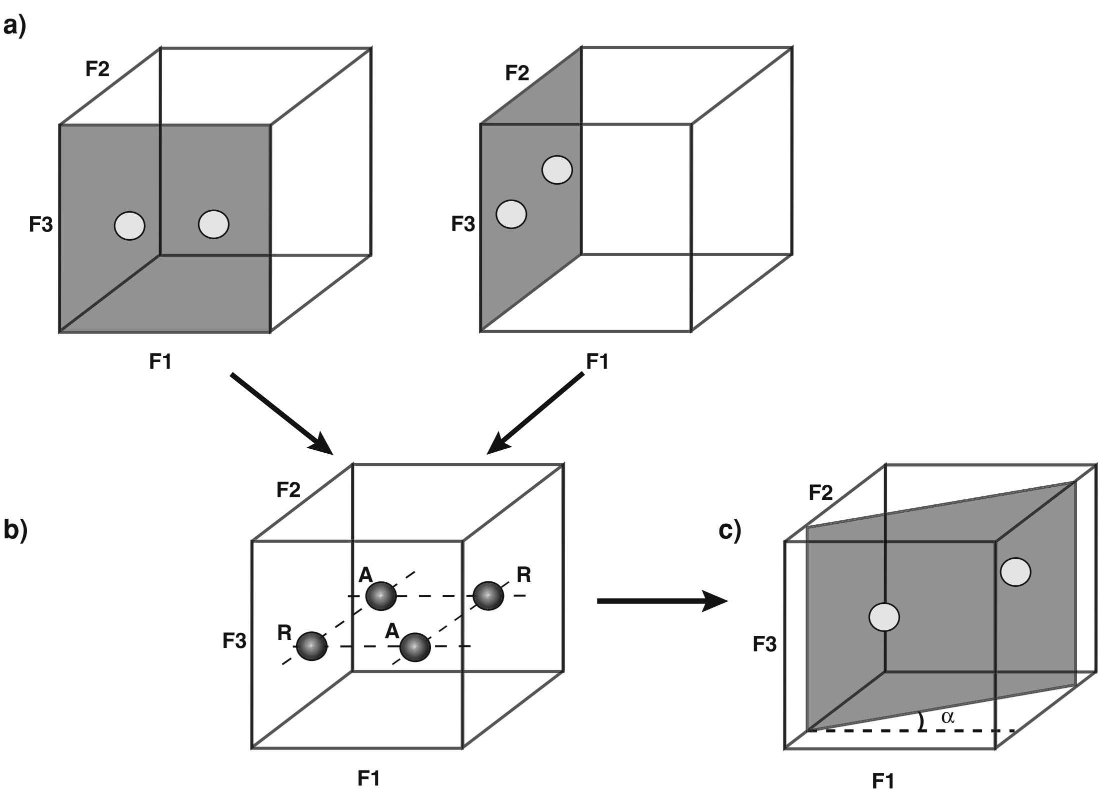

Fig. 1. Reconstruction of a three-dimensional NMR spectrum based on PR NMR techniques. First plane projections obtained for F_1F_3 and F_2F_3 at $t_2 = 0$ and $t_1 = 0$, respectively (a) cannot define unambiguously the positions of the signals in the three-dimensional spectrum (b), but this uncertainty can be resolved by measuring the projection onto a plane tilted by an angle α with respect to the F_1F_3 plane. "A" indicates artefact signals generated when the only information used for the reconstruction are first planes, and "R" indicates real signals that only become apparent when the tilted projection is measured.

For spectra with poor sensitivity, it is an advantage to record a larger number of different projections, usually spaced uniformly around a circle as in the Radon transform methodology. In this case, reconstruction is achieved by adding the contributions from the many different back-projections. There is a strong reinforcement of intensity at positions of genuine NMR peaks, enhancing the sensitivity in proportion to the number of different projections. This is an advantage as long as the number of projections remains smaller than the number of evolution increments in the conventional mode. This additive approach is preferred in situations where the intrinsic signal-to-noise is poor because each new projection enhances the final signal intensities, and the weak artefacts tend to disappear below the general noise level. Under these circumstances, it is better to enhance the signal-to-noise ratio by sampling the time-domain signals at more closely spaced angles of incidence, than to employ multiscan averaging.

In summary, provided that sensitivity is not a limiting factor, it is clear that multidimensional NMR spectroscopy can be sped up by linking the evolution periods together, rather than by varying them independently.

Speeding Up the Assignment Process

A crucial step in determining solution structures of proteins using NMR spectroscopy is the process of sequential assignment, which correlates backbone resonances to corresponding residues in the primary sequence of the protein. It has been recognized for some time that many of the interactive tasks carried out by an expert during the process of spectral analysis, could be carried out more efficiently and rapidly by computational systems. With the advent of triple-resonance and multidimensional strategies for determining resonance assignments and 3D structures, it became increasingly clear that the quality and information content of protein NMR spectra could allow largely automated analyses of assignments.

Successful automated spectral analysis is normally preceded by high-quality (manual or automatic) peak picking. Several high-quality peak-picking programs have been described over the last few years. For example, AUTOPSY [14] is a comprehensive program for automating peak picking with facilities for determining noise level, segmenting the spectra into peak-containing regions, identifying well-separated peaks, resolving spectral overlap and integrating peaks. In this context, SAMPA [15] is the only program attempting to automatically assign proteins in the absence of peak picking. As input, the module uses processed 2D and/or 3D spectra from XWIN-NMR (Bruker Biospin GmbH) and the amino acid sequence of the investigated protein. The result is a sequential assignment of the backbone atoms.

The algorithm is based on the consecutive comparison and analysis of 2D and 3D NMR-spectra whereby 2D spectra of selective experiments and 3D spectra of triple resonance experiments may be included. The program uses basic principles of pattern recognition theory and numerical recipes of mathematical analysis. The main idea is the search for characteristic patterns in different 2D and 3D spectra. A pattern is derived from the relationship of the amino acid type itself and its neighbors in the spectra.

A considerable amount of effort has been devoted in the last few years towards the automated analysis of resonance assignments [16–21] using triple-resonance NMR data. As described in Moseley and Montelione [22], most automation programs use the same general analysis scheme which includes filtering of peaks and referencing resonances from different spectra, grouping resonances into spin systems, identifying the amino acid type of the spin system (typing), linking sequential spin systems into segments, and, finally, mapping the spin-system segments onto the primary sequence of the protein. Linking and mapping can be achieved by two main methods: deterministic best-first methods [18–20,23] that require a one-time, all-to-all, full comparison between every spin system, and optimization algorithms [17,21] that use a pseudo-energy function with simulated annealing to evaluate potential connections between nearest neighbor spin systems. Best-first approaches establish criteria to select the best candidate from several potential connectivities. Unfortunately, wrong choices made early in the assignment process can lead to solutions which can be substantially incorrect [20]. On the other hand, the optimization algorithms are generally rather slow and can be susceptible to becoming trapped in local minima that correspond to incorrect assignment configurations.

Although the development of automated approaches for sequential assignment has facilitated the analysis of triple-resonance experiments, the performance of these programs is usually less satisfactory for large proteins, especially in the cases of missing connectivity or severe chemical shift degeneracy. In addition, successful algorithms must be able to address missing peaks, extra peaks from impurity or multiple conformers, uncertainty in the amino acid type determinations, and broken connectivities due to the uncertainty of resonance positions caused by the distortion or overlap of peaks.

An interesting approach to solve these problems have been proposed by Coggings and Zhou with the introduction of PACES [24], an interactive program for Protein Sequential Assignment by Computer-Assisted Exhaustive Search. The program conducts an exhaustive search of all spin systems both for establishing sequential connectivities and then for assignment. By running the program iteratively with user intervention after each cycle, ambiguities can be eliminated efficiently and backbone resonances can be assigned rapidly. PACES establishes sequential assignment based on the sequential connectivity and residue type information derived from C^{α}, C^{β}, CO, and H^{α} triple-resonance data, or any subset of these data. Additional information derived from other experiments, such as residue types or NOESY constraints, can also be introduced as PACES input. PACES anchors the resonances of a spin system to its HSQC peak, and subsequently refers to spin systems by HSQC peak numbers. The identification of residue type information is done by comparing C^{α}, C^{β}, CO shifts to the statistical chemical shift distribution of each amino acid type derived from the BioMagResBank (BMRB). If the protein under study is perdeuterated, PACES can be directed to adjust its amino acid ranges accordingly [25,26]. The mapping process involves aligning a connectivity fragment at the beginning of the protein sequence, and then moving it down the sequence, one residue at a time. When the C-terminus of the protein is encountered, spin systems are looped back to align with the N-terminus of the protein, until every spin system in the fragment has been examined at every position of the protein sequence. If at any position, the list of possible amino acid types for a spin system includes the amino acid type of the paired residue in the sequence, that pairing is considered a match. If multiple sequentially connected spin-systems match, the algorithm identifies the resulting segment as a matching fragment. Short matching fragments are filtered out unless they contain a spin system with less than five possible amino acid types. The chemical shift data and additional constraints are provided by the user on a properly formatted Excel worksheet, in a text file or from XEASY peak lists. Results are also presented on a formatted Excel worksheet, with one column for each residue. In summary, PACES is based on the methods used by NMR spectroscopists to assign proteins manually, but taking advantage of the abilities of a computer to work through all of the possibilities for connecting peaks and mapping them to the protein sequence.

Another strategy has been proposed by Reed *et al.* [27] for the semi-automated assignment of PGK (394 amino acids) based on a simulated annealing Monte Carlo technique using the following experiments as input: 2D ^{15}N-TROSY, 3D TROSY ct-HNCA, ct-HN(CO)CA, HN(CA)CB, HN(COCA)CB, HNCO, and HN(CA)CO. The program attempts to reorder the spin systems and place them in the amino acid sequence of the protein, by minimising an energy function based on both matching up the chemical shift data for adjacent residues, and on characteristic chemical shift ranges for resonances in particular residue types. Carbonyl chemical shifts are only used at the end of the process to confirm the assignments. After the initial peak picking and one run of the assignment program, a 60–80% complete assignment was obtained for this protein. The final 20–40% of the assignment took up the majority of the assignment time. Improving the level of assignment to 94% and then to 95% involved two further periods of 5 days each.

Finally, Lagnmead and Donald have published a new algorithm [28] that performs Nuclear Vector Replacement (NVR) by Expectation/Maximization (EM) to compute assignment using a combination of experimentally measured residual dipolar couplings, chemical shifts (2D H^N-N HSQC), H^N-H^N NOEs and amide exchange rates to a given *a priori* whole-protein 3D structural model. The authors proposed that this algorithm could form the basis for Molecular Replacement by NMR because of its resemblance with the technique used in X-ray crystallography to solve the phase problem using a close or homologous model. NVR adopts a minimalist approach [29], demonstrating the large amount of information available in a few key spectra. So far, NVR have been only tested on models with both high sequence and structural homology. Consequently, the present form of the algorithm may best be applied to scenarios where a crystal structure of the same protein is available, as may be the case in an SAR by NMR study. Models with significantly less homology will likely have somewhat different networks of hydrogen bonds and NOEs, as well as different amide bond-vector orientations.

Automated Protein Structure Determination

Until very recently, NMR protein structure determination has remained a laborious undertaking that occupied a trained spectroscopist over several months for each new protein structure. It has been recognized that many of the time-consuming interactive steps carried out by an expert during the process of spectral analysis could be accomplished by automated computational approaches [22]. Today automated methods for NMR structure determination are playing a more prominent role and will most likely supersede the conventional manual approaches to solving three-dimensional protein structures in solution [30].

The assignment of NOESY cross peaks requires as a prerequisite a knowledge of the chemical shifts of the spins from which nuclear Overhauser effects (NOEs) are arising. In *de novo* three-dimensional structure determination of proteins in solution by NMR spectroscopy, the key conformational data are upper distance limits derived from NOEs [31–34]. In order to extract distance constraints from a NOESY spectrum, its cross peaks have to be assigned. The NOESY assignment is based on previously determined chemical shift values that result from the chemical shift assignment. Because of the limited accuracy of chemical shift values and peak positions many NOESY cross peaks cannot be attributed to a single unique spin pair, but have an ambiguous NOE assignment comprising multiple spin pairs. Once available, a preliminary three-dimensional structure may be used to resolve ambiguous NOE assignments. Obtaining a comprehensive set of distance constraints from a NOESY spectrum is thus by no means straightforward, but becomes an iterative process in which preliminary structures, calculated from limited numbers of distance constraints, serve to reduce the ambiguity of cross peak assignments. In addition to this problem of resonance and peak overlap, considerable difficulties may arise from spectral artefacts and noise, and from the absence of expected signals because of fast relaxation.

Automated procedures follow the same general scheme but do not require manual intervention during the assignment/structure calculation cycles. Two main obstacles have to be overcome by an automated approach starting without any prior knowledge of the structure. First, the number of cross peaks with unique assignment based on chemical shifts is, in general, not sufficient to define the fold of the protein. Therefore, the automated method must have the ability to make use also of NOESY cross peaks that cannot yet be assigned unambiguously. Second, the automated program must be able to cope with the erroneously picked or inaccurately positioned peaks and with the incompleteness of the chemical shift assignment of typical experiment data sets.

In NOAH [35,36], an automated NOESY assignment routine present in the programs DIANA [37] and DYANA [38], the multiple assignment problem is treated by temporarily ignoring cross peaks with too many assignment possibilities, and instead generating independent constraints for each of the assignment possibilities of the remaining low-ambiguity cross peaks. In order to reduce the impact of these incorrect constraints on the structure, an error-tolerant target function is used [35,36]. NOAH requires a high accuracy of the input chemical shifts and peak positions, and makes use of the fact that only a set of correct assignments can form a self-consistent network.

In the initial assignment cycle with NOAH, all peaks with one or two assignment possibilities are included into the structure calculation. In view of the large number of erroneous conformational constraints that are likely to be included at this stage, it seems non-trivial that the NOAH/DIANA approach may ultimately converge to the correct structure. The explanation is related to the fact that the structure calculation algorithm attempts to satisfy a maximum number of conformational constraints simultaneously. The correctly assigned constraints form a large subset of self-consistent constraints, whereas, in contrast, the erroneously assigned constraints are randomly distributed in space, generally contradicting each other. As a consequence, erroneously assigned constraints may distort the structure, but will not lead to a distinctly different protein fold. One must keep in mind that the elimination of erroneously assigned constraints through contradiction with correct constraints will in general be less efficient in regions of low NOE density than in the well-defined protein core. Another peculiarity of the randomly distributed erroneously assigned constraints is that they are more likely to be long-range than short-range or intra-residual. This contrasts with the overall constraint distribution of a correctly assigned NOESY spectrum, where more than 50% of all cross peaks are from short-range NOEs [39].

Another widely used automated NOESY assignment procedure is ARIA [40–43] that was originally interfaced with XPLOR [44] and later with the program CNS [45]. ARIA introduced many new concepts, most importantly the use of ambiguous distance constraints [46,47] for handling ambiguities in the initial, chemical shift-based NOESY cross peak assignments. Prior to the introduction of ambiguous distance constraints, in general only unambiguously assigned NOEs could be used as distance constraints in a structure calculation. Since the majority of NOEs cannot be assigned unambiguously from chemical shift information alone, this lack of a general way to directly include ambiguous data into the structure calculation considerably hampered the performance of automatic NOESY assignment algorithms.

When using ambiguous distance constraints, each NOESY cross peak is treated as the superposition of the signals from each of its multiple assignments, using relative weights proportional to the inverse sixth power of the corresponding inter-atomic distance. ARIA starts from lists of peaks and chemical shifts in the format of the common spectral analysis programs, and proceeds in cycles of NOE assignment and structure calculation. The experimental peak lists can in practice not be assumed to be completely free of errors, especially in the early stages of a structure determination or if they originate from automatic peak picking. In addition, if the chemical shift assignment is incomplete, even the most carefully prepared peak list will contain peaks that cannot be assigned correctly, namely those involving unassigned spins, because the ARIA algorithm does not attempt to extend or modify chemical shift assignments provided by the user. When building a three-dimensional structure from NOE data, most erroneous distance constraints will be inconsistent with each other and with the correct ones. The erroneous constraints can therefore be identified by analyzing the violations of constraints with respect to the bundle of three-dimensional structures from the previous cycle of calculation. The only drawback with this program could be obtaining a correct fold at the outset of a *de novo* structure determination because the powerful structure-based filters used for the elimination of erroneous cross peak assignments are not yet operational at that stage.

The CANDID algorithm [48] in the program CYANA [49] combines features from NOAH and ARIA, such as the use of three-dimensional structure-based filters and ambiguous distance constraints, with the new concepts of network-anchoring and constraint combination that further enable an efficient and reliable search for the correct fold in the initial cycle of *de novo* NMR structure determination. Network-anchoring exploits the observation that the correctly assigned constraints form a self-consistent subset in any network of distance constraints that is sufficiently dense for the determination of a protein 3D structure. On the other hand, the concept of constraint combination aims to reduce the effect of spurious distance constraints that may arise from misinterpretation of noise and spectral artefacts. It is used in the first two CANDID cycles, and consists of generating distance constraints with combined assignments from different, in general unrelated, cross peaks. Constraint combination is applied only to the long-range peaks because in case of error their effect on the global fold of a protein is more pronounced than that of erroneous short- and medium-range constraints.

The automated CANDID method proceeds in iterative cycles of ambiguous NOE assignment followed by structure calculation with the CYANA torsion angle dynamics algorithm. Between subsequent cycles, information is transferred exclusively through the intermediary three-dimensional structures, in that the molecular structure obtained in a given cycle is used to guide the NOE assignments in the following cycle. Otherwise, the same input data are used for all cycles, that is, the amino acid sequence of the protein, one or several chemical shift lists from sequence-specific resonance assignment, and one or several lists containing the positions and volumes of cross peaks in 2D, 3D, or 4D NOESY spectra.

A CANDID cycle starts by generating for each NOESY cross peak an initial assignment list containing the hydrogen atom pairs that could, based on the chemical shift lists, contribute to the peak. Subsequently, for each cross peak these initial assignments are weighted with respect to several criteria (agreement between the values of the chemical shift list and the peak positions, and compatibility, if available, with the three-dimensional structure from the previous cycle), and initial assignments with low overall scores discarded. For each cross peak, the retained assignments are interpreted in the form of an upper distance limit derived from the cross peak volume. Thus, a conventional distance constraint is obtained for cross peaks with a single retained assignment. Otherwise an ambiguous distance constraint is generated that embodies several assignments. The structure calculations typically comprise seven cycles. Since the precision of the structure determination improves with each subsequent cycle, the criteria for accepting assignments and distance constraints are tightened in more advanced cycles of the CANDID calculation. In the final CANDID cycle, an additional filtering step ensures that all NOEs have either unique assignments to a single pair of hydrogen atoms, or are eliminated from the input for the structure calculation. This allows for the direct use of the NOE assignments in subsequent refinement and analysis programs that do not handle ambiguous distance constraints.

A very different strategy has been proposed by Kuszweski *et al.* [50] with the development of PASD, a new highly error-tolerant Probabilistic Assignment algorithm for Automated Structure Determination. The PASD algorithm which has been incorporated into the molecular structure determination package XPLOR-NIH [51], is conceptually and philosophically different from previously implemented algorithms in that it has been expressly designed with the aim of ensuring that the results from successive iteration cycles are not biased by the global fold of structures calculated in the preceding cycles. No NOE assignment is ever removed permanently, and consequently the likelihood of becoming trapped in a false minimum of NOE assignment space is significantly reduced.

Finally, although it is universally assumed that a protein structure determination by NMR requires sequence-specific resonance assignments, the chemical shift assignment by itself has no biological relevance. It is required only as an intermediate step in the interpretation of the NMR spectra. Several attempts have been made to devise a strategy for NMR protein structure determination that circumvents the tedious chemical shift assignment step. There is an analogy between these approaches and the direct phasing methods in X-ray crystallography [52].

The underlying idea of assignment-free NMR structure calculation methods is to exploit the fact that NOESY spectra provide distance information even in the absence of any chemical shift assignments. This proton-proton distance information can be exploited to calculate a spatial proton distribution. Since there is no association with the covalent structure at this point, the protons of the protein are treated as a gas of unconnected particles. Provided that the emerging proton distribution is sufficiently clear, a model can then be built into the proton density in a manner analogous to X-ray crystallography in which the structural model is constructed into the electron density. The most recent approach to NMR structure determination without chemical shift assignment is the CLOUDS protocol [53,54]. For the first time, the feasibility of the method has been demonstrated using experimental data rather than simulated data sets.

Conclusion

This review has presented some of the new tools available to improve data acquisition, analysis, and protein structure calculation by NMR. Given its wide applicability, NMR ought to play a very important role, in biomedical research and in the development of drugs for novel targets, during the post-genomic era. From the drug discovery perspective, an environment where a fast turnover of structural information is required, NMR will be competitive, if it is able to increase the speed with which assignments and protein structures are generated. This is particularly true if we consider that the sequencing of the human genome suggests that there are between 600 and 3000 genes that code for potential drug targets for human diseases [55]. About 400 of these gene products are currently in the research portfolio of pharmaceutical companies, and marketed drugs target only 120 of them. Therefore, the identification and characterization of new targets is of high interest for pharmaceutical research. NMR can contribute to this effort by determining the solution structure of a potential new target, particularly for monomeric proteins under 40 kDa or oligomeric proteins under 60 kDa [56–58], and in the characterization of proteins that do not have a defined three-dimensional structure [59]. Furthermore, NMR can also be used downstream of the drug discovery process in the identification of new compounds with biological activity against particular targets by fragment-based screening approaches [60], and in the three-dimensional characterization of the ligand-target complexes.

Transferred Cross-Correlated Relaxation: Application to Drug/Target Complexes

T. Carlomagno and C. Griesinger
Max Planck Institut for Biophysical Chemistry, 37077 Göttingen, Germany

Introduction

The NMR spectra of biomolecules without and especially with isotopic labeling provide a wealth of information about interatomic distances and angular geometries that can be used as conformational restraints in structure determination. In this review we will focus on the application of cross-correlated relaxation rates to obtain structural information on a small-molecule/protein complex that has pharmaceutical implications. Cross-correlated relaxation complements information derived from NOEs. The chosen complex: epothilone/tubulin could not be subjected to X-ray crystallography. Electron microscopy can only be performed on tubulin sheets induced with Zn ions, which show an assembly of the tubulin dimers that is not found under physiological conditions. A structure of epothilone when bound to tubulin has been determined by electron crystallography. However, the resolution is too low to deduce the conformation of epothilone in a unique way. Thus, NMR constitutes a unique tool for the investigation of this drug/protein complex to obtain a high-resolution structure of the drug molecule in the bound state.

Cross-Correlated Relaxation for the Measurement of Projection Angles between Tensors [1]

Angular information on molecules is not only encoded in through-bond scalar or through-space dipolar couplings, but can also be derived from measurements of relaxation rates. Relaxation is caused by the correlation of two tensorial interactions. If these interactions are different, then relaxation caused by the cross-correlation of the two interactions is called cross-correlated relaxation. The cross-correlated relaxation rate depends on the strengths of the tensorial interactions as well as on the projection angle between the two tensors. To be effective the time-dependence of the tensorial interactions must be similar. Such a situation exists, e.g. between dipolar interactions of two proximate spin pairs within well-structured parts of the molecule, which display the same time-dependence due to overall tumbling. The most important tensorial interactions are the dipolar coupling and the chemical shift anisotropy. The dipole tensor between two spins I_k and I_l (I_m and I_n) is axially symmetric and the main axis is collinear with the respective internuclear bond vectors.

The cross-correlated relaxation rate observed for double- or zero-quantum coherence involving I_k or I_l and I_m or I_n for two dipolar interactions takes the following form:

$$\Gamma^c_{kl,mn} = \frac{\gamma_k \gamma_l}{(r_{kl})^3} \frac{\gamma_m \gamma_n}{(r_{mn})^3} \left(\frac{\mu_0}{4\pi}\hbar\right)^2 \frac{1}{5}(3\cos^2\theta_{kl,mn} - 1) \times \tau_c \tag{1}$$

The characterization of the angular dependence of the interaction of two nuclear dipoles $I_k I_l$ and $I_m I_n$ is therefore straightforward, namely it depends on the projection angle of the two bonds between I_k and I_l and between I_m and I_n. As can be seen from the equation for the cross-correlated relaxation rates, they depend on the correlation time of the molecule. Therefore, cross-correlated relaxation rates will increase with increasing size of the biomolecule under investigation as opposed to J coupling or dipolar coupling constants whose size does not depend on the molecular weight of the molecule. A second application lies in the fact that in analogy to the transferred NOESY experiment, in which distances are measured for ligands when bound to large target molecules, a transferred cross-correlated relaxation (trCCR) experiment allows to measure projection angles of weakly bound ligands when bound to large molecules.

Effects of Cross-Correlated Relaxation on Spectra

In two pairs of nuclei $I_k I_l$ and $I_m I_n$, projection angle dependent cross-correlated relaxation rates $\Gamma^c_{kl,mn}$ due to two dipolar couplings of double- and zero-quantum coherences between nuclei I_k and I_m leads to differential relaxation of the four submultiplet lines as indicated in Figure 1. The cross-correlated relaxation rate leads to

Fig. 1. Differential relaxation of the four submultiplet lines of a double-quantum coherence. The splitting originates from the J-couplings, while the line broadening originates from the cross-correlation of the two dipole–dipole couplings between k and l, as well as m and n, respectively. The differential relaxation can be expressed by the indicated product operators with evolutions that are sums and differences of exponential decays amounting to cosh and sinh dependencies.

additional line broadening of the outer lines (αα and ββ for the double-quantum coherence and αβ and βα for the zero-quantum coherence), while the inner lines (αβ and αβ for the double-quantum coherence and αα and ββ for the zero-quantum coherence) narrow by the same amount. This statement is true if the cross-correlated relaxation rate is positive ($3\cos^2\theta_{kl,mn}-1>0$) and thus the angle θ is between 0 and the magic angle θ^{magic} or between 180° and $180^\circ-\theta^{\text{magic}}$. In case that θ lies in the remaining region ($3\cos^2\theta_{kl,mn}-1<0$) the outer lines become narrower and the inner lines become broader. The case for positive cross-correlated relaxation rate $\Gamma^c_{kl,mn}$ is represented in Figure 1.

Often, line width measurements suffer from inaccuracies, especially since there are many contributions to the line width. Therefore, it is desirable to perform product operator transformations that create operators exclusively based on cross-correlated relaxation that otherwise could not be created. For that, we write down the product operator transformations that are effected by dipole/dipole cross-correlated relaxation. As pictorially demonstrated in Figure 1, we then find [2]:

$$I_{k,x}I_{m,y}\xrightarrow{\Gamma^c_{kl,mn}t}I_{k,x}I_{m,y}\cosh\Gamma^c_{kl,mn}t-4I_{k,x}I_{m,y}I_{l,z}I_{n,z}\sinh\Gamma^c_{kl,mn}t \tag{2}$$

Similarly we obtain for the evolution of an antiphase operator:

$$2I_{k,x}I_{m,y}I_{l,z}\xrightarrow{\Gamma^c_{kl,mn}t}2I_{k,x}I_{l,z}I_{m,y}\times\cosh\Gamma^c_{kl,mn}t-2I_{k,y}I_{m,x}I_{n,z}\times\sinh\Gamma^c_{kl,mn}t \tag{3}$$

Obviously, operators are formed due to the evolution of cross-correlated relaxation that would not be formed without. The trick to perform now quantitative Γ experiments lies in the observation that the simultaneous evolution of the J_{kl} and J_{mn} couplings will lead to the same transformation as in Equation (3) but with known transfer amplitude provided the size of the coupling constants is known:

$$2I_{k,x}I_{m,y}I_{n,z}\xrightarrow{J_{kl},J_{mn}}2I_{k,x}I_{m,y}I_{l,z}\sin\pi J_{kl}t\sin\pi J_{mn}t-2I_{k,y}I_{m,x}I_{n,z}\cos\pi J_{kl}t\cos\pi J_{mn}t+\text{additional terms} \tag{4}$$

Thus, two experiments can be performed, one that transforms the operator $2I_{k,x}I_{m,y}I_{l,z}$ into $2I_{k,y}I_{m,x}I_{n,z}$ with $\sinh\Gamma^c_{kl,mn}t$ in a so-called quantitative Γ cross experiment and a second experiment, the reference experiment, in which this transformation is effected by evolution of J

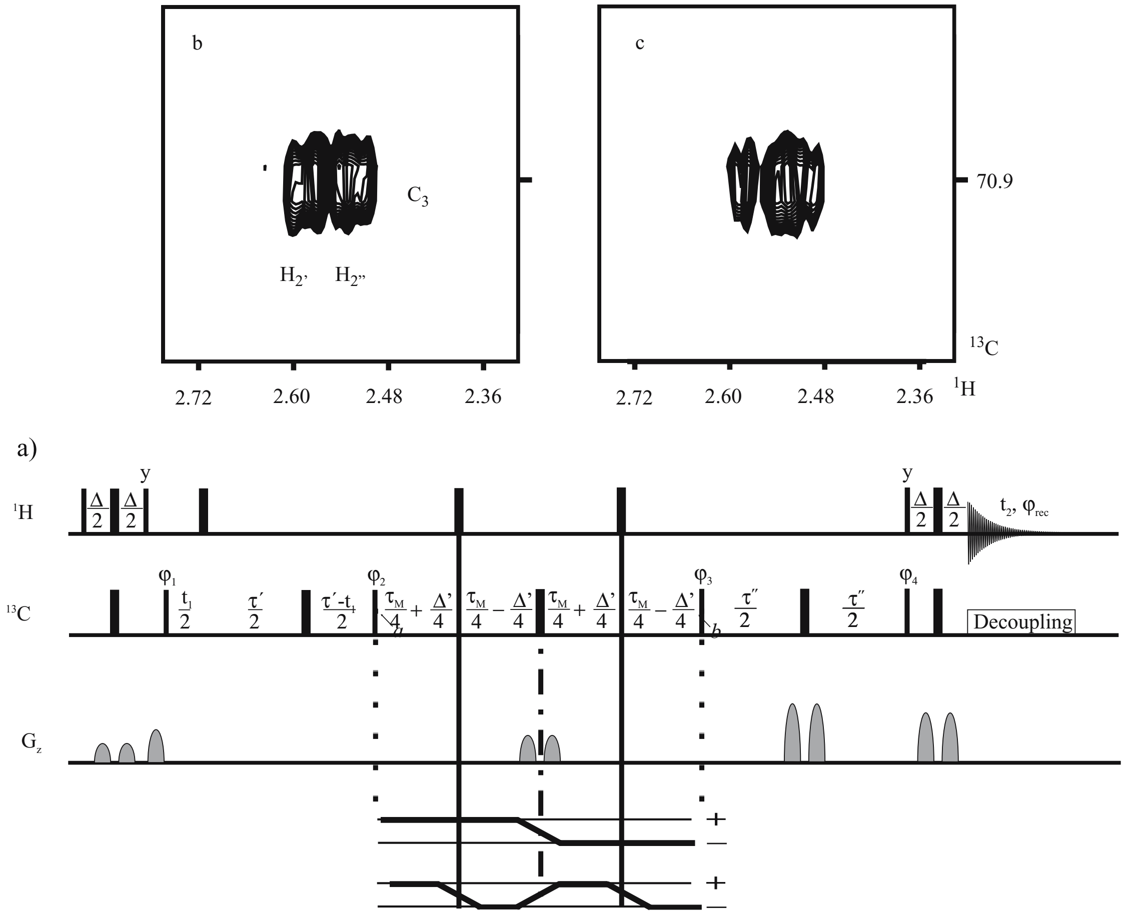

Fig. 2. Quantitative $\Gamma^{c}_{\mathrm{CH,CH}}$HCCH experiment (a) and spectra from reference (b) and cross experiments (c) applied to the H2′(H2″)C2C3H3 moiety of epothilone when bound to tubulin. From the comparison of the peak intensities of the respective peaks the cross-correlated relaxation rates ($\Gamma^{\mathrm{DD,DD}}_{\mathrm{C2H2',C3H3}}) = 2.1. + / - 0.3$ and $\Gamma^{DD,DD}_{C2H2",C3H3} = 3.8 + / - 0.4$) can be derived and related to the torsional angle C1–C2–C3–C4 of −146°.

couplings with the efficiency: $\sin\pi J_{kl}t \sin\pi J_{mn}t$. Provided the coupling constants are known or can be measured by well-known methodology, it is possible by comparing the intensities of a cross peak in the cross to the reference experiment to determine the cross-correlated relaxation rate.

Measurement and Application of the Quantitative Γ Method for Cross-Correlated Relaxation Rates

Quantitative Γ methods have been introduced originally by Felli *et al.* [3] and Pelupessy *et al.* [4] for dipole–dipole cross-correlated relaxation by transferring an initial operator to another operator by the evolution of the desired cross-correlated relaxation rate. Figure 2 shows the quantitative Γ sequence that measures the $\Gamma^{c}_{\mathrm{CH,CH}}$ cross-correlated relaxation rate. In this Γ HCCH experiment, which has been applied to aliphatic side chains or to sugars to measure the pseudorotation phase cross-correlated relaxation $\Gamma^{c}_{\mathrm{C}_i\mathrm{H}_i,\mathrm{C}_j\mathrm{H}_j}$ of the double- and zero-quantum coherence (DQ/ZQ) $4\mathrm{H}_{iz}\mathrm{C}_{ix}\mathrm{C}_{jy}$ generated at time point *a* creates the DQ/ZQ operator $4\mathrm{H}_{jz}\mathrm{C}_{jx}\mathrm{C}_{iy}$. In the second part of the experiment, the operator $4\mathrm{H}_{jz}\mathrm{C}_{jx}\mathrm{C}_{iy}$ is transferred via a 90° *y*-pulse applied to ^{13}C nuclei further to the proton H_j to give rise to a cross peak at $(\omega_{\mathrm{H}_j}, \omega_{\mathrm{C}_i})$. $\Gamma^{\mathrm{CSA,DD}}_{\mathrm{C}_i,\mathrm{C}_j\mathrm{H}_j}$ and $\Gamma^{\mathrm{CSA,DD}}_{\mathrm{H}_i,\mathrm{C}_j\mathrm{H}_j}$ cross-correlated relaxation are refocused by application of the 180° carbon and proton pulses during the mixing time τ_M. The following transfers are achieved in the sequence of Figure 2:

$$\begin{aligned}4H_{iz}C_{ix}C_{jy} \to 4H_{iz}C_{ix}C_{jy}&\left[\cosh\left(\Gamma^{c}_{C_iH_i,C_jH_j}\tau_M\right)\right.\\ &\times\cos^2\left(\pi J_{CH}\Delta'\right)-\sinh\left(\Gamma^{c}_{C_iH_i,C_jH_j}\tau_M\right)\\ &\left.\times\sin^2\left(\pi J_{CH}\Delta'\right)\right]-4H_{jz}C_{jx}C_{iy}\\ &\times\left[\sinh\left(\Gamma^{c}_{C_iH_i,C_jH_j}\tau_M\right)\cos^2\left(\pi J_{CH}\Delta'\right)\right.\\ &\left.+\cosh\left(\Gamma^{c}_{C_iH_i,C_jH_j}\tau_M\right)\sin^2\left(\pi J_{CH}\Delta'\right)\right]\end{aligned} \tag{5}$$

The last term produces a cross peak at $(\omega_{C_i}, \omega_{H_j})$ due to coherence transfer between $4H_{iz}C_{ix}C_{jy}$ and $4H_{jz}C_{jx}C_{iy}$, while the first term produces a cross peak at $(\omega_{C_i}, \omega_{H_i})$ and can therefore be distinguished. In the experiment with $\Delta' = 0$, the intensity of the cross peak (I^{cross}) is proportional to $\sinh(\Gamma^{c}_{C_iH_i,C_jH_j}\tau_M)$ whereas for $\Delta' = 1/2J_{CH}$, the intensity of the cross peak (I^{ref}) is proportional to $\cosh(\Gamma^{c}_{C_iH_i,C_jH_j}\tau_M)$. By comparing the intensity of the cross peak measured in the two experiments one can determine:

$$\frac{I^{\text{cross}}}{I^{\text{ref}}} = \tanh\left(\Gamma^{c}_{C_iH_i,C_jH_j}\tau_M\right) \tag{6}$$

This is applied in Figure 2B and C to the torsion angle defined by C1–C2–C3–C4 of epothilone and an angle of −143° is obtained.

An extension of this method is the measurement of cross-correlated relaxation between a methyl group and a remote HC moiety in a $C^1H_3C^2C^3H$ fragment [5] which yields the torsion angle about the C^2C^3 bond. The pulse sequence used for the measurement of the $\Gamma_{CH,CH}$ rate between the C^3H vector and the C^1H_3 vectors is shown in Figure 3A. Two experiments are recorded, yielding a *cross* and a *reference* spectrum similarly as for the HCCH case except for the fact that the transfer requires one further transfer step and the double-quantum and zero-quantum coherence is excited between geminal instead of directly bound carbons. The CCR rate is extracted from the ratio of peak intensities in the *cross* and *reference* experiment. The pulse sequence is optimized for maximum sensitivity of the cross experiment: the $8H^1_zC^1_yC^2_zC^3_y$ coherence present at point *c* is transformed by $\Gamma^{DD}_{C^1H,C^3H}$ into $8C^1_xC^2_zC^3_xH^3_z$ with efficiency equal to $3\sinh(\Gamma^{DD}_{C^1H,C^3H}\mathrm{T}_{rel})\cosh^2(\Gamma^{DD}_{C^1H,C^3H}T_{rel})$. For the reference experiment, the same operator transformation is achieved with the efficiency: $3\sin(\pi J_{C^1H}\Delta/2)\ \sin(\pi J_{C^3H}\Delta/2)\ \cosh^2(\pi J_{C^1H}\Delta/2)\cosh^3(\Gamma^{DD}_{C^1H,C^3H}T_{rel})$. The last term stems from the fact that the cross-correlated relaxation is active also in the reference experiment. It is obvious that a comparison of the relative intensities based on the knowledge of the respective coupling constants yields the cross-correlated relaxation rate. The $8C^1_xC^2_zC^3_xH^3_z$ term is then transformed into H^3_x for detection. The delays are optimized for optimal refocusing and defocusing of the couplings. Selective π pulses on the carbons prevent loss of magnetization to other passively coupled carbons. The complete coherence transfers are given in the following:

$$\begin{aligned}&\boxed{a}\,2H^1_zC^1_y \xrightarrow[\pi/2(C)]{{}^1J_{C^1C^2}} \boxed{b}\,4H^1_zC^1_yC^2_x \xrightarrow[\pi/2(C)]{{}^1J_{C^2C^3}} \boxed{c}\,8H^1_zC^1_yC^2_zC^3_y\\ &\xrightarrow[{}^1J_{CH}(\text{reference})]{\text{CCR(cross)}} \boxed{d}\,8C^1_xC^2_zC^3_xH^3_z \xrightarrow{\pi/2(C)} 8C^1_zC^2_xC^3_zH^3_z\\ &\xrightarrow[\pi/2(C)]{{}^1J_{C^1C^2}} \boxed{e}\,4C^2_zC^3_yH^3_z \xrightarrow{{}^1J_{C^2C^{23}}} \boxed{f}\,2C^3_xH^3_z \xrightarrow{\text{INEPT}} \boxed{g}\,H^3_x\end{aligned} \tag{7}$$

Transferred Cross-Correlated Relaxation

Due to the fact that cross-correlated relaxation depends linearly on the correlation time it can be used to determine the conformation of ligands when bound to target molecules, provided the off rate is fast enough to enable detection of the cross-correlated relaxation rate via the free ligand [6, 7]. The conditions, under which such an experiment can be performed, are similar to those found for transferred NOEs [8] and for K_ds normally exceeding 10^{-6}M, ligands are in an equilibrium between a protein-bound and a free form. The period during which the molecule is in the bound conformation will contribute to relaxation to the largest extent and hence will heavily weight experiments that are based on relaxation. The population-averaged cross-correlated relaxation rate for dipole, dipole cross-correlated relaxation between two sites with fractions p_L of the free ligand and $p_{ML} = (1 - p_{ML})$ of the bound ligand is given in Equation (8):

$$\begin{aligned}\left\langle\Gamma^{DD,DD}_{C_mH_m,C_nH_n}\right\rangle = \frac{2}{5}\,&\frac{\gamma_C^2\gamma_H^2\mu_0{}^2\hbar^2}{(4\pi)^2 r^3_{C_mH_m} r^3_{C_nH_n}}\\ &\times\left[S^2_{mn,L}\,p_L\frac{3\cos^2\theta_{mn,L}-1}{2}\tau_{c,L}\right.\\ &\left.+S^2_{mn,ML}\,p_{ML}\frac{3\cos^2\theta_{mn,ML}-1}{2}\tau_{c,ML}\right]\end{aligned} \tag{8}$$

Fig. 3. (A) Pulse sequence for the measurement of dipolar–dipolar cross-correlated relaxation between the $(CH)^{22/23}_{ave.}$ vector and the $(CH)^3$ vector in epothilone. $\Delta = 1/(2^1J_{CH})$; $T = 1/(4^1J_{CC}) = 7$ ms; $T_c = 1/(4^1J_{CC}) = 7$ ms; $T_1 = 1/(8^1J_{CC}) = 3.5$ ms; $T_{1c} = T_c$. Delays 1–4 are equal to $T_{rel}/4$ ($T_{rel} = 1/^1J_{CC} = 28$ ms) in the cross experiment; in the reference experiment delay 1 $= T_{rel}/4 + \Delta/8 =$ delay 3 and delay 2 $= T_{rel}/4 - \Delta/8 =$ delay 4. $\phi_1 = y$; $\phi_2 = x, -x$; $\phi_3 = 2(y), 2(-y)$; $\phi_5 = 4(x), 4(-x)$; $\phi_6 = 8(y), 8(-y)$; $\phi_8 = x$; $\phi_{10} = y$.; $\phi_{11} = 2(x,-x), 4(-x,x), 2(x,-x)$; $\phi_4 = \phi_7 = \phi_9 = x$. The pulses with phase ϕ_4 and ϕ_9 are Q3 pulses of 768 ms duration, centered at 63 ppm, to selectively invert the C^3 and C^4 (C^3 resonates at 70.9 ppm and C^4 at 53.0 ppm); the pulse with phase ϕ_7 is a Q3 pulse of 512 ms duration centered at 37 ppm, to selectively invert the $C^{22/23}$ and C^4 (C^{22} resonates at 19.1 ppm and C^{23} at 21.7 ppm). The proton carrier was at 4.78 ppm and the carbon carrier at 37 ppm; spectral widths were 4807.69 Hz for proton and 8333.33 Hz for carbon. Carbon decoupling in acquisition consisted of a GARP modulated pulse train at 2.38 kHz field strength. *Reference* (b) and *cross* (c) spectra acquired with the sequence in (a). The peaks visible in the reference spectrum are at the chemical shift of C^{22} (19.1 ppm) and C^{23} (21.7 ppm) in the carbon dimension and at the chemical shift of H^3 (4.27 ppm) in the proton dimension. The *cross* experiment was four times longer than the *reference* experiment. 1024 and 64 complex points were acquired in t_2 and t_1, respectively. The final matrices were 2048 × 128 points. The gray lines represent negative contours. The sample contained 0.5 mM epothilone A and 5 μM tubulin dissolved in D_2O. (D) Dependence of cross-correlated relaxation rates on the torsion angle about the C3–C4 bond. The two cross-correlated relaxation rates determine the angle to be −45°. (E) Numbering scheme of epothilone A and location of the torsion angles studied (indicated by bars drawn along the relevant bonds. (See also Plate 94 on page XVIII in the Color Plate Section.)

If the correlation time of the free ligand $\tau_{c,L}$ is much smaller than the correlation time of the bound ligand $\tau_{c,ML}$, the observed averaged cross-correlated relaxation rate $\left\langle \Gamma^{\mathrm{DD,DD}}_{\mathrm{C}_m\mathrm{H}_m,\mathrm{C}_n\mathrm{H}_n} \right\rangle$ is dominated by the bound conformation and therefore, precise information on the conformation of a bound ligand can be obtained. This concept has been introduced on the determination of the conformation of a phosphotyrosine peptide weakly bound to STAT-6 [7] []and of a tRNA analog bound to EF-Tu· GDP complex [6]. Here we will show the power of the method on the determination of the epothilone conformation in the tubulin-bound state.

Application to the Epothilone/Tubulin Complex

In this review, we describe the application of trCCR measurements for the determination of the conformation of epothilone when bound to tubulin. Epothilones are microtubule stabilizers and inhibit cell proliferation through a mechanism of action which is analagous to that of the renowned clinical anti-cancer drug Taxol® (paclitaxel).[9] Epothilones exhibit extraordinary antiproliferative activity in vitro and they efficiently induce cell death in paclitaxel-resistant tumor cell lines at up to 5000-fold lower concentrations than paclitaxel [9–11]. In addition, they possess higher water solubility than paclitaxel [10,12] which allows delivery *in vivo* with non cremaphor-containing formulation vehicles, thus eliminating formulation-based side effects [major hypersensitivity reactions (HSR)] [13] The potential clinical utility of epothilones is supported by *in vivo* experiments with epothilone B in a variety of nude mouse human tumor models [10,14].

Fortunately, the kinetic and thermodynamic properties of the complex between epothilone A and tubulin are in the desirable range for trNOE and trCCR experiments. Indeed, the trNOE and trCCR data are found in agreement with a dissociation constant K_d in the range of 10–100 μM. Evidence of *specific* binding of epothilone A to tubulin is provided by the restoration of the NOE spectrum of free epothilone A upon addition of epothilone B to the mixture, which proves the quantitative displacement of epothilone A from tubulin by the tighter binder epothilone B (not shown). The existence of specific and transient binding of epothilone A to tubulin enables the structural analysis of the active conformation of the epothilones by NMR.

The tubulin-bound conformation of epothilone A was calculated from 46 inter-proton distance restraints and seven torsion angle restraints measured for a 0.5 mM solution of epothilone A in water in the presence of 5 μM tubulin. The distance restraints were derived from transferred NOE experiments. To filter out spin-diffusion mediated peaks, only those signals were taken into account which were present with opposite sign to the diagonal peaks in a transferred ROESY experiment. The dihedral angle restraints were obtained by measuring CH–CH dipolar–dipolar and CH–CO dipolar-CSA transferred CCR rates for 60–70% ^{13}C labeled epothilone A. The trCCR experiments [6,7] were indispensable to obtain a unique description of the bound conformation, as more than one structure of the macrolide ring is compatible with the same H–H distance set (NOE intensities). Seven trCCR rates defined the torsion angles C1–C2–C3–C4, C5–C6–C7–C8, C12–C13–C14–C15, C13–C14–C15–O11, and C14–C15–C16–C17 were all determined using the quantitative Γ HCCH. The C2–C3–C4–C5 was determined from the ratio of the cross-correlated relaxation rates between the $\mathrm{C}^{22}\mathrm{H}_3$ and $\mathrm{C}^{23}\mathrm{H}_3$, respectively, with the $\mathrm{C}^3\mathrm{H}$ dipole. The O11–C1–C2–C3 was determined from CSA/DD trCCR (not described here) [15]. Figure 3B and C shows a representation of the methyl group experiment with the cross and reference experiments, respectively. In the cross spectrum the $\mathrm{C}^{23}(\omega 1)$–$\mathrm{H}^3(\omega 2)$ peak is missing, indicating that the dipolar–dipolar CCR between the $(\mathrm{CH})^{23}_{\mathrm{ave.}}$ vector and the $(\mathrm{CH})^3$ vector is close to zero. The quantitative value for the two CCR rates can be extracted according to the equation:

$$I_{\mathrm{cross}}/I_{\mathrm{ref}} = \tanh(\Gamma T_{\mathrm{rel}})/\sin^2(\pi J_{\mathrm{CH}}\Delta/2)\cos^2 \times (\pi J_{\mathrm{CH}}\Delta/2) \quad (9)$$

where I_{cross} and I_{ref} are the intensities of the peaks in the cross and reference experiment, respectively and Γ indicates the cross-correlated relaxation rate. The measured CCR rates between the $(\mathrm{CH})^3$ vector and the $(\mathrm{CH})^{23}_{\mathrm{ave.}}$ and $(\mathrm{CH})^{22}_{\mathrm{ave.}}$ vectors are 0.1 ± 0.1 and -1.4 ± 0.4, respectively. The dihedral angle θ that complies with the ratio between the two CCR rates is $-45° \pm 5°$. We used the ratio of the two CCR rates, instead of the rates themselves, to determine the dihedral angle because this approach is independent from both the τ_c and the internal motion order parameter S^2, if equal internal reorientation of all the CH vectors is assumed. The change in the θ dihedral angle from the gauche + conformation in the free form to the gauche—conformation in the bound form is corroborated by transfer-NOE data.

The tubulin-bound conformation of epothilone A [15] is shown in green in Figure 4 and is compared with the free (unbound) conformation of epothilone A determined by X-ray crystallography, [15,16] which is shown in gray. We choose to compare the tubulin-bound conformation of epothilone with the X-ray structure and not with the solution structure available in $\mathrm{CD_2Cl_2}$, because of the extensive flexibility of epothilone in solution in absence of tubulin [17]. However, the most populated conformer in

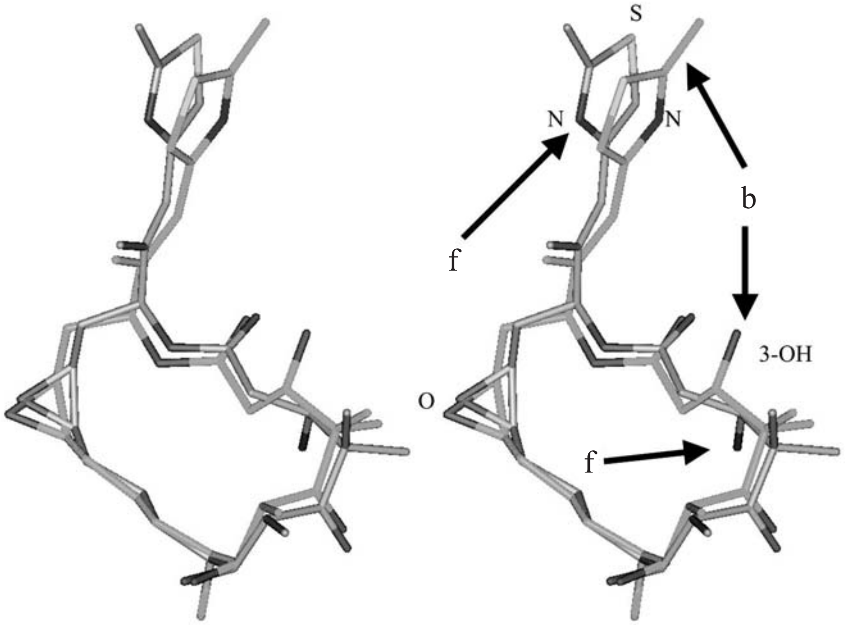

Fig. 4. Comparison of the conformations of epothilone as a stereoview. Arrows indicate free epothilone A (f: X-ray) and epothilone A bound to tubulin (B). Note the inversion of the orientation of the thiazole ring as well as the change in position of the 3-OH group. (See also Plate 95 on page XVIII in the Color Plate Section.)

solution is indeed very similar to the X-ray conformer. The position of the thiazole nitrogen (blue in Figure 4) and 3-OH (red in Figure 4), which are important for the delineation of a pharmocophore model, change significantly upon binding.

The structure of epothilone as derived from transferred NOE and cross-correlated relaxation is not identical with the structure derived from an electron crystallography study on Zn induced tubulin sheets [18]. The difference may be due to differences between the conformation of tubulin when assembled in Zn induced flat sheets as opposed to soluble tubulin or the low resolution of the electron crystallography that required extensive modeling of the epothilone conformation.

Conclusion

In conclusion, we have shown that transfer NOE and tr-CCR rates can be used for the determination of the conformation of epothilone when bound to tubulin in physiological conditions. So far, it has not been possible to obtain crystal structures of tubulin or microtubules. The structure differs from the one proposed from electron crystallography on Zn induced tubulin sheets which could be due to differences in the preparation of the samples under investigation or due to the low resolution of the electron crystallography structure.

Introduction

NMR is a critical tool in current structural biology, and plays a significant role in the understanding of pharmacologically significant proteins, as well as the development of modulators for these proteins. The general approach for structure determination has been well established; however, as the systems of interest become larger (e.g. >25 kDa) and less well behaved in solution (e.g. solubility limits of 50–200 μM), new approaches are required to enable NMR to remain a key player. The introduction of cryogenic probes has dramatically impacted our ability to study lower concentration and/or lower stability proteins. Nevertheless, there has been a need to develop new approaches to provide long-range structural restraints to solve structures of highly deuterated proteins and to determine the orientation of domains in multidomain proteins, or in multimeric complexes. This article will focus on our recent efforts in this area of research, specifically the introduction of paramagnetic metal ions into non-metalloproteins and the unique and powerful structural restraints that can be obtained from this approach.

The ability of paramagnetic centers to provide valuable structural information for proteins has been recognized for a long time [1,2]. The principal significance of this information is the long-range distance (10–40 Å) or global (distance and orientation) nature of the restraints. By augmenting traditional short-range, scalar restraints (such as NOEs) with long-range restraints, more accurate protein structures can be obtained. The relative proximity and/or orientation of protein domains or proteins within a complex can also be investigated. There are three main types of data that are obtainable: paramagnetic relaxation enhancement (PRE), pseudocontact shifts (PCSs), and residual dipolar couplings (RDCs).

Paramagnetic relaxation enhancements provide long-range distance information [3–6]; however, while relaxation enhancement is a powerful tool, we will focus our discussion here on the use of PCSs and RDCs. Paramagnetic induced residual dipolar couplings (pmiRDCs) and cross-correlation rates between dipolar and Curie relaxation pathways offer unique ways for obtaining orientational information on bond vectors in protein molecules [7–10]. PCSs provide both distance and orientational information that is very important for protein structure determination [11–14]. However, until recently, observation of these valuable structural parameters was limited to naturally metal binding proteins. Investigators have now begun to examine ways to introduce paramagnetic centers into non-metal binding proteins. We will illustrate two different approaches to achieve paramagnetic tagging and discuss new methods that enhance this general approach by providing more precise measurements of RDCs. Finally, we will demonstrate the impact of PCSs and pmiRDCs on solving difficult protein structures (>25 kDa) and on defining domain orientation in two pharmacologically significant proteins, STAT4 and hepatocyte growth factor (HGF).

Methods to Bind Paramagnets to Non-Metalloproteins

One way to introduce paramagnetic probes into non-metalloproteins is through chemical modification that introduces a metal-chelating site. A facile modification site is either a unique, natural cysteine residue or an engineered cysteine residue within the protein of interest. Two early examples of this type of protein modification with paramagnetic agents involved the attachment of nitroxide spin labels to lysozyme and bovine pancreatic trypsin inhibitor [15,16], allowing the measurement of relaxation enhancements. One limitation of this approach is evident for proteins with multiple, structurally important cysteine residues, wherein complications due to cross-linking, aggregation or refolding of the unmodified protein may occur. In this case, alternative approaches to attachment of the metal binding ligand can be utilized (*vide infra*). More recently, EDTA based ligands were successfully employed for paramagnetic labeling of macromolecules. Proteins modified with

S-(2-pyridylthio)-cysteaminyl-EDTA have been shown to bind Co^{2+} and allow measurement of PCSs and pmiRDCs. This approach has been demonstrated on barnase and the N-terminal domain of STAT4 [17,18]. Other paramagnetic ions, e.g. lanthanides, can be bound to the EDTA ligands and yield a wealth of PCS and pmiRDC data. It has been shown that under some conditions the EDTA-metal complex can exist in two forms, believed to be stereoisomers. The two forms result in two different paramagnetic ansisotropic susceptibility (PAS) tensors and two sets of shifted resonances, as observed for two proteins, trigger factor and ArgN [19,20]. Further inspection indicates that the multiple forms may be due to the protonation state of the EDTA moiety at the time of complexation (Gaponenko *et al.*, to be published). Additionally, a different cysteine-ligation paramagnetic tagging reagent has been proposed [21]; however, multiple isomers were observed and the reagent may prove problematic. To address the problem of multiple forms, a slightly modified and enantiometrically pure EDTA-derived tag has been proposed [19]. This new ligand is anticipated to facilitate broader use of the cysteine-ligation approach, and it is clear that further advances in ligand design will be forthcoming soon. A related approach employed cysteaminyl-EDTA-derivatized 4-thio-deoxythymidine incorporated into DNA that was subsequently used to form a protein-DNA complex. By binding Mn^{2+} to the EDTA moiety, long-range intermolecular distances were derived from PREs of protein resonances [22,23].

Since PCSs are dependent on the distance and orientation of nuclei from the paramagnet, it is likely that not all segments of a molecule will reveal PCS data using a single ligation site. However, it is straightforward to serially engineer multiple ligand attachment sites, thereby obtaining PCS data for all segments of secondary structure (Figure 1) [17]. The multiple ligand attachment sites also yield separate, distinct alignment tensors, relative to the molecular coordinate system. This is particularly attractive, since it is often difficult to reduce the degeneracy for RDC solutions with one alignment [24,25], while multiple alignments can be difficult to achieve due to protein interactions with the alignment media or correlation of the tensor orientations (C.A. Fowler *et al.*, in preparation).

A second method of achieving paramagnetic binding to proteins is through the use of chelating peptide tags. Several peptides that can be cloned at either terminus of an expressed protein have been reported to bind paramagnetic metals. ATCUN (amino terminal Cu^{2+}(Ni^{2+}) binding) motifs [26] with bound Cu^{2+} have been used to provide distance restraints by PRE in both ubiquitin [27] and several calmodulin-peptide complexes [28]. Another short peptide tag, HHP (His-His-Pro), has been cloned at the N-terminus of thioredoxin [29], allowing the measurement of PRE in the presence of Ni^{2+}. Longer peptides can also chelate metals. A 17 residue lanthanide binding peptide tag has been cloned at the N-terminus of ubiquitin and used to obtain partial orientation and observe pmiRDCs [30]. Finally, chelated metals can be bound using a combination approach. A 26 residue, calmodulin binding peptide was attached via a short linker to the C-terminus of dihydrofolate reductase (DHFR) and Tb^{3+}-saturated calmodulin was added and observed to bind to DHFR, transferring a degree of paramagnetic alignment and allowing the measurement of pmiRDCs [31].

We have proposed a simpler, common peptide tag that is used in immobilized metal affinity chromatography (IMAC) [32–35]. IMAC is a technique generally used to purify recombinant proteins expressed with a chelating peptide tag. The tag binds to partially chelated metal ions in the column resin, allowing contaminants to be washed away followed by elution of the purified protein. One of the most common tags used for IMAC is hexahistidine (the so called his-tag) [36,37], which can be added at either the N- or C-terminus of a protein. Since his-tags can bind resin-associated metal ions, it follows that they can also bind free metal ions in solution.

It has recently been shown that several his-tagged proteins are capable of binding free cobalt ions in solution. The paramagnetic anisotropy of the cobalt-his-tag complex allows measurement of PCSs and also leads to partial alignment of the sample in a magnetic field, allowing the observation of pmiRDCs. The PCSs and pmiRDCs measured from the protein-his_6-Co^{2+} species

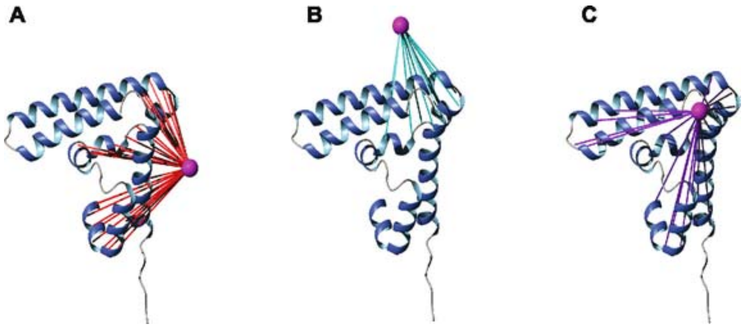

Fig. 1. Co^{2+} ligation at three distinct sites on $STAT4_{NT}$. (A) wt-C107, (B) T50C, and (C) K92C. The vectors illustrate the PCSs observed for H^N protons.

Table 1: Magnitudes of pmiRDCs observed for various protein-metal complexes

Protein and chelating tag	Metal or metal chelate	Largest magnitude ^{1}H-^{15}N RDC (Hz)
NK1-his$_6$	Co^{2+}	−3.0
Ubiquitin-his$_6$ (N-terminus)	Co^{2+}	−2.5
Ubiquitin-his$_6$ (C-terminus)	Co^{2+}	−0.7
Ubiquitin-LBP	Tb^{3+}	−7.6
Ubiquitin-LBP	Dy^{3+}	−6.6
Ubiquitin-LBP	Tm^{3+}	+4.5
DHFR-CBP	calmodulin(Tb^{3+})$_4$	−7.4
YmoA-his$_6$	Co^{2+}	+2.0
NusB-his$_6$	Co^{2+}-NTA	+2.0
STAT4-EDTA	Co^{2+}	−4.0
Trigger factor-EDTA-carbonic acid	Dy^{3+}	+8.0

LBP, lanthanide binding peptide; DHFR, dihydrofolate reductase; CBP, calmodulin binding peptide; NTA, nitrilotriacetic acid

have been shown to be relatively small; however, they are structurally significant and readily obtained (*vide infra*). Table 1 lists the magnitudes of observable pmiRDCs for several different chelating tags and conditions.

PCS Assignment and Use of PCSs and pmiRDCs as Structural Restraints

First, we will consider the PCSs. The presence of a metal ion introduces a PAS that results in the observation of PCSs for the NMR resonances. PCSs are measured as differences ($\Delta\delta_{pc}$) in chemical shift between the paramagnetic and diamagnetic species. Such differences are readily measured in the metal-free and metal-bound states. PREs can degrade the sensitivity of NMR experiments for sites close to the metal. For this reason, we have chosen to use Co^{2+}, which provides less relaxation enhancement than lanthanides or Mn^{2+}. Assignment of PCSs can be achieved using traditional NMR assignment strategies [38]. An alternative assignment strategy utilizes a preliminary structure of the macromolecule to estimate the PAS tensor orientation from several unambiguous PCSs [11], which have been assigned by inspection of HSQC spectra. The subsequent assignment of the remaining PCSs is accomplished by an iterative procedure of predicting the PCS values, using the PAS tensor orientation and the preliminary structure coordinates, and then re-optimizing the PAS based on new assignments. We have found that this procedure can assign all observable PCSs, including shifts up to 650 ppb, which were not previously assignable by inspection or other methods (Gaponenko *et al.* in preparation, 2005).

If the metal is chelated only by the EDTA or His$_6$ ligand, then there is no Fermi-contact contribution to $\Delta\delta_{\text{pc}}$, since there is no direct overlap of the molecular orbitals of the paramagnetic center with the protein atoms [2,12]. The pseudocontact shift is described by the following equation:

$$\Delta\delta_{\text{pc}} = \frac{P_{\text{ax}}}{r^3}\left(3\cos^2\theta - 1\right) + \frac{P_{\text{rh}}}{r^3}\sin^2\theta\cos(2\varphi). \quad (1)$$

where P_{ax} and P_{rh} are the axial and rhombic components of the PAS, r is the distance between the unpaired electron and the observed nucleus, and θ and ϕ are the polar angles describing the orientation of the electron-nucleus vector in the PAS tensor frame. PCSs follow the same functional form as RDCs and the structural restraints are very similar to homonuclear dipolar couplings [39]. However, the PCS restraints are more useful than homonuclear dipolar couplings because the sign information is readily available.

It is a straightforward procedure to incorporate PCS restraints into structure calculation programs, e.g. Xplor-NIH, that already have utilities for RDC refinement. The restraint is expressed in terms of the actual PCS and does not have an explicit input distance or orientation. Since many PCS restraints are included (for each tagged site) and combined with other NOE and torsion-angle restraints, a unique solution can be obtained. The distance of the atom, corresponding to the PCS, from the paramagnetic center is determined from the final structures. The corresponding distances range from 10 to 40 Å for the two cases described below.

The use of RDCs in protein structure determinations has become very significant and has been recently reviewed [40]. In the present application, partial alignment of the protein arises due to the paramagnetic susceptibility of the tagged protein. The alignment is known to be small [9]; nevertheless, the pmiRDCs are readily obtained without the need for steric alignment media, and have shown to be extremely valuable, both in terms of structure determination and domain orientation (*vide infra*). The pmiRDCs obtained from paramagnetic alignment are used in structure calculations exactly as has been described for steric alignment induced RDCs. They have also been useful for cross-validation.

New Approaches to Measurement of Small, Paramagnetically Induced RDCs

Paramagnetic alignment can induce relatively small RDCs (±2 to ±8 Hz for H^N-N), and it is important to have accurate methods to measure these couplings. Typical procedures for measuring RDCs involve the use of direct frequency measurements of resolved multiplet components, often augmented with the IPAP procedure [41]. These methods can suffer from measurement precision for small couplings. We have recently introduced a suite of experiments, based on the principal of J-modulation, that facilitate the measurement of H^N-N, H^{α}-C^{α}, C^{α}-C', and C^{α}-C^{β} RDCs [58]. The experiments encode the coupling of interest into peak modulation within familiar two-dimensional H^N-N (equivalent to HSQC spectra) or HN-C' correlation spectra.

Briefly, J-modulation can be incorporated into a pulse sequence in several different forms (see Figure 2), and the underlying principal remains that the coupling of interest is evolved for an amount of time, Δ, which can be varied. The observed resonance intensity is modulated by the coupling of interest in a sinusoidal manner dependent on Δ. Different types of J-modulation can be introduced into pulse sequences and result in different modulation functions of the coupling of interest. Simple, non-constant time J-modulation (Figure 2A) measures coupling for a total time 2Δ, but the intensity is a composite of J-modulation and I-spin relaxation, which complicates data analysis. Constant-time J-modulation incorporates the J-modulation delay into a constant time period, keeping relaxation effects constant and providing a means to decouple a third spin (Figure 2B). Chemical shift evolution can be reintroduced to constant time J-modulation rather easily (Figure 2C), thus expanding the repertoire of experiments that can be designed. Acquiring a series of spectra in which Δ is incremented allows the coupling of interest to be extracted from a plot of resonance intensity vs. total evolution time (Figure 2D). Examples of simple J-modulation [42–45], and constant-time J-modulation [46] have appeared, and we have extended these concepts and developed a suite of experiments to facilitate the rapid and precise measurement of a complete set of RDCs. With adequate signal-to-noise and a sufficient number of data, the precision of J-modulated couplings can exceed those of direct and E.COSY measurements. For a detailed discussion of these methods and the overall suite of experiments see McFeeters *et al.* [58].

In general, the precision of RDC measurement using the J-modulation experiments can be of the order of ±0.1 Hz and is significantly improved compared to IPAP methods or three-dimensional methods used to decrease spectral overlap. The convenience of spectral analysis for the familiar HSQC-like H^N-N 2D spectra facilitates a rapid, accurate measurement of multiple RDCs for samples with even weak alignment, such as found for paramagnetic induced alignment. These advances ensure that the maximum amount of structural data can be obtained from the paramagnet-tagged protein system.

Structural Applications of PCSs and pmiRDCs

We have addressed two difficult problems in protein structure determination: (1) improving structural accuracy for large, perdeuterated proteins, and (2) orientation of protein domains (or separate molecules) without the use of interdomain/intermolecular NOEs. Each of these problems reflects the use of NMR methods in larger, more biologically and pharmacologically significant proteins. The use of deuteration and selective methyl-protonation to enable structural studies of proteins $\geq$25 kDa is becoming common and has been reviewed [47].

Structural accuracy can be significantly improved by combining observed H^N (Figure 1) and methyl-^{1}H PCSs with the limited NOE-restraints available from an ILV-labeled protein to calculate the three-dimensional structure, as demonstrated for the N-terminal domain of STAT4 [17]. When PCSs were included in structure calculations the RMSD for backbone atoms in secondary structure elements between the solution structure and the crystal structure decreased from 2.9 to 2.0 Å, while the quality factor, Q [48], calculated from pmiRDCs *not used* in structure refinement decreased from 0.6 to 0.2. Furthermore, PCSs restraints for methyl groups of Ile, Leu, and Val afforded improvement in accuracy of the sidechain positions for these residues. The RMSD values for all heavy atoms in Ile, Leu, and Val sidechains relative to the crystal structure decreased from 2.97 to 2.43 Å, while the precision within the ensemble improved from 2.37 to 1.66 Å. Using the N-terminal domain of STAT4, we have also demonstrated that it is possible to break magnetic symmetry in homodimers, including the difficult case of head-to-head dimers, thus yielding unique structural information for each monomeric domain within the dimer [38] By binding subequimolar amounts of the paramagnet, only one monomer was tagged with paramagnet, and the PCSs to otherwise symmetric residues rendered the two sites magnetically inequivalent. The asymmetric system provided structural restraints, in the form of PCSs and pmiRDCs for each monomer, which enabled the

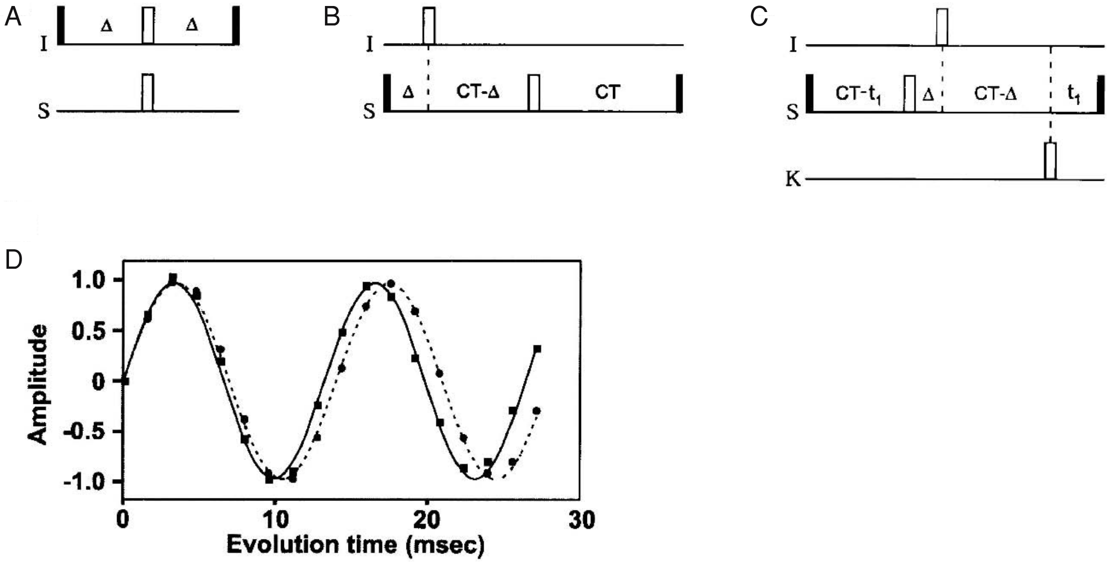

Fig. 2. Improved measurement of RDCs via J-modulation. (A) Basic pulse sequence element for non-constant time J-modulation. Intensity as a function of Δ, is a composite of both relaxation and modulation according to $\sin(2\pi J_{IS}\Delta)\bullet\exp(-R2\Delta)$. (B) Constant-time J-modulation removes relaxation damping resulting in modulation by $\sin(2\pi J_{IS}\Delta)$. (C) Frequency labeling can be reintroduced into constant-time J-modulation with no alteration in the form of modulation. (D). positioning of the two monomers with respect to one another (Gaponenko, unpublished). The improvements in structure calculations derive directly from the fact that PCSs, unlike one-bond RDCs, contain translational (distance) information in addition to orientational information. This fact heightens the value and future impact of using PCS restraints in general for protein structure determinations.

The second problem that we address is the ability to orient domains relative to one another within a multidomain protein or complex in the absence of traditional, NOE-based distance restraints, which is especially pertinent where deuteration is employed. This is a general form of the problem relating to the positioning of monomers within a homodimer structure (see above). The general approach assumes that any relatively rigid molecular fragments can be oriented relative to one another, provided enough data can be measured to determine the alignment tensor for each fragment. If the overall molecule is determined to behave as a single rigid unit, then each fragment must experience the same degree of alignment. Superimposing the alignment tensors allows the fragments to be correctly oriented with respect to one another. This technique has been successfully applied to fragments as small as a few residues [49,50], as well as to the problem of orienting entire protein domains. Recent examples of domain orientation using RDCs include the B and C domains of barley lectin [51], the domains of maltodextrin binding protein [52], and sequential domains in polyubiquitin chains [53–55]. The tensorial information may also be obtained from relaxation analyses [56,57]; however, we will focus on the use of RDCs and PCSs in this discussion.

Although useful, domain orientation using RDCs poses two significant challenges. The first of these is overcoming the well known “inversion problem” [25]. Although an alignment tensor can be determined using as few as five RDCs, it is impossible to determine which direction along each axis is positive and which is negative. This leads to four degenerate orientations, and additional independent data is required to overcome this inversion problem. A second problem is that while domains can be properly oriented, RDCs provide no translational (or distance) information and additional data must be used to position the two domains relative to one another.

We have recently combined PCSs with RDCs to orient the two domains in the NK1 fragment of HGF (C.A. Folwer *et al.*, in preparation, 2005). RDCs for the two domains were measured in phospholipid bicelles, yielding four possible domain orientations. Several additional alignment media were screened to find a second, independent alignment tensor; however, the protein either interacted with the media or the alignment tensor was

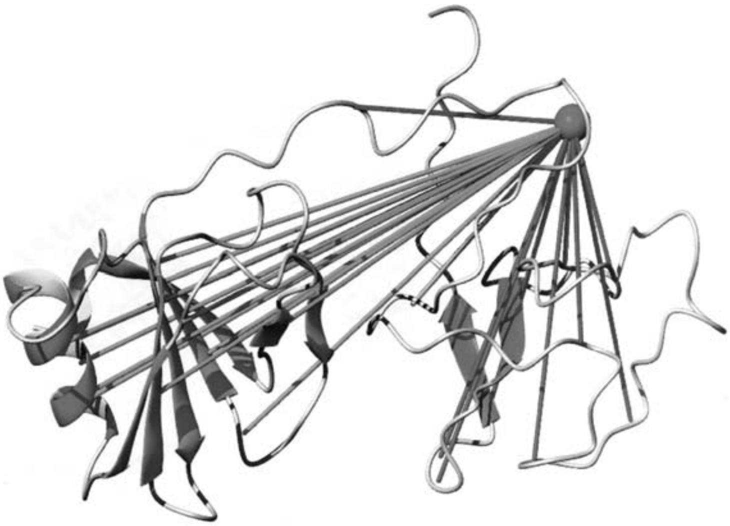

Fig. 3. Solution structure of NK1 refined against bicelle RDCs and cobalt PCSs (PCSs illustrated as orange and purple vectors to the N and K1 domains, respectively). (See also Plate 96 on page XIX in the Color Plate Section.)

not sufficiently different to solve the inversion problem. The protein was then re-cloned with a his-tag at the C-terminus, and shown to bind cobalt specifically to the his-tag. A saturating amount of cobalt was added to the sample, resulting in the observation of PCSs (±80 ppb) for amide protons in both domains. Furthermore, partial alignment of NK1 in the magnetic field, due to paramagnetic anisotropy, allowed the observation of H^N-N pmiRDCs on the order of ±3 Hz. The alignment tensor determined from the pmiRDCs was unique relative to the steric alignment tensors and was used to resolve the inversion problem, leading to a unique orientation of the two domains. The observed H^N PCSs for both domains were subsequently used as restraints and combined with RDCs measured from bicelle alignment, in a structure calculation to position the two domains of NK1 with respect to each other. The PCSs provided the requisite translational (distance) restraints to achieve a unique structural solution, and the significance is clearly seen in the long-range distances (10–40 Å) that correspond to the PCS restraints (Figure 3). The cobalt pmiRDCs were withheld from the structure calculations and subsequently used for cross-validation, which confirmed the structure. The final structure was obtained without the use of *any* intermolecular NOEs, and it is currently being analyzed to improve our understanding of the interaction of HGF with the cMet receptor.

Conclusion

We have summarized some of the exciting new applications of paramagnets in non-metalloprotein systems. The structures generated using the newly accessible restraints are of high quality and hold the potential for more accurate structures, access to larger structures, and more rapid structure determinations. While, to date, a limited number of applications of paramagnetic labeling have been described in the literature, it is already clear that this approach offers a wealth of valuable structural information. Improved tagging techniques and better software for data analysis should further enhance the advantages offered by this methodology for NMR structure determination and studies of molecular dynamics.

Abstract

^{15}N-HSQC spectra of ^{15}N-labeled proteins are widely used to identify ligand-binding sites on protein surfaces, providing a way to assess protein–protein interactions as well as to screen for the binding of small chemical compounds. The method is particularly powerful if the cross peaks in the ^{15}N-HSQC spectrum have been sequence-specifically assigned. The present article reviews the use of paramagnetic labeling to obtain these resonance assignments quickly with the use of ^{15}N-labeled protein, provided the crystal structure of the protein is known and the protein can be labeled with a paramagnetic ion. The method also yields the anisotropy tensor of the magnetic susceptibility, which can be used to model the orientation of the ligand with respect to the protein.

Introduction

^{15}N-HSQC spectra of uniformly ^{15}N-labeled proteins play a unique role in pharmaceutical research by providing a two-dimensional fingerprint of the protein, where each amino acid residue, except proline, is represented by a peak from its backbone amide proton [1,2]. The cross peaks serve as sensitive reporters of ligand binding, as changes in the local chemical environment affect their chemical shifts and line widths, providing positive evidence of binding and information about the location of interacting surfaces. The binding of small molecules and interactions with macromolecular partners can both be assessed in this way. The method presents a tool for target validation (e.g. where do natural interaction partners bind?) but is even more attractive for the screening of chemical compound libraries (which compounds bind?) [3,4], since weak and strong binding can be detected equally well.

Assignment of the spectral changes observed in ^{15}N-HSQC spectra to specific binding sites (where does the compound bind?) requires the assignment of the cross peaks to the individual amino-acid residues in the protein. Traditional ways of assigning the ^{15}N-HSQC spectrum of a protein of molecular weight above 15 kDa require the preparation of doubly- (^{15}N and ^{13}C) or triply labeled (^{15}N, ^{13}C, and ^{2}H) samples and the recording of three-dimensional NMR spectra. These experiments are much less sensitive and more time consuming than recording of a ^{15}N-HSQC spectrum. Although uniformly labeled protein samples can, in principle, readily be prepared by expressing the protein in cell cultures grown in isotope-labeled media, labeling with isotopes other than ^{15}N proves prohibitively expensive in many cases. Therefore, resonance assignments are restricted to proteins which can be expressed in high yields and which are sufficiently soluble to record the NMR spectra necessary for resonance assignment. As a result, NMR resonance assignments seem to be out of reach for many target proteins of pharmaceutical interest, even when crystal structures and ^{15}N-HSQC spectra may be available.

The present article describes a different strategy for assigning ^{15}N-HSQC spectra of ^{15}N-labeled proteins. It requires prior knowledge of the three-dimensional protein structure and a lanthanide-binding site in the protein. The strategy has been demonstrated for the 30 kDa complex of the subunits ε (N-terminal segment with residues 2–186) and θ of *Escherichia coli* DNA polymerase III, where ε had been selectively labeled in three separate samples with ^{15}N-labeled Leu, Val, and Phe [5]. Resonance assignments are obtained from the comparison of two highly sensitive ^{15}N-HSQC spectra, recorded with and without a paramagnetic lanthanide ion bound to the complex.

ε186–θ Complex

The crystal structure of the N-terminal domain of ε (ε186) has been solved by X-ray crystallography [6]. The same fragment has been studied by NMR spectroscopy, both free and in complex with θ, using doubly and triply

Graham A. Webb (ed.), Modern Magnetic Resonance, 1263–1269.

isotope-labeled samples [7,8]. Two Mn^{2+} ions are bound to the active site of the enzyme in the crystal structure. In analogy to the related domain of DNA polymerase I, these two ions can be replaced by a single lanthanide [9].

Paramagnetic Restraints Derived from ^{15}N-HSQC Spectra of Paramagnetic and Diamagnetic ε186–θ Complexes

^{15}N-HSQC spectra of the complex between ε186 and θ with a Dy^{3+} ion bound (the paramagnetic complex) and of the complex without an ion bound or with La^{3+} bound (the diamagnetic complex) were recorded at a ^{1}H NMR frequency of 600 MHz. Spectra recorded in the presence or absence of La^{3+} were very similar; either spectrum provided an adequate diamagnetic reference for the measurement of paramagnetic restraints.

The cross peaks recorded for the paramagnetic complex are strongly shifted with respect to those of the diamagnetic spectrum (Figure 1). The chemical shift difference between the paramagnetic and diamagnetic spectrum presents the pseudocontact shift (PCS). The PCS values, measured in ppm, are almost the same in the ^{15}N and ^{1}H dimension of the spectrum. Consequently, the paramagnetic signals are shifted along approximately parallel lines, enabling the pairwise association of diamagnetic and paramagnetic cross peaks. Ambiguities resulting from situations of cross-peak overlap (Figure 1) can often be resolved by the assignment algorithm discussed below.

The ^{15}N-HSQC spectra are best recorded without decoupling during the acquisition time [5], resulting in a shorter pulse sequence and hence, reduced loss of magnetization by relaxation. More importantly, analysis of the doublet fine structure provides access to paramagnetic parameters, which would not be observable in a decoupled spectrum (Figure 2). For example, differential line broadening of the doublet components reflects the cross-correlated relaxation (CCR) between dipole–dipole (with the amide proton and amide nitrogen as the dipolar-coupled spin system) and Curie relaxation of the paramagnetic center [10–12]. In addition, the coupling constant displayed by the doublet contains the residual dipolar coupling (RDC) which arises from the partial alignment of the paramagnetic molecule with the magnetic field [13,14]. Finally, the overall broadening of the doublet components reflects the paramagnetic relaxation enhancement (PRE) by the paramagnetic center. The PRE effect is a function of the distance from the Dy^{3+} ion [15,16]. In practice, cross peaks from amide protons closer than 14 Å from the metal ion were broadened beyond detection.

PCS, RDC, CCR, and PRE effects [17] present four paramagnetic parameters arising from different structural information (Figure 3). Of these four effects, PCS data of protons are most easily measured with high accuracy. Their dependence on the anisotropy of the magnetic

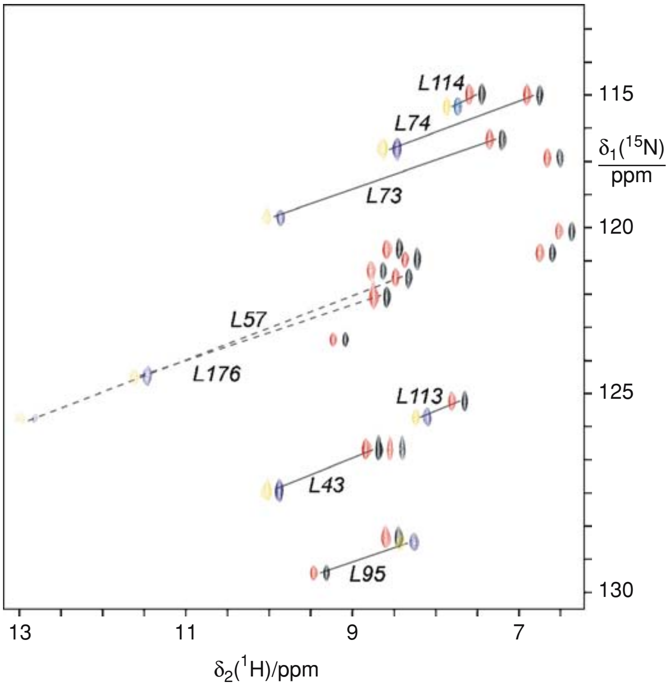

Fig. 1. ^{15}N-HSQC spectra of ^{15}N-Leu labeled ε186 complexed to unlabeled θ. Two spectra are superimposed, one recorded with paramagnetic Dy^{3+} and the other with diamagnetic La^{3+} complexed to ε186. No decoupling was applied during the acquisition time. The cross peaks appear as antiphase doublets split by the one-bond ^{1}H–^{15}N coupling constant. Positive and negative contours are plotted, respectively, with blue and yellow lines for the spectrum of the paramagnetic complex and black and red lines for the spectrum of the diamagnetic complex. Straight lines connect pairs of diamagnetic and paramagnetic cross peaks. Dashed lines identify the two most strongly shifted paramagnetic cross peaks for which the diamagnetic partners could not be identified by simple visual inspection. The spectra were recorded with 0.5 mM solutions of the complex at 25°C and pH 7.0, using total recording times of 5 and 16 h for the diamagnetic and paramagnetic samples, respectively, on a Varian Inova 600 MHz NMR spectrometer. susceptibility tensor also provides stringent geometric restraints that are relatively insensitive with respect to local structural variations. In contrast, in our experience PRE effects yield the least accurate data, partly because line widths can vary between samples due to aggregation effects and chemical exchange phenomena [5]. The values of all four paramagnetic effects can be predicted provided that the three-dimensional structure of the protein, the position of the metal ion, and the susceptibility anisotropy tensor are known (Figure 4) [17].

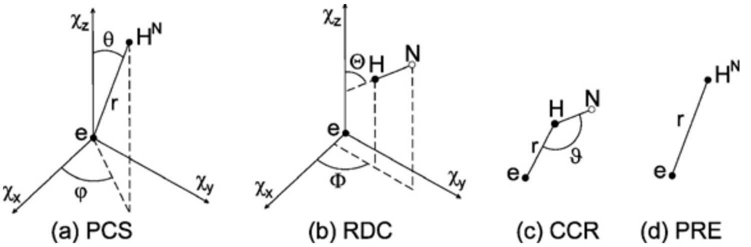
PLATYPUS Algorithm for Resonance Assignments from Paramagnetic Restraints

In our assignment strategy, the resonance assignment is obtained from a comparison of the experimentally measured paramagnetic data with the data predicted from the three-dimensional structure of the protein. An exhaustive evaluation of all $n!$ possible assignments, however, is not viable when the number of cross peaks, n, is large. Consequently, a novel algorithm named PLATYPUS (paramagnetic labeling for assignment with terrific yields of proteins using their structures) was developed to derive the resonance assignments from the paramagnetic data automatically (Figure 5). Since the parameters defining the susceptibility anisotropy tensor are not known a priori, the algorithm employs a grid search with a large number of different tensors. A target function, defined as the sum of the squared deviations between experimentally measured and back-calculated paramagnetic data, is minimized to determine the best-fitting resonance assignment. Starting from each grid point, PLATYPUS uses the "Hungarian method for minimal cost assignment" [18] to arrive at resonance assignments that are continuously updated, while the tensor parameters and rotational correlation time are optimized by gradient minimization of the target function (Figure 5).

In principle, the grid search over different possible susceptibility anisotropy tensors is five-dimensional, since five parameters are required to define the shape and orientation of the tensor. In practice, the algorithm



(a) PCS (b) RDC (c) CCR (d) PRE

Fig. 3. Dependence of paramagnetic effects on local geometry. (a) Pseudocontact shifts (PCS) depend on the location of the nuclear spin with respect to the susceptibility anisotropy tensor. They result in chemical shift changes of the NMR signal. (b) Residual dipolar couplings (RDC) depend on the angle formed between the vector connecting the coupled spins and the axes of the alignment tensor resulting from alignment of the paramagnetic protein in the magnetic field. They are manifested in altered multiplet splittings. (c) Cross-correlated relaxation (CCR) between the Curie spin of the paramagnetic protein and the dipole–dipole interaction between two nuclear spins depends on the angle between the internuclear vector and the vector between the nuclear and electronic spins. This relaxation mechanism results in different line widths of the two doublet components. (d) Paramagnetic relaxation enhancements (PRE) depend on the distance from the paramagnetic center. The relaxation enhancement results in equal line broadening of both doublet components.

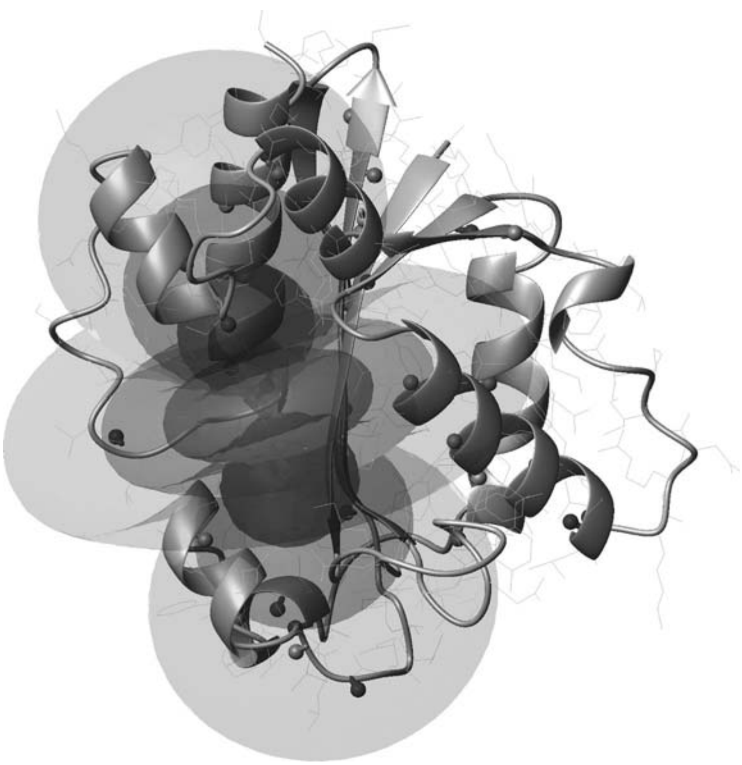


Fig. 4. Iso-surfaces indicating pseudocontact shifts of ±1, ±0.5, and ±0.2 ppm, respectively, superimposed onto the crystal structure of ε186 (drawn in a ribbon representation). Blue and red colors identify positive and negative pseudocontact shifts, respectively. The N–H groups of Leu (blue), Phe (pink), and Val (orange) residues are displayed in a ball-and-stick representation. The figure was plotted with Molmol [39]. Reproduced with permission from Ref. [5]. © 2004 Am. Chem. Soc. (See also Plate 97 on page XIX in the Color Plate Section.)

converges even when starting from any plausible combination of axial and rhombic components of the tensor and using increments as large as 20° between different tensor orientations.

PLATYPUS presents a very fast algorithm because the search space is limited to the optimization of the assignments initially suggested for each of the grid points. Its efficiency allows the extension of the search to test in a systematic way all conceivable pairings of diamagnetic and paramagnetic cross peaks, even in cases where the pairings are ambiguous due to cross-peak overlap (Figure 1). For those cross peaks, minimization of the target function yields not only the resonance assignment of the paramagnetic cross peaks but also the identification of their diamagnetic partners.

Results Obtained with Selectively Labeled ε186–θ Complexes

ε186 contains 17 leucine residues. All their ^{15}N-HSQC cross peaks were observable in the diamagnetic ε186–θ complex containing selectively ^{15}N-Leu labeled ε186. In the presence of Dy^{3+}, however, the ^{15}N-HSQC cross peaks of only eight of them could be observed; the other leucine residues were too close to the paramagnetic center and their resonances were broadened beyond detection. Despite the limited number of cross peaks which could be evaluated and ambiguities in pairing some of the paramagnetic cross peaks with diamagnetic partners (Figure 1), PLATYPUS yielded assignments in complete agreement with those determined previously in the conventional manner with triply isotope-labeled protein preparations [8]. This result is particularly remarkable, since the description of the shape and orientation of the susceptibility anisotropy tensor alone requires five independent variables, i.e. information from at least five different ^{15}N–^{1}H cross peaks. The assignment of ^{15}N-HSQC cross peaks broadened beyond detection in the presence of Dy^{3+} can be achieved by the use of a different, less strongly paramagnetic lanthanide ion. In the case of the ε186–θ complex, all 17 leucine residues yielded observable cross peaks in the presence of Ce^{3+}. Paramagnetic effects from Ce^{3+} are limited to the closer vicinity of the metal ion, providing complementary data to those obtained with Dy^{3+} [5].

Besides resonance assignments, PLATYPUS also provides a measure of the reliability of the individual assignments by checking for their resilience against variations of the three-dimensional structure. This is achieved by

Fig. 5. Pictorial representation of progressing assignments in PLATYPUS. Different orientations and shapes of the susceptibility anisotropy tensor are systematically varied in a grid search. The figure illustrates the procedure for the case of pseudocontact shifts only. For each grid point the paramagnetic effects are calculated and the back-calculated paramagnetic data sorted by magnitude (lower lines). Comparison with experimental values, also sorted by magnitude (top lines), generates an assignment (a). The tensor parameters are subsequently optimized by gradient minimization. Recalculation of the predicted paramagnetic effects with the new tensor parameters may require some reassignments to maintain the match of predicted versus experimental data when sorted by magnitude (b and c). The assignment with the lowest residual target function (the sum of the squared differences between experimental and back-calculated data) obtained from any of the starting grid points is presented as the correct assignment (d). The Hungarian method for minimal cost assignment [18] is used to perform the sorting and minimization in the *m*-dimensional space spanned by *m* different paramagnetic parameters.

the deliberate addition of structural noise to the coordinates of the protein structure, including variations in the orientations of chemical bonds and changes in the locations of protein atoms and of the paramagnetic ion, followed by repetition of the assignment procedure. As expected, availability of more than a single selectively ^{15}N-labeled sample improves the reliability of the resonance assignment.

Alternative Methods

Two other protocols have been reported [19,20] which use a similar approach to determine NMR resonance assignments with the help of an available three-dimensional protein structure. These protocols back-calculate residual dipolar couplings and diamagnetic chemical shifts from the structure and use combinatorial optimization algorithms for the assignment. However, they require doubly ^{15}N/^{13}C-labeled samples and the time-consuming measurement of two or three residual dipolar couplings per amino acid residue.

Paramagnetic data are much easier to evaluate from straightforward ^{15}N-HSQC spectra. Furthermore, PCSs are less sensitive than residual dipolar couplings to small differences between protein structures in solution and in single crystals. Finally, PLATYPUS yields the magnetic susceptibility anisotropy tensor simultaneously with the resonance assignment (Figure 4). With Dy^{3+}, sizable PCSs can be observed for distances up to 40 Å from the metal ion [21]. This opens unique opportunities for the study of intermolecular complexes with ligands.

Outlook

The assignment strategy outlined here provides access to resonance assignments with unprecedented speed. For comparison, 56 days of NMR spectrometer time were used to assign the resonances of ε186 in complex with θ[7,8]. Although our strategy provides resonance assignments of only a few ^{15}N-HSQC cross peaks for each selectively labeled sample, complete resonance assignments of all cross peaks observable for a uniformly ^{15}N-labeled protein are often not necessary in pharmaceutical applications.

The main drawback of the method is the requirement of a lanthanide-binding site. Most proteins are diamagnetic and do not possess a specific lanthanide-binding site. In principle, lanthanide-complexing reagents have been reported which can be covalently attached to side-chain amine, carboxylate, or sulfhydryl groups on the protein surface [22,23]. The most generally applicable technique for site-specific attachment of a lanthanide-complexing reagent may be via formation of a disulfide bond with a single Cys residue on the protein surface. A suitable reagent needs to have a short linker [24] to avoid poorly defined positioning of the lanthanide ion with respect to the protein surface [25,26]. Furthermore, formation of different diastereomeric complexes must be suppressed which would otherwise increase the number of NMR signals [27–29]. Corresponding reagents are not yet commercially available.

It has been demonstrated that fusion proteins can be designed with lanthanide-binding peptide motifs

[30–34]. Lanthanide-binding peptide motifs avoid the generation of different diastereomers, but restrict the choice of attachment sites to the terminal ends of the protein. Furthermore, many of the paramagnetic effects are reduced when the linker to the lanthanide-binding peptide is flexible.

A paramagnetic tag attached to a selected site on the protein surface offers a powerful tool for the detection and structural characterization of ligand binding. The attachment of TEMPO spin labels has been shown to enhance the sensitivity of NMR methods for the screening of compound libraries by several orders of magnitude [35]. TEMPO spin labels have also been shown to provide long-range structural information in large biomolecules as well as access to the study of transient interactions in partially or completely unfolded proteins. The relaxation enhancement effect of TEMPO spin labels is, however, governed by a $1/r^6$ distance dependence, whereas PCSs induced by lanthanide ions follow a $1/r^3$ distance law, resulting in effects observable over longer distances. Furthermore, the isotropic nature of the magnetic susceptibility tensor in TEMPO prohibits the observation of the PCS, CCR, and RDC effects that contain the most valuable structural information (Figure 3). Therefore, more information can be obtained from site-specifically attached lanthanides. In addition, lanthanide ions could not only detect the presence of ligand binding, but also provide a detailed picture of the relative orientation of the ligand with respect to the magnetic susceptibility anisotropy tensor and hence, with respect to the protein. This information could be obtained with a minimal number of resonance assignments of the protein.

The present version of PLATYPUS was designed for the assignment of selectively ^{15}N-labeled proteins. For some proteins, cell-free protein expression systems offer a cost-effecitve and fast route to protein samples with selectively labeled amino acids [36–38]. Selective labeling of proteins becomes expensive when the proteins cannot be expressed in high yields. For those situations, a modified strategy would be desirable, which provides reliable cross-peak assignments for uniformly ^{15}N-labeled proteins. Work towards this goal is in progress.

Acknowledgments

Complete resonance assignments of ε186 or ε186 in complex with θ were not available at the time we published the ^{15}N-HSQC assignments of Leu, Val, and Phe labeled ε186 in complex with θ. We thank Drs. Eugene F. DeRose and Robert E. London for making their resonance assignments available to us afterwards to confirm the correctness of the assignments. G.P. thanks the EU for a postdoctoral fellowship within the Research Training Network on Cross Correlation (HPRN-CT-2000-00092). G.O. thanks the Australian Research Council for a Federation Fellowship. Financial support by the Australian Research Council is gratefully acknowledged.

Introduction

The design of drugs that modulate membrane bound receptors has always been of prime importance to the pharmaceutical industry. It is increasingly being recognized that the cellular membrane plays an important role in drug action and that understanding the manner in which drug molecules interact with lipid bilayers can enhance our abilities to design and develop improved medications. It has been proposed that lipophilic drugs reach their sites of action through cell membrane penetration and lateral diffusion within the membrane leaflet [1–4]. The protein supporting lipid membranes may be capable of a high degree of structural discrimination by positioning the ligand in a proper location, orientation, and active conformation for a productive interaction with the receptor. Therefore, acquiring detailed knowledge of drug and ligand physical properties that underlie their interaction profiles with the cellular membrane is of great interest in the discovery, design, and delivery of novel therapeutic agents. Information related to drug–membrane interactions, however, can rarely be derived directly from experiments with complex and labile natural membranes. Thus, various membrane models with different levels of complexity have been developed in order to exploit all the biophysical techniques available [5–7]. Whether it is in the form of liposomes, micelles, or other membrane mimetics, the interplay between the ligand and membranes is central to many aspects in pharmaceutical research.

Liposomes (in most cases, multilamellar vesicles) have been extensively utilized to study the manner in which drug molecules perturb cellular membranes as well as the location, conformation, and preferred orientation of a drug molecule within the membrane bilayer using differential scanning calorimetry (DSC), nuclear magnetic resonance (NMR) spectroscopy, and small angle X-ray diffraction [3,8–15]. Among these techniques, NMR spectroscopy holds a prominent place by being particularly sensitive to the fine structural and dynamic details of drug molecules within the bilayer system. However, liposomes are not suitable model membrane systems for exploring the conformational properties of embedded ligands since even the smallest lipid vesicles are too large to yield a quality high-resolution NMR spectrum [16]. Alternatively, fast tumbling micelles consisting of various detergents have been widely used to mimic the membrane environment in high-resolution NMR conformational analysis [5,17–19], even though it has long been a concern that micelles may not accurately represent cellular membrane bilayers [20,21]. Recently, phospholipid bilayered-micelles (often referred to as bicelles) have received much attention as promising membrane-mimetic systems [22–27]. Work in our laboratory has demonstrated that bicelle systems can serve as excellent bilayer membrane models for studying drug–membrane interactions using high-resolution NMR. We have developed an isotropic bicelle system for studying the conformational properties of small- and medium-sized ligands without the need of isotopic labeling [21]. We also used magnetically oriented bicelles to determine the preferred orientations of several lipophilic drugs from deuterium NMR experiments [28].

In this chapter, we briefly review the commonly used model membrane systems for studying drug–membrane interactions using NMR with an emphasis on phospholipid bicelles. To highlight the advantages of using bicelle systems for such work, we have sought to determine the conformational properties as well as the preferred orientation of two lipophilic ligands in different membrane-mimetic systems. A comparison of the ligand spectra in

Graham A. Webb (ed.), Modern Magnetic Resonance, 1271–1277.

the different media clearly demonstrates the value of phospholipid bicelles in such studies.

Membrane Systems for NMR Studies

Cell membranes consist of a variety of glycerolphospholipids, sphingolipids, and cholesterol with local heterogeneities and segregated microdomains. Although much work has been dedicated to understand their structural and dynamic properties, many questions still remain unanswered [29]. Opportunities for studying the drug–membrane interactions with native membranes are presently confined to the use of solid-state NMR methods. Only few published examples can be found of the interactions between small- or medium-sized molecules with native membranes where the ligand is isotopically labeled in specific positions for effective NMR observation [30,31]. Simplified model membranes composed of certain synthetic or native lipids have become the most commonly used systems for such work.

It can be argued that notwithstanding their great functional diversity, membranes share the common features of an anisotropic bilayer system consisting of a hydrophobic interior and a hydrophilic headgroup region. This fundamental structure defines many of the key structural and functional properties of biological membranes. For this reason, it is possible to use simplified lipid systems as legitimate mimics of the cellular membrane.

Liposomes

Liposomes are the most used and best-characterized model membrane system. They can be produced in a variety of sizes and lipid compositions including multilamellar vesicles and small or large unilamellar vesicles [32,33]. Liposomes are generally prepared from glycerolphospholipids, mainly phosphatidycholines such as DPPC, DMPC, and POPC, while cholesterol and charged lipids can also be added. Because multilamellar vesicles are relatively easy to prepare and multilayering makes it possible to incorporate larger amounts of drug, they have been extensively employed for studying drug–membrane interactions using various solid-state NMR techniques, such as stationary ^{2}H, ^{31}P, and ^{13}C NMR as well as the cross polarization magic angle spinning (CP/MAS) experiments [11,34,35]. Liposomes in the L_α liquid crystalline phase have been used to determine the preferred orientations of native and xenobiotic molecules and the effects of these ligands on the membrane system [8,9,11,12,14,36–39]. Liposomes are usually not suitable for studying the conformation of a ligand using solution NMR because of the relatively slow tumbling rates resulting from their large size. For such applications, other model membrane systems consisting of much smaller aggregates must be used.

Organic Solvent Mixtures

The simplest membrane-mimetic environment resembling the membrane interior and interfacial regions can be obtained by carefully mixing two organic solvents of low and intermediate polarity [40]. However, such systems are overly simplified membrane models and are of limited value.

Micelles

The most commonly used spherical micelle preparations can be obtained from SDS, DPC, or DHPC. Because of effective motional averaging, the small and uniformly sized micelles can yield satisfactory high-resolution NMR spectra of an enclosed ligand. Micelles have been extensively utilized as membrane-mimetic media for studying the conformational properties of small molecules and peptides [18,19]. However, as micelles do not consist of natural cell membrane lipids and have a highly curved surface, their value as a reliable model membrane system is somewhat reduced [21,26].

Phospholipid Bicelles

An optimal membrane-mimetic system for solution NMR experiments should consist of a relatively smaller lipid aggregate with a bilayer structure. With a short correlation time, such a membrane preparation enables more detailed structural studies of drugs in a bilayer environment. In order to form such a lipid aggregate, the mean chemical potential μ_N^0 must initially decrease and reach its minimum at a certain aggregation number N. If there were no free energy contributions, such small lipid aggregates would be entropically favored. However, because of the large cohesive binding energies of lipid molecules, discrete planar bilayer systems have never been observed when only one type of lipids is present. For a hypothetical planar bilayer disc, the free energy for molecules sequestered along the rim is expected to be much higher than that of molecules in the planar center. The mean free energy per molecule in such a planar bilayer disc is [41]:

$$\mu_N^0 = \mu_\infty^0 + \alpha kT/N^{1/2}$$

where μ_∞^0 is the mean free energy in an aggregate of infinite size, k is the Boltzmann constant and T is the temperature. As μ_N^0 decreases monotonically with N, the expectation is that an infinite number of lipid molecules will aggregate spontaneously at critical micelle concentrations while single component lipid bilayers with exposed edges are not favored.

However, discrete planar bilayer disc assemblies can be obtained if detergents are added to stabilize the energetically unfavorable edges [23,26]. Such systems,

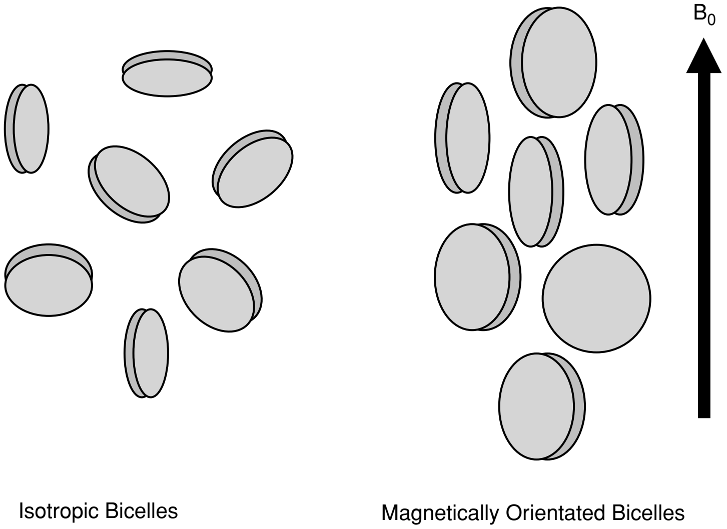

Fig. 1. Isotropic (left) and magnetically oriented bicelles (right).

commonly referred to as phospholipid bicelles, are typically composed of DMPC with either DHPC or a bile-salt derivative CHAPSO in 0.1 M KCl solution [26]. Above the phase transition temperature (T_m), the DMPC-rich domain resembles the liquid crystalline L_α phase multilamellar membrane bilayers [22,42]. Phospholipid bicelles combine the attractive structural and dynamic properties of both micelles and lipid vesicles and maintain most of the key bilayer properties that are absent in the micellar systems. Additionally, compared to the liposome preparations, bicelles are relatively small, noncompartmentalized, effectively monodisperse and ideally suited for high-resolution NMR studies.

Phospholipid bicelles (Figure 1) are a versatile model membrane system whose morphology and dynamic properties can be adjusted over wide ranges of lipid to detergent ratio (q), total lipid concentration, buffer pH, and temperature [26]. With appropriate manipulation, bicelles can provide isotropic membrane systems suitable for studying the conformational properties of embedded ligands using high-resolution NMR [21,43]. Alternatively, bicelles can serve as anisotropic membrane preparations capable of orienting in an applied magnetic field [23,25].

Optimizing Isotropic Bicelles for Drug Conformational Studies

At a DMPC to DHPC molar ratio (q) of 0.5 and an overall lipid concentration of 15% (w/v), the bicelle system has been shown to be at the isotropic state and the bicelles are small enough for high-resolution experiments NMR [43]. This is promising in that without isotopic labeling, such a preparation can be used to explore the conformational properties of incorporated drugs. However, such bicelles may not serve as an ideal membrane environment for studying our lipophilic drugs. As the diameter of the bicelle is estimated to be approximately 80 Å [44], the embedded drugs may have much higher chances of interacting with the stabilizing detergents rather than with the lipids. In addition, small bicelles are incapable of incorporating adequate quantities of lipophilic drugs and precipitation has been frequently observed in our research.

For these reasons, we have sought to develop larger isotropic bicelles that would better represent cellular membrane bilayer systems. Our approach to maximizing bicelle size while maintaining isotropic conditions was to systematically adjust the lipid to detergent ratio (q) as well as the overall lipid concentration. Additionally, preparations free of KCl allow us to use higher values of q and the stability of bicelles can be significantly improved by adding trace amount of amphiphiles. We found that a preparation of a much higher DMPC/DHPC ratio ($q = 2.0$) and an overall lipid concentration of 8% (w/v) is optimal for not only allowing effective drug incorporation, but also providing an isotropic system suitable for high-resolution NMR studies. In such a preparation, no precipitation of either the drug or lipid was observed over the course of several days. Well-resolved proton resonances reflect the isotropic nature of the optimized bicelle membrane media within the NMR time scale. This can be attributed to the ample spacing between the individual bicelles, which allow for faster motional averaging [25]. Although a certain degree of broadening in the ^{1}H resonances is still observed, the spectral resolution is adequate for standard 2D-NMR experiments such as DQF-COSY

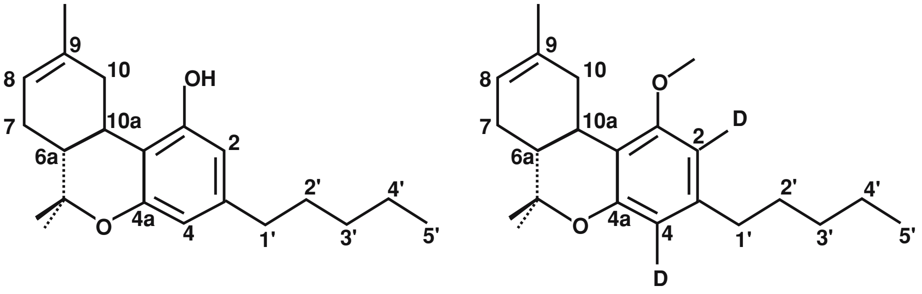

Fig. 2. The structure of Δ^8-THC (left) and Me-Δ^8-THC (right).

and NOESY from which ligand conformational properties can be obtained.

To evaluate the experimental benefits of our isotropic bicelle preparation, we compared the ^{1}H spectra of Δ^8-THC (Figure 2) in chloroform, SDS micelles, and two different isotropic bicelle preparations with $q = 0.5$ and $q = 2.0$, respectively. Figure 3 shows the NOE patterns observed between the aromatic ring protons and protons of the pentyl tail. In chloroform, only two NOEs were observed between the H2, H4 aromatic protons, and the pentyl tail H1′ protons. Additional NOEs were observed between the aromatic H4 resonance and resonances due to protons beyond H1′ of the pentyl sidechain with their relative intensities varying depending on the membrane

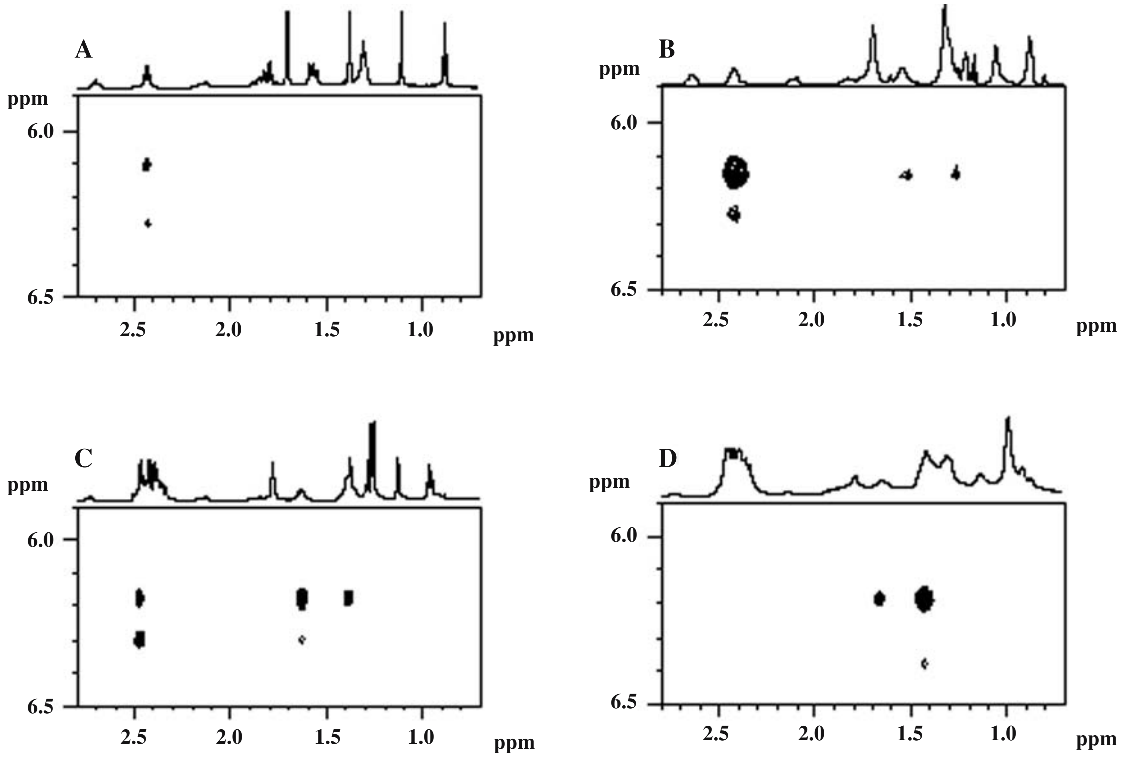

Fig. 3. Expansions of NOESY spectra showing NOEs between the aromatic ring and the pentyl-tail of Δ^8-THC in (A) $CDCl_3$; (B) SDS micelles; (C) $q = 0.5$ bicelle, and (D) $q = 2.0$ bicelle.

preparations used. In SDS micelles, the NOESY spectrum from Δ^8-THC is comparable to that observed in chloroform where strong NOEs were observed between the H2, H4 aromatic protons, and the H1′ protons in the pentyl group. Two weak NOEs were also observed between H4 and H2′, and H3′, H4′ overlapping protons, suggesting a conformational preference for orientation of the pentyl chain towards the H4 side of the tricyclic ring system. In the $q = 0.5$ bicelle solution, the H4–H2′ and H4–H3′/H4′ NOEs are similar in intensity to the H4–H1′, H2–H1′ NOEs; while in the $q = 2.0$ solutions, the former set of NOEs are significantly stronger than the latter. This observation shows that higher proportions of DMPC within the bicelle lead to an increased preference for an "amphipathic" conformation of the pentyl sidechain towards the H4 side of the tricyclic ring system.

The above results indicate that the choice of model membrane systems can greatly influence the structural and dynamic properties of the incorporated drugs. It is also worth noting that in both the SDS micelle and the $q = 0.5$ bicelle preparations, Δ^8-THC was observed to precipitate over 3–6 h whereas it was well solubilized in the $q = 2.0$ bicelle solution. Our results obtained from the $q = 2.0$ bicelle preparation are congruent with previous studies using DPPC multilamellar membrane bilayers [11,14,15], which we attribute to the more bilayer-like morphology of the $q = 2.0$ lipid bicelles compared to the SDS micelle and $q = 0.5$ bicelle solutions. Therefore, the $q = 2.0$ bicelles represent a satisfactory membrane bilayer system suitable for high-resolution NMR conformational studies.

Magnetically Aligned Bicelles for Studying Drug Orientation

The formation of magnetically oriented phospholipid bicelles under various conditions and the corresponding properties of the bicelles have been reviewed [22,45]. By using a series of titration studies, it has been found that the liquid crystalline L_α DMPC/DHPC bicelles with q ranging from 2.0 to 3.5 are well aligned in the applied magnetic field as indicated by their ^{31}P and ^{2}H NMR spectra, while addition of KCl can drastically improve the degree of orientation.

The orientation may be explained by the anisotropy of the diamagnetic susceptibility tensor χ of the lipid molecule. If we assume an axis of rotational symmetry, the diamagnetic anisotropy $\Delta\chi$ will be the difference between the susceptibilities parallel and perpendicular to this axis. For the bicelle forming long acyl chain lipid DMPC in the L_α phase, $\Delta\chi$ was found to be $(-1.0 \pm 0.1) \times 10^8$ erg cm^{-3} G^{-2} [46]. Since the magnetic potential energy ΔU can be expressed by:

$$\Delta U = -N \Delta\chi B_0^2$$

where N is the number of long acyl chain DMPC lipids within one bicelle disc, and B_0 is the external magnetic field, when $\Delta\chi$ is less than zero, the energically favorable orientation of a bicelle aggregate will be with its principal axis perpendicular to the applied magnetic field.

In earlier work, we have described how the preferred orientation of a drug molecule within the membrane bilayer system can be obtained from the quadrupolar splittings ($\Delta\nu_Q$) of ^{2}H-labels introduced in specific sites of the molecule [9,11]. We have, thus, sought to explore whether such data could be obtained in a magnetically oriented bicellar system. Figure 4 compares three deuterium spectra of 2,4-D_2-Me-Δ^8-THC (Figure 2) obtained in DHPC micelles, DPPC multilamellar vesicles, and magnetically oriented DMPC/DHPC bicelle preparations, respectively. The spectrum acquired in a DHPC micelle solution displays a single isotropic deuterium peak, while that from the DPPC multilamellar vesicles corresponds to two pairs of overlapping Pake patterns from which the quadrupolar splittings can be extracted. Conversely, in magnetically oriented bicelles, the spectrum is reduced to two pairs of doublets representing the two and four deuterium atoms in Me-Δ^8-THC. The sharp deuterium resonances indicate that the bicelles are completely aligned in the magnetic field. Due to the fact that the bicelles with the incorporated drug molecules are magnetically oriented with their

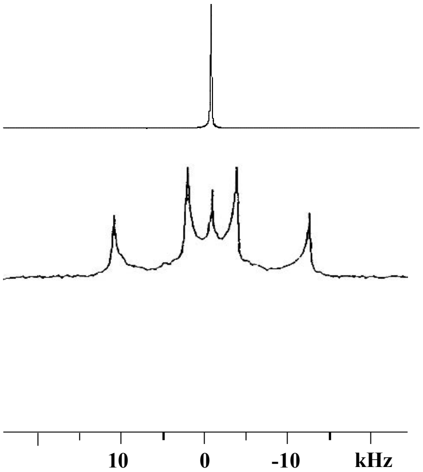

Fig. 4. A comparison of deuterium spectra of 10% 2,4-D_2-Me-Δ^8-THC in DHPC micelles (top), DPPC multilamellar bilayers (middle), and magnetically oriented DMPC/DHPC bicelles (bottom).

bilayer normal perpendicular to the external magnetic field, the observed splittings in the ^{2}H spectrum correspond to the 90° edges of the respective Pake patterns from the semi-solid hydrated DPPC sample. However, the $\Delta\nu_Q$ values are much reduced in the bicelle system, reflecting a lower order parameter (S_{mol}) when compared to that from the multilamellar preparations. The calculated orientation of Me-Δ^8-THC (to be reported elsewhere) closely matches our result from the multilamellar vesicles, thus attesting to the reliability of the bicelle system as a model membrane.

In contrast to micelle preparations where quadrupolar couplings are completely averaged out due to fast isotropic tumbling, magnetically oriented bicelles can serve as an alternative to multilamellar membrane preparations for studying the orientation of a ligand in an anisotropic membrane system. In addition, the experiment described above was carried out under solution NMR conditions and offers the advantages of higher sensitivity and more accurate direct measurement of the $\Delta\nu_Q$ values from the sharp ^{2}H doublets.

Conclusion

Bicelles can serve as satisfactory membrane systems for isotropic and anisotropic NMR experiments aimed at studying the conformational properties and preferred orientation of lipophilic drug molecules in the cell membrane. Using the lipophilic Δ^8-THC as an example, we have demonstrated that high-resolution NOESY spectra of this ligand in optimized isotropic bicelles can be obtained without the need for isotopic labeling. Our results clearly showed that isotropic bicelle systems are better membrane bilayer models than the commonly used micelles. Arguably, the specific "amphipathic" conformation of Δ^8-THC obtained in the optimized bicelles may be necessary for a productive interaction with its receptor. We also demonstrated that the preferred orientation of the embedded cannabinoids can be determined by adjusting bicelle conditions to produce larger bicelle aggregates capable of aligning in the magnetic field.

Phospholipid bicelles offer many opportunities for use as successful membrane mimetics. The preparation may be further improved by using lipids with certain negative charges and some degree of unsaturation, and by incorporating appropriate amounts of cholesterol to more closely resemble native cell membranes. A most recent application of bicelles is for determining the relative stereochemistry of multiple stereocenters [47]. Also, crystallization of membrane proteins has been achieved from bicelle-forming lipid/detergent mixtures [48], an experiment which may be extended to study the drug/membrane–protein complex.

Partial Alignment for Structure Determination of Organic Molecules

Burkhard Luy and Horst Kessler
TU München, Department Chemie, Lehrstuhl für Organische Chemie II, Lichtenbergstrasse 4, D-85747 Garching, Germany

Introduction

NMR spectroscopy is the most important method for structure elucidation in solution. Once the atomic connectivity is established (constitution of the molecule) the proof of stereochemistry is the next step. NMR as an achiral method provides only relative stereochemical information unless chiral environments (solvents, interaction with shift reagents, chemical modification via chiral auxiliaries) are used. For determining the relative stereochemistry, the classical parameters are NOE effects and J coupling constants. Only recently, two different new sources of stereochemical information have been introduced for biomolecules: cross-correlated relaxation [1] and residual dipolar couplings (RDCs) [2,3]. We will here consider the application of RDCs for small molecules such as drugs or drug-like molecules.

Residual Dipolar Couplings

Magnetically active nuclei in molecules interact through space, as they are magnetic dipoles. These couplings, which depend on the relative orientation of the dipoles and their distance, are on the order of several kHz and cause immense numbers of splittings in solid-state NMR. In solution, the rapid isotropic molecular tumbling averages out all dipolar couplings, resulting in the narrow line width of high-resolution NMR spectroscopy. With the removal of all anisotropic interactions, however, there is also a significant loss in potential structural information. Therefore, an intermediate state between solid and liquid is desirable in which the narrow line width is maintained, but anisotropic interactions are re-established and measurable. In general, there are two ways to reach this intermediate state: if the sample of interest is available in a microcrystalline phase, high-speed magic angle spinning can effectively reduce the dipolar interactions to give resolved resonances similar to the liquid state; in contrast, a sample in solution can be transferred into a directional molecular lattice, which then partially aligns the molecule to have measurable anisotropic interactions. For example, if the molecules are oriented to a low percentage, let us say on the order of 0.1%, the dipolar coupling is also reduced to ~0.1% of its original size. A molecule containing a CH fragment, which would normally exhibit a $^1J_{\mathrm{CH}}$ coupling of about 130 Hz in isotropic solution will give rise to an additional RDC that adds or subtracts to this coupling depending on the tiny preferred orientation. If one measures the $^1J_{\mathrm{CH}}$ coupling constant with and without partial orientation, the difference directly yields the RDC.

The Alignment Tensor

In the following section, a very brief and handwavy introduction to the alignment tensors is given and includes only basic equations. For a more detailed and exact derivation of key equations, we refer to [4].

In the static case, the dipolar coupling constant is given by [5]

$$D = \frac{\kappa}{R^3}\left(\cos^2\theta - \frac{1}{3}\right), \tag{1}$$

where θ is the angle between an internuclear vector and the magnetic field B_0. The term

$$\kappa = -\frac{3}{8\pi^2}\gamma_I\gamma_S\mu_0\hbar \tag{2}$$

only depends on physical constants [5]: the gyromagnetic ratios γ_{I} and γ_{S} of the two vector-spanning spins I and S, respectively, the Planck constant $\hbar = h/2\pi$ and the permeability of vacuum μ_0. For example, for ^{1}H–^{1}H and ^{13}C–^{1}H spin pairs, $\kappa = -360.3$ and -90.6 kHz Å^3, respectively. However, in the case of a tumbling molecule, the dipolar coupling is further averaged in the way that

$$\bar{D} = \frac{\kappa}{R^3}\left(\overline{\cos^2\theta} - \frac{1}{3}\right) \tag{3}$$

represents the so-called RDC constant between the two spins, which depends on the average alignment of the molecule.

In the case of isotropic tumbling as in conventional liquid-state NMR, $\overline{\cos^2\theta} = 1/3$ in all three dimensions

Graham A. Webb (ed.), Modern Magnetic Resonance, 1279–1285.
© 2008 *Springer.*

and the dipolar interaction is quenched. In a partially oriented molecule instead, the term $\overline{\cos^2\theta}$ generally is a three-dimensional tensor. This tensor is equivalent to the probability tensor **P** to find the axis of the magnetic field $B_0(t)$ along the internuclear vector **r** expressed in a reference frame, which is fixed to the molecule. This (3×3) probability tensor is symmetric with respect to the diagonal and the diagonal elements must fulfill the condition $P_{xx} + P_{yy} + P_{zz} = 1$, which implicitly leads to five independent tensor components. In reverse, this implies that in an arbitrary case a minimum of five non-identical RDCs have to be measured to unambiguously identify a probability tensor of a given sample.

Although the concept of the probability tensor **P** is very intuitive and sufficient to completely describe RDCs in rigid molecules, it is more common in the NMR literature to express the partial orientation of a molecule by the so-called alignment tensor **A**. This tensor is related to the probability tensor **P** via

$$\mathbf{A} = \mathbf{P} - \frac{1}{3}\mathbf{1} \tag{4}$$

and is therefore proportional to the anisotropy of the magnetic field distribution in the molecular frame. The eigenvalues of **A** are usually denoted as A_{xx}, A_{yy}, and A_{zz} and fulfill the condition $A_{xx} + A_{yy} + A_{zz} = 0$. For further definitions like the axial and rhombic components of an alignment tensor of the Saupe matrix, we refer to the appendix of [4].

Alignment Media

So far, we have not discussed how to partially orient the molecules. When a molecule has considerable magnetic susceptibility anisotropy, the molecule orients partially under the strong magnetic field. But this effect—although already observed in the eighties [6]—is normally too small to be observed. On the other hand, orientation can also be induced by an oriented molecular lattice, which then partially aligns the molecule of interest via steric or electrostatic interactions. All known alignment media can basically be assigned to one of two classes: liquid crystalline phases and stretched polymer gels.

Liquid Crystalline Phases

In 1963, the first spectrum of benzene partially oriented in the nematic mesophase of 4,4′-di-*n*-hexyloxyazoxybenzene was reported, a spectrum with at least 30 resonances and a width of the multiplet pattern of approximately 2500 Hz [7]. Following this result, a large number of liquid crystals for partially aligning small molecules was found in the sixties and seventies (see, for example, reviews [8–10]), but it turned out that the orientation introduced by liquid crystalline phases generally is very strong, yielding numerous large splittings by RDCs that can hardly be interpreted for more complex organic molecules. Poly-γ-benzyl-L-glutamate, dissolved in solvents like dichloromethane, chloroform, or dimethylformamide, was introduced by Panar and Phillips [11]. It was one of the least orienting liquid crystals known at that time and was used for the first successful measurements of RDCs in an organic solvent to obtain structural information of a small molecule [12–14]. Currently, new liquid crystalline phases for organic solvents have been developed that can achieve lower degrees of anisotropies. 4-*n*-Pentyl-4′-cyanobiphenyl [15] and poly-γ-ethyl-L-glutamate [16] seem to be two promising candidates for the measurement of RDCs in small molecules. The existence of liquid crystalline phases with very low induced anisotropies was proven in the last 7 years in the field of biomolecular NMR. Several lipid/detergent mixtures [2,3], filamentous phage [17], and other liquid crystalline phases [18,19] were used to successfully measure RDCs for structure refinement of proteins and nucleic acids. These alignment media are, of course, also applicable to small molecules in aqueous solutions [20–26].

Stretched Polymer Gels

Deloche and Samulski showed in their pioneering work in 1981 that partial alignment can also be achieved by stretching polymer gels [27], usually mechanically. This technique now is a standard approach in polymer NMR to obtain information about polymer properties. Not until 2000 was the use of these stretched polymer gels for aligning molecules dissolved inside the gel to obtain RDCs for structural investigations realized. The new approach is called “strain-induced alignment in a gel” and is demonstrated on stretched polyacrylamide [28–31] and polyacrylamide/acrylate [32] copolymers. Several ways of aligning by using a shigemi plunger [28], teflon funnels [33], or glass capillaries [32] have been developed and successfully applied to proteins as well as small molecules.

Recently, we were able to show that stretched polymers can also be used to partially align small molecules in organic solvents [34]. Cross-linked polystyrene (PS) sticks were simply swollen in NMR tubes, where they are automatically stretched by the boundaries of the glass walls (cf. Figure 1). In the meantime, the approach was successfully applied to a number of other cross-linked polymers like polymethylmethacrylate (with no polymer signals in the aromatic region, unpublished results) and polydimethylsiloxane (with strongly improved spectral quality [35]). Very recently, the gap of alignment media for polar

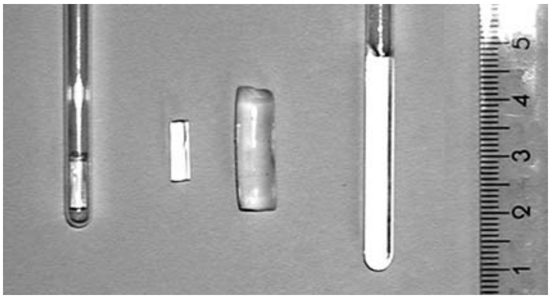

Fig. 1. Photographs of a cross-linked PS stick designed for partial alignment in different states of swelling. From left to right: unswollen polymer stick in standard 5-mm NMR tube, polymer stick directly after polymerization, free polymer stick completely swollen, and polymer stick swollen in the NMR tube.

solvents was closed by stretched gels that swell in DMSO [36,37] and other solvents like methanol, acetonitrile, or acetone [36]. The main advantage of stretched polymer gels compared to liquid crystalline phases is that no lower limit of alignment is imposed because an unstretched gel principally does not show any alignment. The induced anisotropy is generally field independent, but as in liquid crystals, a significant temperature dependence is observed (35,72). Despite the microheterogeneity of the gels, line widths below 1 Hz can be achieved. Very importantly, the strength of alignment can be adjusted in many ways, like changing the diameter of the polymer sticks, the amount of cross-linking agent, or the polymerization conditions [34–36]. Of course, swelling properties and thus the strength of alignment are different in different solvents. It is also interesting to note that the orientation and overall form of the alignment tensor not only depends on the polymer chosen but also on the solvent used [36, 72].

RDC Measurement

NMR experiments on partially aligned samples are special with respect to some details in the setup. The lock, for example, is usually split by the quadrupolar coupling of the deuterium nuclei. As a consequence, the spectrometer might lock on one or the other half of the doublet and built-in spectrometer frequency references that are based on the defined lock signal typically lead to wrongly referenced chemical shifts. Also, shimming is affected: since the lock signal is split, it cannot be used for shimming purposes. Instead, it is necessary to shim on the integral of the FID. Having learned how to deal with these specialties, the acquisition of NMR experiments is straightforward. Some general considerations concerning the practicability of measuring certain RDCs should, however, be taken into account. We therefore have a quick look at the relative size of different types of RDCs before we give an overview of a number of available experiments.

Relative Size of RDCs

Equations (1) and (2) contain all the information necessary to estimate the relative size of different types of RDCs. The dipolar coupling is proportional to the gyromagnetic ratios γ_I and γ_S and to the inverse cube of the internuclear distance r of an arbitrary pair of spins. Since the RDCs also depend on the angle θ, their size generally cannot be predicted without knowing the alignment tensor. Nevertheless, the maximum possible RDC values can be estimated and we will concentrate on these maximum values in the following text. In Figure 2, the relative size of maximum ^{1}H-X-RDCs is shown for different nuclei with respect to the internuclear distance r. It turns out that typical D_{HH} RDCs over two or three bonds and one bond D_{CH} RDCs show the strongest couplings, while long-range D_{CH} or direct D_{CC} RDCs (one-fourth of the D_{CH} couplings for a given distance r) are one order of magnitude smaller in size. Because of potential line broadening and to avoid strong coupling or second order effects in NMR spectra, the largest occurring RDCs should be ideally limited to be $\leq\sim 30$ Hz by adjusting the alignment medium. In this range, one bond D_{CH} and D_{HH} couplings can be accurately measured and provide valuable structural information. All other RDCs to carbon nuclei, however, are very small in size and require highly accurate techniques to obtain structural information. Therefore, the goal must be to measure as many strong RDCs as possible and only in cases where the easily obtained information is not sufficient, more advanced techniques should be used to measure the weaker RDCs, which generally have a larger relative error. In addition to proton and carbon bound RDCs, one bond D_{NH} couplings should provide useful structural information with RDCs of intermediate size. Whenever present, D_{HF} and D_{FF} RDCs behave very similar to D_{HH} RDCs. Although having a high gyromagnetic ratio and 100% natural abundance, RDCs involving ^{31}P nuclei are usually small because of the large internuclear distance to the next NMR-active nucleus.

Experimental Methods

After having the assignment, RDCs are in principle measurable in 1D experiments. Proton-coupled ^{13}C spectra provide useful information in this regard. In fact, if the alignment is so strong that RDCs are on the order of $^1J_{CH}$ coupling constants, one-dimensional experiments provide the only viable way to measure RDCs [12]. However, if the largest RDCs are in the desired range of ±30 Hz

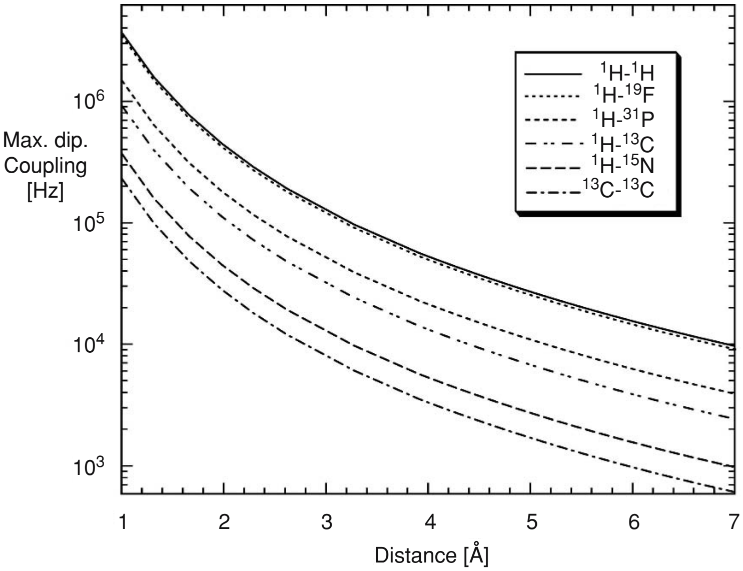

Fig. 2. Relative size of maximum dipolar couplings for protons for various NMR-active nuclei with respect to the internuclear distance *r* [see Equations (1) and (2)]. ^{13}C–^{13}C dipolar couplings are one-fourth of the ^{1}H–^{13}C dipolar couplings.

more advanced NMR experiments with high sensitivity and better resolution can be applied. The most easily measurable RDCs are one bond D_{CH} couplings, which can be measured using standard coupled HSQC or HMQC experiments [12–14,25,26,31,34–36] (cf. Figure 3, for example, spectra of strychnine in PS/CDCl$_3$ gel). Because of the variation in ($^1J_{\mathrm{CH}} + D_{\mathrm{CH}}$)-effective couplings, a procedure in which every multiplet component is phased separately should be applied to get reliable coupling constants [25].

If the resolution of standard HSQC/HMQC experiments is not sufficient, a large number of specialized techniques developed in the field of biomolecular NMR spectroscopy are available to accurately measure one bond D_{CH} and D_{NH} couplings. Spin-state selective excitation [38,39] and coherence transfer [40], IPAP [41],

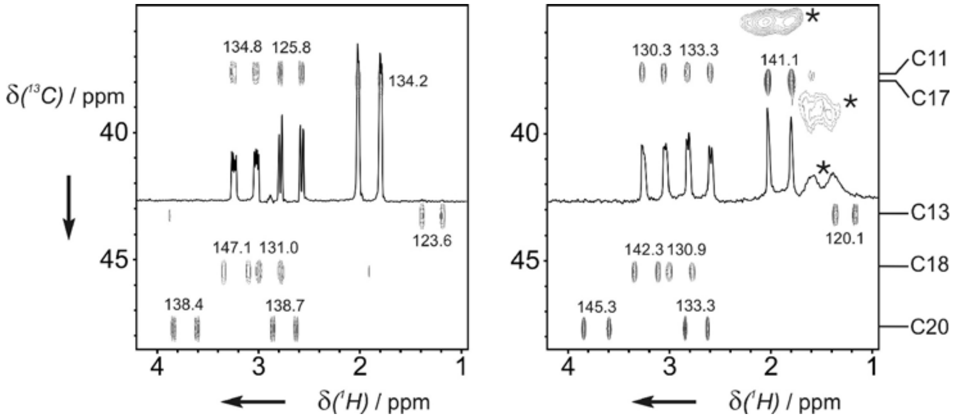

Fig. 3. Region of the ^{1}H,^{13}C-correlation spectra (HSQC) acquired on ~50 mg strychnine in CDCl$_3$ (left) and in a PS gel swollen in CDCl$_3$ (right) at 300 K. $^1J_{\mathrm{HC}}$ and $^1J_{\mathrm{HC}} + D_{\mathrm{HC}}$ couplings, respectively, are given next to the corresponding cross peaks. As can be seen from the 1D slice at 37.8 ppm D_{CH} RDCs are easily measured. The broad signals of the PS polymer are indicated with an asterisk (*).

J modulation [42], JE-TROSY [43], and quantitative J [44] experiments are some useful examples. For methylene groups, the so-called SPITZE-HSQC provides a separation of multiplet components in four spectra that allow RDC determination in more crowded regions [45]. It should also be mentioned that in almost all experiments, the use of BIRD filtering techniques can further improve spectra by selectively decoupling long-range C–H couplings [46–48]. The experiments designed for measuring D_{CH} RDCs should also be easily adaptable to the D_{NH} case. Due to the fast averaging D_{CH} RDCs of methyl groups cannot be used directly as structural information. However, they can be converted to D_{CC} RDCs to the attached carbon via the formula $D_{CC} = D_{CH_3}(-3\gamma_C/\gamma_H)(r^3_{CH}/r^3_{CC})$ [13].

The measurement of D_{HH} couplings is more difficult: in simple cases $(J + D)$ splittings can be measured directly in a one-dimensional experiment. However, since the sign of the splitting is not known and J and D are of comparable size, two possible RDC values must be considered (e.g. $J = 5$ Hz, $|J + D| = 7$ Hz leads to either $D = 2$ or -12 Hz). A sign-sensitive measurement of coupling constants is therefore highly desirable, which can be achieved in principle by E-COSY [49–51] and S^{3}E-E-COSY [39,52] methods. Unfortunately, the applicability of at least the homonuclear E-COSY methods might be strongly reduced because of the broadened lines of partially aligned samples. A more sophisticated homonuclear approach to accurately measure RDCs is the SIAM-TOCSY [53,54], which uses in-phase and anti-phase components in TOCSY-type experiments in combination with the Keeler–Titman fitting procedure [55]. Integration-based techniques like the CT-COSY [56,57] or even the integration of conventional COSY cross peaks [58] offer an alternative for measuring the size of RDCs. The sign of couplings might then be determined with additional pulse sequences that use recently developed Hartmann–Hahn like multiple pulse elements [59]. The sign of the dipolar coupling might also be measurable by slightly changing the strength of alignment in the same alignment medium. The difference in measured RDCs should then lead to the sign of the dipolar coupling relative to the scalar coupling.

Long range D_{CH} couplings can basically obtained in two ways: if the carbon atom has a proton attached, S^{3}E-E-COSY type methods [52,60] provide an efficient, sign-sensitive procedure; in the case that the carbon of interest does not have a proton attached, recently developed HMBC-based methods can be applied that use a sophisticated fitting procedure to obtain the size of the coupling [13,61,62].

Methods for measuring D_{CC} couplings at natural abundance are the well-known INADEQUATE [63,64] and ADEQUATE [65,66] experiments, which inherently have very low sensitivity. RDCs to ^{31}P nuclei have been measured in nucleic acids [67,68]. Fluorine with its high gyromagnetic ratio and 100% natural abundance is perfectly suited for RDC measurements. D_{CF} couplings should be measurable the same way as D_{CH} RDCs. In the case when a rather strong J_{HF} coupling is present, specially designed E-COSY and S^{3}E-E-COSY type experiments allow the very sensitive measurement of D_{HF}, D_{HH}, and D_{FF} couplings [69,70].

Applications

The first applications to obtain structural information from RDCs for sugars were reported in 2000 and for medium-sized molecules in organic solvents in 2003. Considering this short time-span, the demonstrated uses of RDCs are quite remarkable.

Maybe the most elegant application of RDCs is found in six-membered chair-like rings, where RDCs can be used directly to distinguish axial and equatorial protons without having the need to derive an alignment tensor [25]. The method uses the fact that all axial C–H vectors are oriented in the same direction and therefore must have virtually identical D_{CH} couplings. The assignment then simply can be achieved by looking at the occurrence of identical RDCs: all protons with very similar D_{CH} RDCs are axial while all others are equatorial (cf. Figure 4).

But even for arbitrary molecules the prochiral assignment of methylene groups can be achieved in most cases without having to rely on NOE connectivities as long as the alignment tensor is known [12,13]. This is especially important for isolated CH$_2$ groups, which have few neighbors for NOE identification.

A major application can also be found in the determination of Z/E configurations [14] and the determination of the relative chirality of stereochemical centers [26,35] even in different parts of a molecule that might be spatially distant. For this technique, structural models of all possible configurations have to be built first. The measured RDCs are then compared with RDCs backcalculated from the different structures. The quality of the fits expressed in

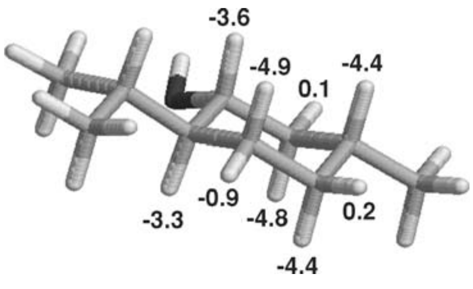

Fig. 4. Measured D_{CH} RDCs for menthol in a PS/CDCl$_3$ gel. Axial and equatiorial protons can easily be distinguished without knowing the alignment tensor.

χ^2 or the correlation factor R^2 leads to the best structural model.

A challenging application is the determination of the sugar pucker with RDCs. Freedberg [24] has shown that the RDCs measured for sucrose cannot be explained by a single conformation. On the other hand, a large number of potential sugar puckers can be ruled out, giving more insight into the population of structures and the dynamic behavior of sugars.

Dynamic regions in molecules are generally difficult to handle and there is no exception in the case of RDCs. RDCs in dynamic regions are averaged over all populated states and might lead to misinterpretations if the populated structures differ significantly. However, the use of several different alignment media should make it possible to unambiguously identify flexible regions in a molecule and together with the improved prediction of alignment tensors [71], the determined RDCs might be fitted to a small ensemble of structures in the future.

A potential application of RDCs as upper distance restraints surprisingly has not yet been reported. RDCs over distances larger than 7Å have been measured. For a given measured RDC, an upper distance restraint can be immediately specified, as long as the axial component of the alignment tensor is known.

Conclusion

The development of partial alignment media over the last years allows for the first time the broad use of anisotropic parameters like RDCs or residual chemical shift anisotropy in high-resolution NMR spectroscopy. Liquid crystalline phases and stretched polymer gels with scalable alignment properties for practically all useful NMR solvents are available. The RDCs of these samples can be measured by simply calculating the difference of couplings measured in isotropic solution and couplings measured in aligned samples. So far mostly solutes in aqueous solutions have been studied. Recently developed alignment techniques in stretched polymer gels will open the measurement of RDCs to structural studies in all NMR relevant solutions. Quite a number of applications with small organic molecules have been demonstrated, including the assignment of axial/equatorial or prochiral methylene protons, and the determination of relative stereochemistry and configuration. The method significantly widens the potential of modern liquid-state NMR spectroscopy and it will be interesting to see new developments in this promising young field.

Measurement of Residual Dipolar Couplings and Applications in Protein NMR

Keyang Ding and Angela M. Gronenborn

Laboratory of Chemical Physics, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD 20892

Abstract

Residual dipolar couplings (RDCs) provide important constraints for the determination and refinement of protein NMR structures. Based on echo–anti-echo manipulation or IPAP principle, a suite of sensitivity enhanced experiments are described for measuring backbone $^1H^N$–^{15}N, ^{15}N–$^{13}C'$, $^1H^N$–$^{13}C'$, $^{13}C'$–$^{13}C^\alpha$, $^{13}C^\alpha$–$^1H^\alpha$, $^{15}N(i)$–$^{13}C^\alpha(i)$, $^1H^N(i)$–$^{13}C^\alpha(i)$, $^{15}N(i)$–$^{13}C^\alpha(i-1)$, and $^1H^N(i)$–$^{13}C^\alpha(i-1)$ dipolar couplings in proteins. The accuracy of the measured couplings can be assessed by comparing the experimentally obtained values with those predicted based on high resolution structures. Even for very small RDCs, such as the $^{15}N(i)$–$^{13}C^\alpha(i-1)$ couplings that are smaller than 0.3 Hz, a correlation coefficient of 0.83 is obtained, attesting to the accuracy of couplings obtained with these sensitivity-enhanced IPAP experiments. We also present a novel application for the use of RDCs. Under certain conditions, the folded state of a protein comprises detectable, conformational sub-states. Such sub-states at local sites, so-called melting hot spots, are characterized by re-orienting bond vectors. Determination of RDCs allows for efficient and easy detection of such hot spots.

Introduction

The importance of being ordered has been highly recognized in the field of protein NMR spectroscopy [1]. When a protein is placed into a magnetic field, it will experience a small degree of alignment. This causes any pair of spins within the protein to exhibit a dipolar interaction in addition to the scalar interaction that is manifested in the J coupling. It was noted earlier [2,3] that these small dipolar couplings are a direct reflection of the protein structure, since they provide a measure of the distance and the orientation of the vector connecting the two nuclei. Most proteins lack sufficient intrinsic magnetic susceptibility anisotropies for practical alignment purposes, however, alignment of any biological macromolecule can be achieved using liquid crystalline media. Generally, there are two major aspects that need to be addressed in the residual dipolar coupling (RDC)-related techniques: selection and optimization of the alignment media to yield measurable dipolar couplings and the development of accurate methods for measuring these small couplings.

Any alignment medium should be inert to the solutes (proteins) under investigation and needs to be stable over reasonably wide pH and temperature ranges. In addition, it should not cause any adverse effects on the NMR line widths, so that the NMR spectra in the alignment media remain at comparable resolution to those in the isotropic aqueous solution. The first alignment medium ever used was a lyotropic liquid crystal consisting of binary mixtures of dihexanoyl phosphatidylcholine and dimyristoyl phosphatidylcholine [3]. At present, a large variety of different alignment media are in use, including suspensions of charged, rod-shaped viruses, such as tobacco mosaic virus and filamentous bacteriophages fd/M13 and Pf1, quasi-ternary systems of surfactant/salt/alcohol or aqueous alkyl-poly(ethylene glycol)/alcohol mixtures, known to form stacked lamellar phases, and vertical or radial strained polyacrylamide gels [4–10]. Such gels are generally believed to be the most inert media for proteins. The degree of alignment can be tuned by adjusting the concentration of the liquid crystalline materials or the degree of strain/compression in case of the polyacrylamide gels. A suitable degree of alignment results in RDC values for $^1D_{NH}$ between 15 and 25 Hz.

The most commonly investigated dipolar couplings for proteins are the five backbone one-bond ^{15}N–$^1H^N$, ^{15}N–$^{13}C'$, $^{13}C'$–$^{13}C^\alpha$, and $^1H^\alpha$–$^{13}C^\alpha$ and two-bond $^1H^N$–$^{13}C'$ RDCs [11]. In addition, one-bond $^{13}C^\alpha$–$^{13}C^\beta$ and $^1H^\beta$–$^{13}C^\beta$, and one-bond ^{13}C–^{13}C and ^1H–^{13}C couplings in methyl groups are also of interest [12,13]. Long-range ^1H–^1H RDCs of protons close in space or connected via multiple bonds may yield important information with respect to quantitative NOE connectivity or local conformation [14].

Accurate measurement of these small dipolar couplings is still a challenge in protein NMR spectroscopy. Generally, all presently available methods for RDC determination can be classified into two major categories.

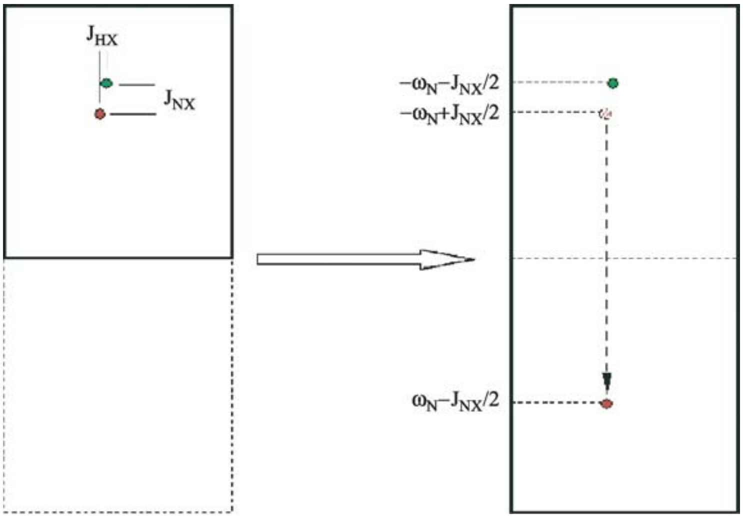
Fig. 1. Schematic representation of the echo–anti-echo manipulation. The upper left box displays the normal area of a 2D ^{15}N–^{1}H^{N} HSQC spectrum. Only one ^{15}N–^{1}H^{N} cross peak is shown, split by the coupling J_{NX} and J_{HX} along the ^{15}N and ^{1}H dimensions, respectively. Using echo–anti-echo manipulation, a spectrum such as shown in the right box is obtained. One peak of the pair remains at its original position, while the other one is flipped around the zero ^{15}N frequency line. In this manner, coupled ^{15}N–^{1}H^{N} cross peaks are separated. The splitting J_{NX} and J_{HX} can be the active coupling J_{NH}, or the passive coupling from a third spin X.



One methodology is called the quantitative J correlation and is based on intensity analysis [15]. Here, the coupling constant is often estimated from two points in the period during which this coupling evolves. If the measurement is based on a series of points, the resulting experiment is equivalent to a three-dimensional (3D) experiment. The accuracy of quantitative J correlation experiments relies critically on the uniqueness of the selected magnetization transfer pathways and the model employed to de-convolute the coupling from all other complex relaxation processes. The second methodology for the determination of dipolar couplings involves measuring the corresponding splitting directly from coupled multidimensional spectra. In these spectra the number of peaks is doubled due to coupling splitting, resulting in a reduction of resolution in these coupled spectra compared to their decoupled counterparts. In some cases, the splitting may actually be too small to be resolved with respect to the digital resolution of the spectra. It therefore is highly desirable to separate the two peaks within a split doublet.

In the following section, we describe techniques for separating the two peaks within a coupled doublet. They result in a suite of sensitivity-enhanced experiments for accurately and efficiently measuring backbone RDCs in proteins [16–20]. In addition, we describe some of the applications with respect to using RDCs to study protein folding and unfolding [21].

Measurement of Backbone Residual Dipolar Couplings in Proteins

Generally, there are two methods to separate the couplings within a split pair of resonances in a coupled spectrum: echo–anti-echo manipulation [16–18] and spin-state-selective technique [22–24]. The echo–anti-echo manipulation is schematically represented in Figure 1. The two peaks within a doublet are manipulated into P-type and N-type peaks [18], respectively. In a series of FIDs, the t_1-modulation alternates between echo and anti-echo for one peak and between anti-echo and echo for the other peak within the doublet. In this way, sensitivity enhancement is achieved naturally and directly. The loss in resolution of such coupled spectra, when compared to the decoupled spectra, can be easily compensated for by setting the spectral width in the ^{15}N dimension to twice the chemical shift range and by implementing TPPI [25,26] to shift the carrier frequency to the edge of the ^{15}N chemical shift range. In special cases, either J_{NX} or J_{HX} may be zero. Based on the echo–anti-echo manipulation, four sensitivity-enhanced experiments [16,17] were devised for measuring one-bond ^{1}H^{N}–^{15}N dipolar couplings and one sensitivity-enhanced experiment [18] for simultaneously measuring one-bond ^{15}N–^{13}C′ and two-bond ^{1}H^{N}–^{13}C′ dipolar couplings. We demonstrated the accuracy of the developed experiments using the protein GB1 aligned in liquid crystalline Pf1 (15 mg/ml) in 95% H_2O/5% D_2O at pH 7 and 25 °C and measured a large set of RDCs. Comparing the experimentally obtained RDCs with those calculated from a previously obtained high resolution model structure [27] (PDB code: 3GB1), excellent agreement between these values can be noted [16–18]. For one-bond ^{15}N–^{1}H^{N}, ^{15}N–^{13}C′ and two-bond ^{1}H^{N}–^{13}C′ RDCs the correlation coefficients are 0.998, 0.98, and 0.96, respectively. Interestingly, the presence of cross-correlated relaxation between ^{15}N–^{1}H^{N} and ^{1}H^{N}–^{1}H$^{\alpha}$ dipolar interactions causes one-bond ^{15}N–^{1}H^{N} couplings measured in the ^{15}N dimension to be different from those measured in

$2n=(4n-1)-(4n)$	$\cos[\omega_{\mathrm{H}}t_2+(\omega_{\mathrm{N}}-\pi kJ_{\mathrm{MX}})t_1]$	$-\sin[\omega_{\mathrm{H}}t_2+(\omega_{\mathrm{N}}-\pi kJ_{\mathrm{MX}})t_1]$

the ^{1}H dimension [17]. Therefore, it is in general preferable to measure the amide RDCs in the ^{15}N dimension in these spectra, although the orientational information is identical in both dimensions.

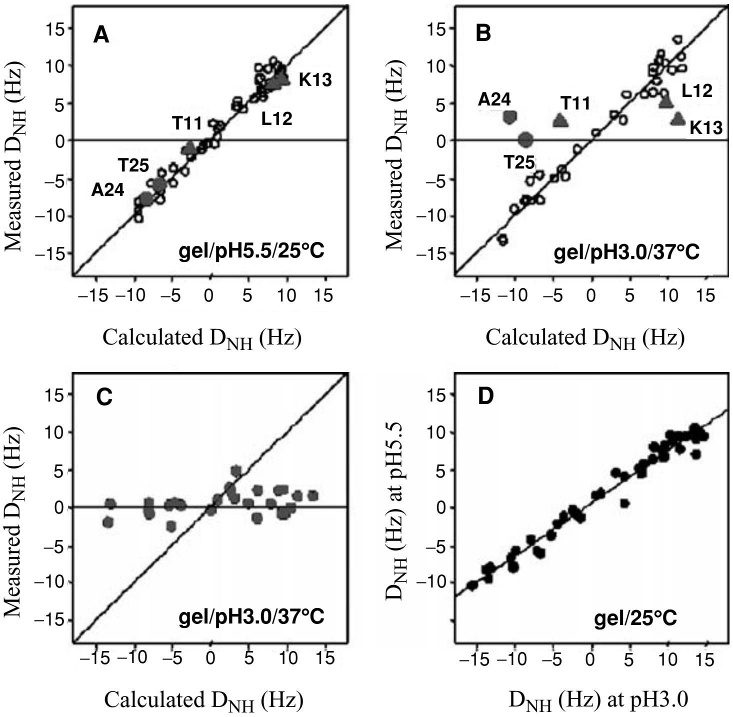
The spin-state-selective technique combined with sensitivity enhancement and interleaved data acquisition is summarized in Table 1 [19]. This approach is especially useful for the cases where the coupling is to be measured and the ^{15}N chemical shift evolve during different time periods. In these cases, it is often necessary to record a 3D experiment, which in turn is reduced in dimensionality from 3 to 2 [28–30] using the accordion principle [31,32]. Generally, a scaling factor of k can be introduced to scale the J_{MX} coupling evolution. By carefully setting the t_1-modulation according to Table 1, sensitivity-enhanced experiments were implemented for measuring one-bond ^{13}C′–^{13}C$^\alpha$ and ^{1}H$^\alpha$–^{13}C$^\alpha$ dipolar couplings [19]. In this way, two sub-spectra with resolution comparable to the decoupled spectra are obtained and the corresponding peak displacement along the ^{15}N dimension provides a direct measure of the one-bond ^{13}C′–^{13}C$^\alpha$ and ^{1}H$^\alpha$–^{13}C$^\alpha$ dipolar couplings. Again, the applicability of these experiments was demonstrated for protein GB1 aligned in liquid crystalline Pf1 (15 mg/ml) in 95% H_2O/5% D_2O at pH 7 and 25 °C. Excellent correspondence between measured and calculated one-bond ^{13}C′–^{13}C$^\alpha$ and ^{1}H$^\alpha$–^{13}C$^\alpha$ dipolar couplings was found [19], with correlation coefficients of 0.96 and 0.96, respectively.

In a further application of the spin-state-selective techniques, sensitivity-enhanced experiments for measuring ^{15}N(i)–^{13}C$^\alpha$(i), ^{1}H$^{\mathrm{N}}$(i)–^{13}C$^\alpha$(i), ^{15}N(i)–^{13}C$^\alpha$($i-1$), and ^{1}H$^{\mathrm{N}}$(i)–^{13}C$^\alpha$($i-1$) dipolar couplings were also developed [20]. Since the ^{15}N(i)–^{13}C$^\alpha$(i) and ^{15}N(i)–^{13}C$^\alpha$($i-1$) coupling evolution and the ^{15}N chemical shift evolution are in a common time period, there is no need for the accordion principle. Every cross peak in the two sub-spectra exhibits E.COSY splittings from the intra-residue ^{13}C$^\alpha$ spin. Because one-bond ^{15}N–^{13}C$^\alpha$ J couplings are small, ranging from 8.5 to 13.5 Hz, very high digital resolution in ^{15}N dimension is necessary for resolving the E.COSY doublet. Consequently, the application of this type of experiment is limited to small proteins with an apparent ^{15}N line width $\leq$8.5 Hz. The comparison between measured and calculated one-bond and two-bond ^{15}N–^{13}C$^\alpha$, as well as two-bond and three-bond ^{1}H$^{\mathrm{N}}$–^{13}C$^\alpha$ RDCs for the protein GB1 aligned in liquid crystalline Pf1 (15 mg/ml) in 95% H_2O/5% D_2O at pH 7 and 25 °C, yields correlation coefficients of 0.983, 0.833, 0.976, and 0.944, respectively. We wish to point out that the two-bond ^{15}N–^{13}C$^\alpha$ RDCs are extremely small, namely ≤ 0.3 Hz, still yielding a remarkable correlation coefficient of 0.833 [20]. This implies that the experimentally measured values have to be highly accurate and that the quality of the model structure is also very good.

Applications of Residual Dipolar Couplings in Proteins

The most direct application of RDCs in protein NMR is their use as orientational constraints for 3D structure determination. For a rigid molecule, the orientations of all the two-spin vectors are fixed with respect to the molecular frame. Therefore, the corresponding RDC is proportional to the scalar product between a 3 × 3 traceless order tensor, global to any pair of spins, and the second-order tensor of the two-spin vector [33]. It is this relationship between the order tensors that is the basis for using RDCs in NMR structure determination. If, however, the directions of some two-spin vectors reorient with respect to the molecular frame, the proportionality to the scalar product is broken and the corresponding RDCs cannot

Fig. 2. Characterization of melting hot spots in a destabilized mutant of GB1 (S14) by RDC measurement. The measured D_{NH} for S14 against the predicted values are shown in (A) and (B), and data points associated with local melting hot spots are displayed as filled triangles (T11, L12, K13) and filled circles (A24, T25). (C) Measured D_{NH} of S14 in the molten state vs. those predicted from the folded structure. (D) Correlation between measured D_{NH} of folded S14 at 25 °C in a stretched gel at pH 5.5 and at pH 3.0. (Data points for the residues comprising the melting hot spots are excluded.)



provide meaningful structural constraints. They can, on the other hand, reveal important information about motions, either relating to inter-domain motions [34] or local melting events [21]. Local melting hot spots are easily identified since local order tensor parameters will be different from the global tensor, caused by the local reorientation motion at this site. For example, we examined the structure and dynamics of a series of core mutants of the protein GB1. For one of these, S14, local melting was discovered under destabilizing conditions based on RDC measurements. The identification of the melting hot spots is illustrated in Figure 2 [21]. RDCs were measured in a stretched polyacrylamide gel at temperatures between 25 and 37 °C and at pH 5.5 they correlate well (Pearson correlation coefficient = 0.99) with calculated values based on the refined NMR structure of wild-type GB1 (PDB code: 3GB1). However, at pH 3.0 and 37 °C, the data points for residues T11, L12, K13, A24, and T25 deviate from the diagonal correlation line and are scattering along a horizontal line (Figure 2B). Under those experimental conditions S14 exists in a folded and unfolded state, as evidenced by a second set of resonances, not belonging to native state. For the unfolded protein, no correlation with the native, folded structure is preserved and all experimental RDCs scatter along the same horizontal line (Figure 2C) as noted before for the outliers of the folded state. We also established that the changes in RDCs are not caused by a pH change on the gel, since the couplings of the folded GB1 at pH 3.0 and 5.5 are in excellent agreement (Figure 2D).

In conclusion, our application of RDC measurements to the GB1 folding landscape clearly demonstrates their power for identifying melting hot spots in proteins.

Discussion

There is now ample data available (see above) that indicate the importance of RDC derived constraints for NMR structure determination of proteins as well as for identifying local areas of mobility. Proteins are also rich in ^{1}H–^{13}C spin pairs in the side chains. Therefore long-range ^{1}H–^{1}H RDCs will probably attract more and more attention since they will be able to provide quantitative distance constraints. Once accurate and efficient methods are developed for measuring these side-chain ^{1}H–^{13}C and the long-range ^{1}H–^{1}H dipolar couplings, NMR structural biology will move into a new area again.

Using Chemical Shift Perturbations to Validate and Refine the Docking of Novel IgE Antagonists to the High-Affinity IgE Receptor

Melissa A. Starovasnik and Wayne J. Fairbrother
Department of Protein Engineering, Genentech Inc., South San Francisco, CA 94080, USA

The binding of IgE to its high-affinity receptor, FcεRI, is fundamental to allergic disease. Molecules that block this interaction could therefore act as useful therapeutics for the treatment of asthma, allergic rhinitis, and other forms of atopy. To this end, binding selections using the extracellular portion of the α-chain of FcεRI (FcεRIα) and polyvalent peptide-phage libraries have yielded two distinct classes of peptide ligands that antagonize IgE binding to its receptor and prevent downstream IgE-mediated signaling events in basophils [1,2]. NMR spectroscopy has been used to characterize the structures of these peptide antagonists and their modes of binding to FcεRIα.

Structure determination of the ~32-kDa peptide/receptor complexes by NMR methods was not feasible for these systems because the heavily glycosylated receptor protein could not be bacterially expressed and thus could not be isotopically labeled (at least not readily). The high carbohydrate content of the receptor also makes these systems challenging for structure determination using X-ray crystallography. As described below, however, large ^{1}H chemical shift perturbations observed for the isotopically labeled peptide ligands upon binding to the receptor protein in solution could be used qualitatively to validate hypothesis-driven models of ligand binding, and quantitatively to refine these models. The resulting structural models will be useful in the development of novel IgE antagonists.

Hairpin Peptide Structure

The first family of peptides identified by phage display have the general form $X_4CX_2GPX_4CX_4$ and bind FcεRIα with affinities in the 1–10 μM range [1]. Analysis of one of these peptides, IGE06, by NMR spectroscopy revealed that the peptide has a well-defined three-dimensional (3D) structure in solution comprising two β-strands (residues 5–8 and 11–14) connected by a type I β-turn centered at residues Pro9 and Trp10 (Figure 1A). The three N-terminal residues are not as well defined by the NMR data and appear to be more flexible in solution than residues Cys5-Cys14. Residues required for structure and/or function were identified by analysis of peptide variants using both NMR and activity measurements. Importantly, NMR analysis of peptides having alanine substitutions for Gly8, Pro9, and Trp10 indicate that these substitutions do not disrupt the hairpin structure even though they have a significant impact on FcεRIα-binding affinity (Figure 1A).

Zeta Peptide Structure

Using an expanded set of peptide-phage libraries, a second family of peptides with a simpler motif, X_2CPX_2CYX, was identified [2]. When synthetic peptides were assayed for inhibition of IgE binding to cell-surface FcεRI, however, IC_{50} values of 250 μM or greater were obtained. Surprisingly, this activity improved over time and stabilized at 64 μM when assayed similarly 10 days after solubilization. One-dimensional (1D) and two-dimensional (2D) NMR analysis of a freshly prepared nine-residue monomeric disulfide-bonded peptide demonstrated at least four conformationally distinct forms, with the major form showing no evidence of stable structure (Figure 2). Analysis of 1D NMR spectra over time showed changes in the relative populations of the different forms (Figure 2), and after 7 days at room temperature ~90% of the peptide had converted to a single new form that also showed significantly longer retention time than the original sample in an analytical HPLC run. This form had a stable structure in solution as evidenced by significant chemical shift dispersion relative to "random coil," and extreme values for backbone and side chain ^3J coupling constants. Mass spectra of the new peptide form showed it to be a covalent disulfide-linked dimer. Comparison of analytical HPLC chromatograms and NMR spectra of synthetic parallel or antiparallel dimeric peptides confirmed that the active state of the phage-derived peptide was an antiparallel dimer with two intermolecular disulfide bonds. Subsequent linking of the monomeric peptides with a three-residue linker sequence to make a 21-residue "single-chain dimer" species, and further optimization on phage, resulted in a 32 nM-affinity peptide antagonist (e131).

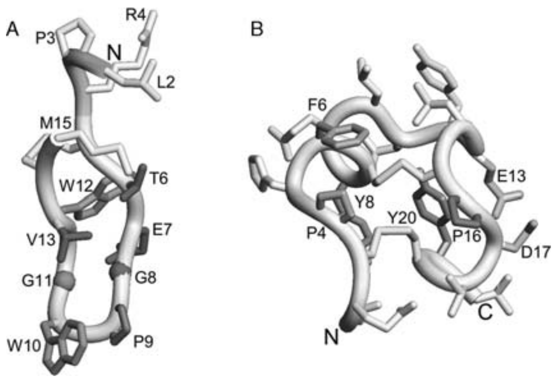

Fig. 1. Solution structures of representative (A) hairpin and (B) zeta peptides. Shown are ribbon diagrams of the first structure from the ensembles in PDB files 1JBF (hairpin) [1] and 1KCO (zeta) [2]. Side chains are colored to indicate those residues that are important for maintaining the structure of the peptide (green; disulfide bonds in yellow), and those that are important for receptor binding, but are not important for maintaining a stable structure of the peptide (from most important to least, red > orange > blue). The backbone of residues 2–4 of the hairpin peptide is colored to indicate that truncation of this region results in significant loss in receptor-binding affinity. (See also Plate 98 on page XIX in the Color Plate Section.)

NMR structural analysis of e131 showed that the peptide adopts a stable structure comprised of two small antiparallel 3_{10} helices connected by two disulfide bonds and a flexible linker region (Figure 1B). The helical backbone conformation is stabilized by packing of two Tyr side chains (Tyr8 and Tyr20) "below" the disulfide bonds, with each Tyr hydroxyl donating a hydrogen bond across the "dimer interface" to the carbonyl oxygen of a Cys residue. The backbone structure is pseudo-symmetric with residues 1–9 adopting essentially the same conformation as residues 13–21. Peptides of this class were designated "zeta" peptides due to a resemblance between the structurally conserved regions and the Greek letter zeta (ζ). As with the hairpin class of peptides, residues in the zeta peptide required for structure and/or function were identified from analysis of peptide analogs both by NMR and activity measurements. Again, the most important residue for high-affinity receptor binding was found to be a proline (Pro16) (Figure 1B).

Receptor Binding

Despite their significantly different structures, the two-peptide classes were shown to compete for binding at the same site on the receptor. Alanine-scanning mutagenesis of FcεRIα demonstrated further that the peptides bind to a region of the receptor that had been shown previously to contact IgE. This aromatic-rich IgE interaction site is centered around two tryptophan residues on the receptor (Trp87 and Trp110), between which Pro426 of bound IgE is buried [3]. In order to characterize further the receptor-binding modes of the different peptide classes, ^{13}C/^{15}N-labeled peptides were obtained by expression of protein A Z-domain fusion proteins [4] in *Escherichia coli* using a previously described alkaline phosphatase induction system [5], followed by cleavage (using trypsin or CNBr for the zeta or hairpin peptide, respectively) and purification of the peptides [6]. Isotopic labeling of FcεRIα was not practical because the heavily glycosylated extracellular domain (average molecular mass ~30 kDa) could be produced only via baculoviral infection of insect cells [6].

NMR Analysis of Zeta Peptide/Receptor Complex

The 23-residue zeta peptide selected for NMR structural studies (e117) was shown previously to bind FcεRI and block IgE binding with an IC_{50} of 80 nM [2]. The resonances of the free zeta peptide were assigned readily by standard analysis of 2D ^{1}H/^{15}N-HSQC, 3D ^{1}H/^{15}N-TOCSY-HSQC, 2D ^{1}H/^{13}C-HSQC, 2D CBCA(CO)NH, and 2D ^{1}H/^{13}C-HCCH-TOCSY spectra [7]. Resonance assignments of the receptor-bound zeta peptide were complicated, however, by the overall reduced sensitivity of J-correlated spectra for the ~32 kDa complex, and by large variations in line widths, with those residues at the peptide termini and in the GGH "linker" being sharper and more intense than those from the rest of the peptide. Nevertheless, unambiguous assignments were obtained for a majority of the zeta peptide resonances based on analysis of 3D ^{15}N-edited and ^{13}C-edited NOESY spectra.

Comparison of the resonance assignments of the free and receptor-bound peptide showed that many of the peaks from residues within the "disulfide-bonded core" of the peptide experienced significant chemical shift perturbations; the most dramatic chemical shift changes upon receptor binding were seen for the ^{1}H resonances of Pro16 (Hα, Hβ, Hγ, and Hδ all shifted upfield by 1.7–3.1 ppm; Figure 3A). Shifts of this magnitude observed for all proton resonances within the proline side chain can be explained if the proline is packed between aromatic rings in the protein/peptide complex, in much the same way as Pro426 of IgE is found "sandwiched" between two tryptophan residues in the crystal structure of the Fc fragment of IgE in complex with FcεRIα [3]. By contrast, the sharper peaks from the bound state of the zeta peptide underwent only minimal changes in chemical shift relative to the free state (Figure 3A), consistent with this group of residues being of minimal importance for receptor binding [2].

In addition to the chemical shift perturbations indicating that the zeta peptide binds proximal to aromatic residues on the receptor, ^{13}C-edited/^{12}C-filtered NOESY

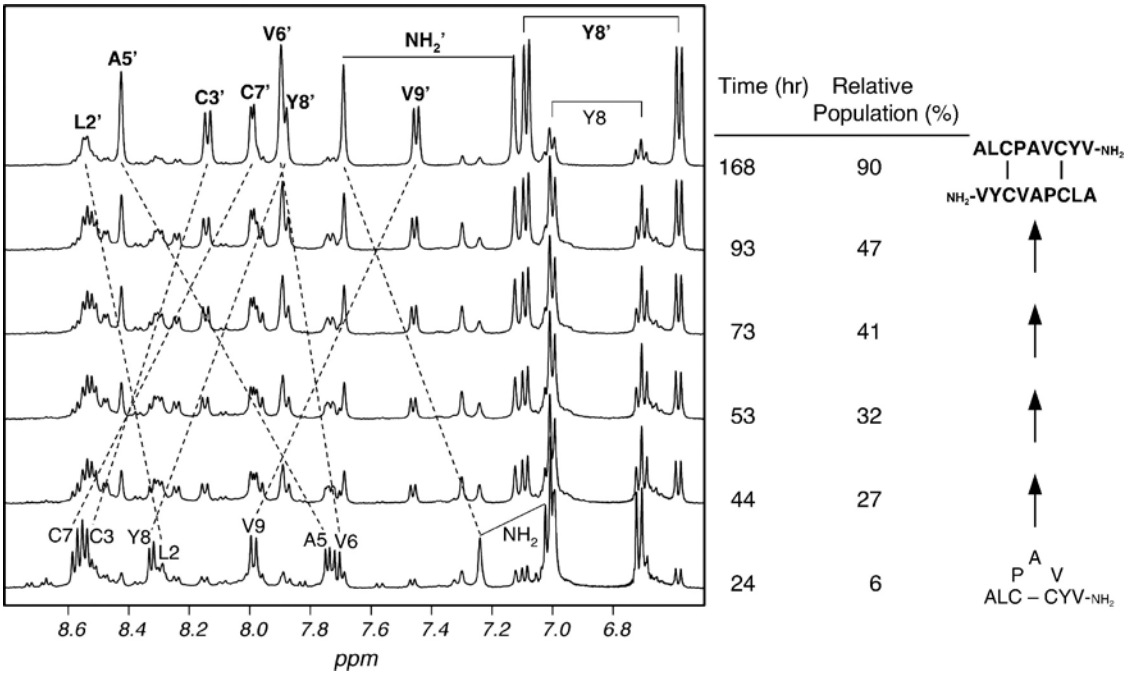

Fig. 2. Spontaneous rearrangement of a monomeric 9-mer peptide into a covalent disulfide-linked dimer monitored by 1D NMR spectroscopy. Amide and aromatic region of a series of 1D ^{1}H NMR spectra acquired at 500 MHz, 25 °C, on a sample of peptide e101 (ALCPAVCYV-NH$_2$), originally synthesized and purified as a monomeric peptide with an intramolecular disulfide bond. Lyophilized peptide was resuspended in water and spectra were acquired intermittently over the course of a week, with the time after resuspension indicated. The population of well-folded dimeric peptide present over time is estimated based on the relative intensities of the two most upfield peaks shown, corresponding to the Tyr8 ^{1}H$^\varepsilon$ resonance in the ordered dimeric state and in the monomeric or intermediate states. Note that if the peptide existed in a single conformation in solution, that no more than 11 peaks would be expected in this region of the spectrum.

spectra [8] showed NOE correlations between at least two distinct aromatic groups on the receptor and peptide residues Val1, Leu14, and Val18. Peptide residues Val1, Gln2, and Pro4 also had NOE correlations with a pair of peaks resonating at 0.75 and 0.73 ppm that were assigned tentatively to a pair of methyl groups on the receptor based on resonance intensity and frequency. No NOE correlations were observed from Pro16 of the peptide, despite the large chemical shift changes observed for this residue, due to the increased line widths in the receptor-bound state. The resonance broadening is most likely due to the large chemical shift gradient in which the proline is located; even small changes in the orientation of Pro16 with respect to the aromatic residues on the surface of the receptor would cause chemical shift changes resulting in the observed resonance broadening.

Receptor contacts involving aromatic and methyl-containing side chains are consistent with the zeta peptide binding to the IgE-binding site as identified by receptor mutagenesis. The peptide was therefore docked manually into the IgE-binding site of FcεRIα using coordinates of the free peptide and the previously published crystal structure of the IgE/FcεRIα complex [3]. The initial peptide placement was based on the assumption that the functionally important proline residue, Pro16, which experienced the most significant ^{1}H chemical shift perturbations upon receptor binding (Figure 3A), would bind between Trp87 and Trp110 of the receptor, in approximately the same way as observed for Pro426 of IgE. The resulting peptide orientation appeared consistent with the observed intermolecular NOE correlations; in particular, intermolecular NOE correlations between zeta peptide residues Val1, Gln2, and Pro4 and the unidentified pair of receptor methyl groups could be assigned tentatively to Leu158 of the receptor because these are the only methyl groups in this region of the receptor.

The aliphatic ^{1}H chemical shifts of the manually docked peptide were calculated using the program SHIFTS 4.1 (X. Xu and D.A. Case, The Scripps Research Institute, La Jolla, CA; http://www.scripps.edu/case/

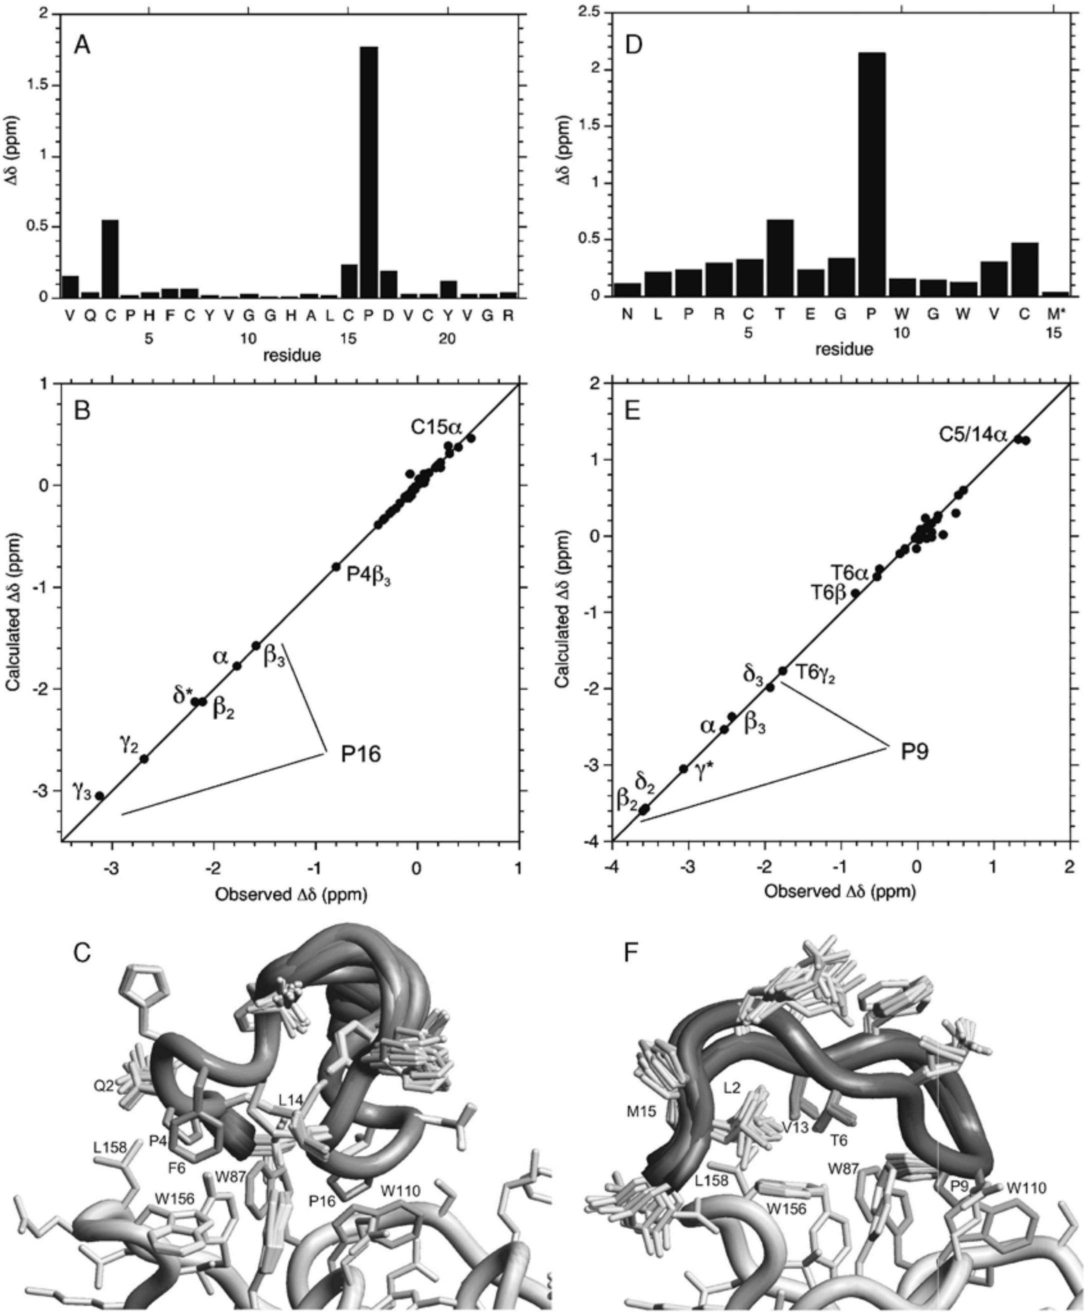

Fig. 3. (A) Plot of the net change in zeta peptide ^{1}H$^\alpha$ chemical shifts upon binding FcεRIα ($\Delta\delta = [\Delta\delta^2_{^1\mathrm{H}^\alpha}]^{1/2}$). (B) Correlation between observed and calculated chemical shifts ($\Delta\delta = \delta_{\mathrm{total}} - \delta_{\mathrm{random\ coil}}$) following refinement of the zeta peptide/FcεRIα complex structure using AMBER 6.0 (rms error = 0.038 ppm, $R^2 = 0.9978$). (C) Superposition of 20 models of the zeta peptide/FcεRIα complex structure obtained by docking and refinement against the ^{1}H chemical shifts of the peptide (average rms error = 0.041 ± 0.005 ppm). (D) Plot of the net change in hairpin peptide ^{1}H$^\alpha$ chemical shifts upon binding FcεRIα. (E) Correlation between observed and calculated chemical shifts following refinement of the hairpin peptide/FcεRIα complex structure using AMBER 6.0 (rms error = 0.090 ppm, $R^2 = 0.9954$). (F) Superposition of 20 models of the hairpin peptide/FcεRIα complex structure obtained by docking and refinement against the ^{1}H chemical shifts of the peptide (average rms error = 0.12 ± 0.02 ppm). (See also Plate 99 on page XX in the Color Plate Section.)

qshifts/qshifts.htm), in which the "structural" effects on chemical shifts due to contributions of ring currents of aromatic groups [9,10], magnetic anisotropy from peptide groups [11], and electrostatic effects arising from charges and dipoles [12], are calculated using empirical functions [13–15]. The total chemical shift of a given resonance is defined as the sum of the "random coil" value, as observed in short disordered linear peptides [16,17], and the conformation-dependent contributions ($\Delta\delta$). The conformation-dependent contribution to the total chemical shift, as calculated by SHIFTS 4.1, is thus defined as:

$$\Delta\delta = \delta_{\text{total}} - \delta_{\text{random coil}} \approx \sum \delta_{\text{rc}} + \sum \delta_{\text{m}} + \sum \delta_{\text{el}} + \delta_{\text{const}} \qquad (1)$$

where rc, m, and el, refer to ring current, magnetic anisotropy, and electrostatic contributions, respectively. The δ_{const} term is an empirical "fitting" parameter that includes contributions from δ_{m} and δ_{el} that are present in the random coil state [14]. Good general agreement was found between the calculated and experimentally observed chemical shifts, although differences suggested that the manually docked model could be refined further.

The docked model was therefore refined by optimizing the agreement between the calculated and observed ^{1}H chemical shifts of the receptor-bound peptide using functionally equivalent code within the molecular modeling package AMBER 6.0 (http://amber.scripps.edu/doc6/). All the unambiguously assigned aliphatic ^{1}H chemical shifts were incorporated as restraints (force constant = 25 kcal/·mol/·ppm) in a simple simulated annealing protocol. For initial rounds of refinement the chemical shifts of prochiral methylene and methyl protons were averaged. The chemical shifts of all peptide protons were subsequently back-calculated using SHIFTS 4.1 and compared to the experimentally determined chemical shifts. In some cases the chemical shifts of prochiral proton pairs were sufficiently different, and the agreement between the calculated and experimentally observed values was sufficiently close, to allow for stereospecific assignments that could be incorporated into subsequent rounds of refinement. In this way stereospecific assignments were possible for Pro4 ^{1}H$^\beta$, Leu14 ^{1}H$^\beta$, and Pro16 ^{1}H$^\beta$ and ^{1}H$^\gamma$.

In addition to the chemical shift restraints, distance and dihedral angle restraints derived from those used to calculate the solution structure of the free peptide were incorporated into the refinement to ensure that the peptide structure was maintained. The coordinates of the receptor were restrained to be nearly fixed during the simulated annealing and subsequent restrained minimization calculations using a harmonic potential with a force constant of 5 kcal/·mol. A weak harmonic potential (force constant = 0.5 kcal/·mol) was also used to restrain the disulfide-bonded core (residues Cys3-Tyr8 and Ala13-Tyr20) of the zeta peptide. Finally, tentatively assigned intermolecular NOE distance restraints were incorporated iteratively into the refinement calculations as upper-bound distance restraints of 5.8 Å, only if they were clearly satisfied in the current models; in total, 17 intermolecular distance restraints were included in the final simulated annealing calculation. Importantly, the intermolecular distance restraints were not required for convergence of the refined models. Indeed, trial calculations in which the starting zeta peptide and receptor molecules were separated by ~20 Å still converged to essentially the same peptide/receptor orientation as those starting from manually docked models, even in the absence of intermolecular distance restraints (W.J. Fairbrother, unpublished results).

The resultant agreement between the calculated and experimentally observed ^{1}H chemical shifts was excellent (Figure 3B), suggesting that the refined model of the zeta peptide/receptor complex (Figure 3C) represents a good approximation of the structure. In this model Pro16 packs between Trp87 and Trp110 on the receptor, and the N-terminal region of the peptide makes additional hydrophobic contacts near Leu158. A subsequent 3 Å-resolution X-ray crystal structure of the complex between a closely related zeta peptide (e131) and FcεRIα was in very close agreement with the NMR-based model [6], confirming the validity of the approach.

NMR Analysis of Hairpin Peptide/Receptor Complex

Resonances of the free 15-residue hairpin peptide, IGE32, were assigned by analysis of 2D ^{1}H/^{13}C-HSQC, 2D CBCA(CO)NH, and 2D ^{1}H/^{13}C-HCCH-TOCSY spectra [7]. Assignments of the receptor-bound state were obtained by analysis of 2D ^{1}H/^{13}C-HSQC and 3D ^{13}C-edited NOESY spectra. However, as observed for Pro16 of the zeta peptide, the resonances of the functionally important Pro9 were broad and did not show observable cross peaks in the ^{13}C-edited NOESY spectrum; assignment of these resonances was thus confirmed by analysis of a 2D ^{1}H/^{13}C-HSQC spectrum of a sample prepared with ^{13}C-Pro9 specifically labeled hairpin peptide generated by chemical synthesis.

Similar dramatic chemical shift changes to those found for the zeta peptide were observed when the hairpin peptide was added to FcεRIα (Figure 3D). In particular the ^{1}H resonances of residues Thr6 and Pro9 were shifted upfield by 1.7–3.2 ppm upon binding the receptor. As for the zeta peptide, these large chemical shift changes imply that the hairpin peptide packs closely with aromatic rings in the complex. In this case, a total of 40 intermolecular NOE correlations involving peptide residues Asn1, Leu2, Pro3, Thr6, Val13, and Met15, were identified. These included NOE correlations between peptide residues Val13 and Met15 and a pair of methyl groups on the receptor; as with the zeta peptide complex, the receptor methyl resonances could be assigned tentatively to Leu158. This assignment allowed for manual docking of the hairpin peptide so that the C-terminal residues were proximal to Leu158 on the receptor while, at the same time, Pro9 packs between Trp87 and Trp10 in the IgE-binding site. The resulting docked model was refined in a similar fashion to the refinement of the zeta peptide complex, as outlined above. In the case of the hairpin peptide calculations, however, the weak harmonic potential (force constant = 0.25 kcal/·mol) used to restrain the peptide structure was applied only during the initial iterations, and was never applied to peptide residues Asn1, Leu2, Thr6, Trp10, or Trp12. Conformational freedom of these residues was found to be necessary in order to satisfy the ^{1}H chemical shift restraints; in particular the side chain conformation of Trp10 changed significantly during the refinement. Stereospecific ^{1}H resonance assignments were possible for Pro9 $^1H^\beta$ and $^1H^\delta$, and Val13 $^1H^\gamma$, and using the same criteria as for the zeta peptide complex a total of 22 intermolecular distance restraints could be included in the final simulated annealing calculations.

The final correspondence between the calculated and observed ^{1}H chemical shifts was again excellent (Figure 3E) indicating that the resulting model (Figure 3F) is a good approximation of the structure of the hairpin peptide/receptor complex. As was found for the zeta peptide complex, and consistent with original assumptions, the functionally important Pro9 is sandwiched between Trp87 and Trp110 on the receptor. Thr6 is proximal to Trp156 on the receptor, which accounts predominantly for the upfield shifts observed for resonances of this residue.

Comparison of the zeta and hairpin peptide/FcεRIα complex models reveals that even though the phage-derived peptides are structurally distinct they make remarkably similar contacts with the receptor. For instance, in addition to the zeta peptide Pro16 and the hairpin peptide Pro9 being "sandwiched" between Trp87 and Trp110 of the receptor, Pro4 and Phe6 of the zeta peptide occupy essentially the same space on the receptor as Val13 and Thr6, respectively, of the hairpin peptide (Figure 3C and F). Interestingly, the latter interactions are not utilized by the natural ligand, IgE, and thus, together with the proline pocket defined by Trp87 and Trp110, represent a novel binding epitope for IgE antagonists.

Conclusion

In the examples presented above the readily obtained ^{1}H chemical shifts of peptide ligands were used to validate docked models of the peptide/receptor complexes that were based originally on assumption and limited experimental data, such as mutational analysis. More extensive data, such as receptor chemical shift assignments, and consequently assigned intermolecular NOE correlations, were not available. The ^{1}H chemical shifts of the bound peptides, and in particular the large upfield shifts of ^{1}H resonances observed for some of the peptide residues, could be accounted for quantitatively by directly refining the models against the observed chemical shifts.

Some caveats of the approach are worth mentioning. First, this is not a *de novo* docking method, but rather a docking validation method, and thus requires some degree of independent data in order to localize the binding site. Starting models could come from *de novo* docking algorithms, or could be based on experimental data such as obtained from mutational analysis, as used here. Secondly, reasonably accurate structural models of the ligand and receptor are necessary and conformational changes upon binding should be minimal (although as noted in the hairpin peptide example some degree of conformational flexibility can be accommodated and might be necessary in order to obtain a good fit). Finally, the most sensitive restraints of ligand orientation are the ring current contributions of aromatic groups. Thus, the presence of aromatic groups that cause significant perturbations in the ligand chemical shifts is likely a prerequisite for successful application of this approach.

Dual-Region Hadamard-Encoding to Improve Resolution and Save Time

Ronald Crouch
Varian NMR Systems, NC 27513, USA

The advent of indirect detection has revolutionized the world of NMR spectroscopy in all areas of chemistry. For the purpose of assembling fragments of moieties as defined by NMR resonances into meaningful structural fragments or even complete structures, HMBC [1] is one of the most powerful tools available to the modern NMR spectroscopist. In situations of low sensitivity brought about most commonly by the availability of vanishingly small amounts of sample to analyze, direct observation of ^{13}C resonances can be difficult or impossible. Accordingly, the sensitivity afforded by indirect detection with HMBC and variants provides a tool that has the potential to access the key and difficult quaternary ^{13}C atoms while at the same time assembling the puzzle pieces into a coherent structure.

The strength of ^{1}H detection, thereby casting the ^{13}C chemical shift information into the indirect dimension, is also the weakness of HMBC. This is especially true in the more difficult situations where there are a large number of ^{13}C resonances spread out over a large chemical shift range. At a ^{1}H observe frequency of 500 MHz, 225 ppm of ^{13}C chemical shift represents nearly 28,000 Hz of frequency space. Resolving two ^{13}C resonances separated by10 Hz would require $\sim$2800 t1 increments (or $\sim$1000 t1 increments with high enough signal to noise to allow reliable linear prediction) in F1! Region selection in the ^{13}C dimension with HMBC is a very old idea [2–3]. Utilization of excitation sculpting [4–5] added considerable robustness to the method. Combination of excitation sculpting with a simple Hadamard-encoding step [6] provides a simple and reliable methodology to greatly reduce the number of t1 increments required for a needed resolution. This encoding methodology affords a mean to either record lower resolution HMBC information in less time or much higher resolved spectra in equivalent time relative to traditional sampling methods.

Consider the simplest two-element Hadamard matrix $+,+$ and $+,-$. Addition of the two elements leads to one enhanced signal to noise in one region, whereas subtraction results in cancelation of the first region and enhanced signal to noise in the second region. Bear in mind that with modern NMR spectrometers, given an actual ^{13}C spectrum from which to build the needed shaped ^{13}C pulses, a Hadamard matrix can automatically be created to record and construct a complete 2D HMBC spectrum in *n* increments, where *n* represents the number of ^{13}C resonances [7–10]. A major advantage of using a simple two-element matrix is that the regions can be quite wide and general and not require a precise understanding of carbon chemical shifts. It is quite reasonable to simply divide the carbon regions by half, and immediately obtain a time saving of a factor of two, because by employing Hadamard-encoding, the number of t1 increments is cut in half to maintain exactly the same digital resolution as in a full single-region HMBC. The magic is in the encoding pulses and it is quite practical to create whatever is needed on the fly to obtain the two required pulses for a simple two-element matrix. Alternatively, a pair of pulses appropriate for a routine experiment with any desired frequency bounds can be created, and the pulse width and power parameters remembered for future use. A pulse sequence optimized for long-range ^{1}H–X correlation spectroscopy with an option for single or multiple X-band selection is presented in Figure 1 [11].

As an introduction to the illustration of the method, consider the gHMBC spectrum acquired with a sample of cyclosporine-A shown in Figure 2. The F1 window required to observe all ^{13}C resonances is not particularly large. A ^{13}C chemical shift range from 0 to 190 ppm is more than enough. Inspection of the data in Figure 2 reveals that is quite practical to consider splitting the F1 window into two $\sim$80 ppm regions; 0–80 and 105–185 ppm. Simply acquiring a simultaneous dual F1 region-selected long-range ^{1}H/^{13}C chemical shift correlation experiment with the pulse sequence shown in Figure 1, immediately affords a time saving of a factor of two over the full single-region data set, simply because the number of t1 increments for equivalent digital resolution in the ^{13}C dimension can be cut in half.

A direct comparison of a single-region gHMBC and the simultaneous dual F1 region-selected gHMBC variant is presented in Figure 3, panels A–D. The two data sets

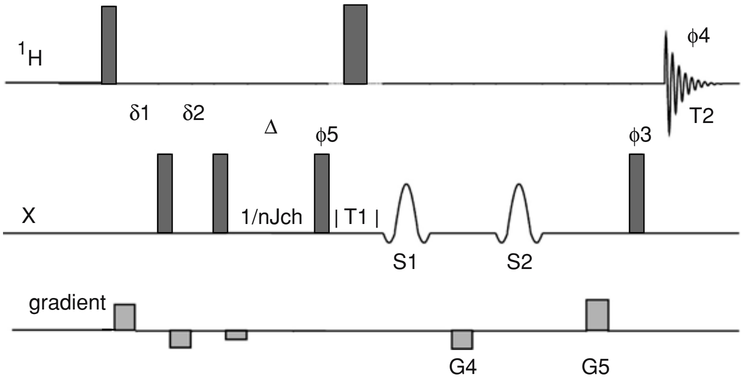

Fig. 1. Gradient coherence-selected pulse sequence for HMBC with adiabatic swept refocusing. Narrow bars denote 90° pulses. The wide bar and two selective pulses (S1 and S2) are 180° pulses with the t1 evolution time split by the ^{1}H 180. All of the data presented in this note were acquired with a constant adiabaticity cosine^2 (WURST2i) 180° pulse [12–13]. Gradients G4 and G5 are for coherence selection and can be in ratios of −3/5 or 5/−3 for N or P type selection of $^{13}CH_n$ resonances. The $\delta 1$ and $\delta 2$ delays in the low pass filter are optimized for $^1J_{\max}$ of 165 Hz and $^1J_{\min}$ of 130 Hz, as described by Sorensen and co-workers [14]. The delay for long-range XH coherence selection (Δ) can be set as desired. The gradients in the low pass filter are in the ratios of 9, −6, and −3. The basic phase cycling is as follows: $\phi 3 = x, x, -x, -x$; $\phi 5 = x, -x$; $\phi 4 = x, -x, -x, x$. Pulses S1 and S1 are adiabatic shaped pulses with downfield to upfield inversion sweep.

were obtained in precisely the same time with 128 t1 increments in each. The dual-region data (panels B and D) were acquired with two scans per t1 increment (with the two required band-selected shapes) and the single-region data (panels A and C) used four scans. Clearly the digital resolution and overall quality of data are improved for the dual-region Hadamard-encoded data presented in Figure 3, panels B and D.

A simple single-region band-selected experiment can be performed with the pulse sequence shown in Figure 1 to obtain extremely high digital resolution with efficient selection of the desired F1 region and rejection of other responses. Figure 4 shows a very high ^{13}C resolution long-range ^{1}H–^{13}C correlation experiment wherein the correlations between the protons and only the carbonyl ^{13}C resonances have been selected. The time to acquire the data was once again ~20 min. Comparison with the data in Figure 2 (or Figure 3, panel C) reveals the much higher digital resolution afforded by confining the F1 sampling solely to the carbonyl region of the ^{13}C spectrum.

At this point, it is useful to address the details of the experiment in terms of the requirements imposed by the band-selected pulses. A good means for illustration would be to graphically compare the pulses required for the acquisition of the single-region data presented in Figure 4, with those required to acquire the simultaneous dual-region data presented in the Figure 3 panels. This comparison is shown in Figure 5. Application of a very narrow band ^{13}C inversion pulse pair, as illustrated in Figure 5A, affords the possibility of quite high ^{13}C digital resolution with relatively few t1 increments precisely because only the portion of the ^{13}C frequency space refocused by the narrow band pulse is detected.

For simultaneous dual-region selection, it is necessary to interleave data acquisition using the two pulses graphically presented in Figure 5B and C. After data acquisition, 2DFT sum of the two interleaved data sets would result in full signal to noise for the upfield region of the ^{13}C frequency space, whereas 2DFT difference would give full signal to noise for the downfield ^{13}C frequency space. It is important to understand that the upfield and downfield regions are the result of two separate data processing steps that are graphically represented in Figure 5D and E.

The method presented here is both robust and simple to implement. It is the author's feeling that the full Hadamard-encoded techniques outlined in Refs. [7–10] may well represent the beginnings of a major revolution in the general approach to multi-dimensional NMR spectroscopy typically used in support of the elucidation of chemical structure in the pharmaceutical industry. It is hoped that the presentation of this simple two-step procedure serves to illustrate the general concepts.

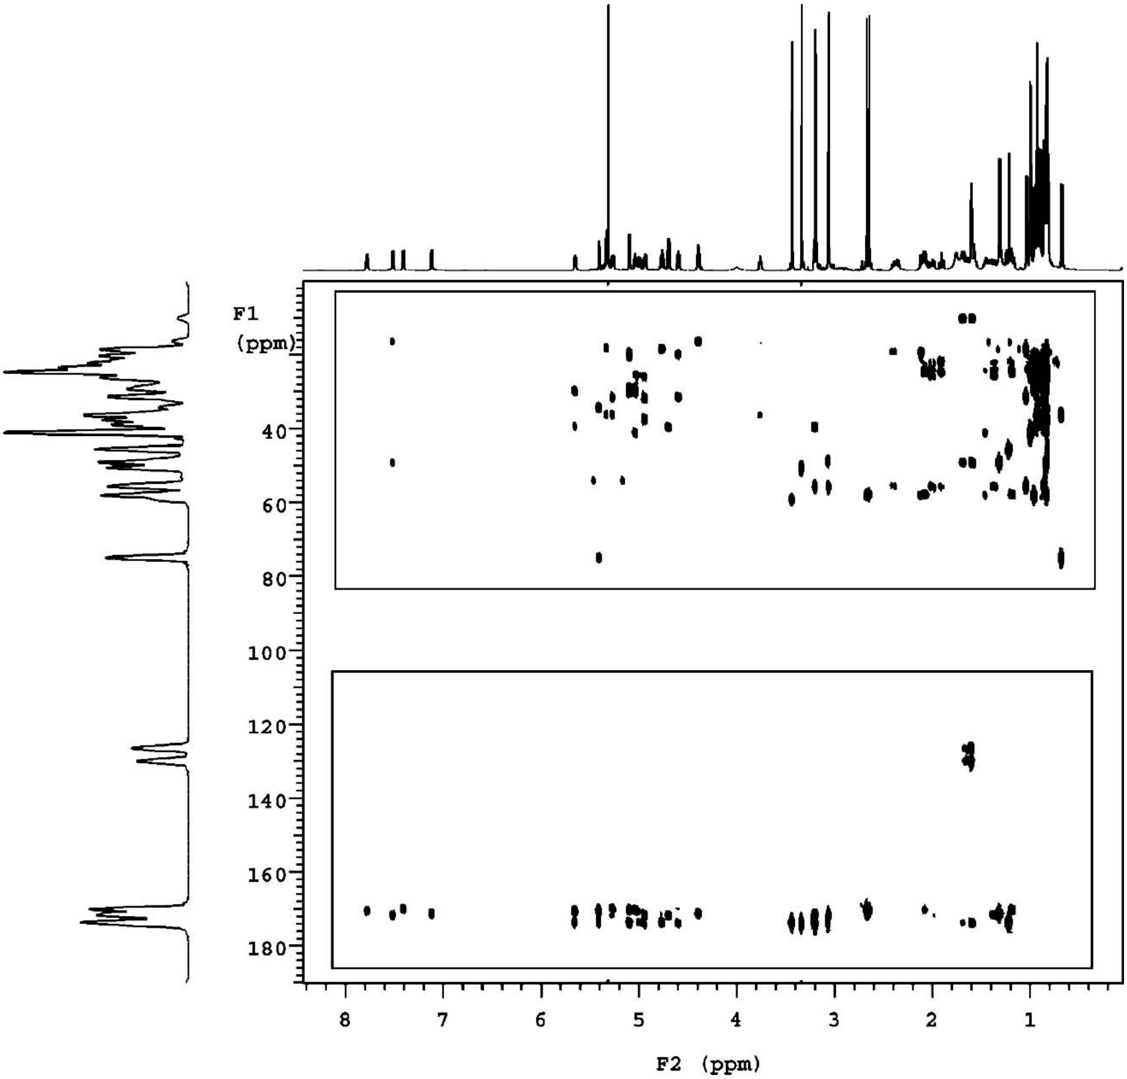

Fig. 2. Plot of the full single-region gHMBC acquired with a 2 mg sample of cyclosporine-A using an INOVA 600 with HCN Cold Probe. Data were acquired with four scans in each of 128 t1 increments in 22 min. A normal ^{1}H spectrum is on top and a projection showing the detected ^{13}C resonances is shown on the side. The boxed areas denote the regions to be selected in subsequent dual Hadamard-encoded experiments.

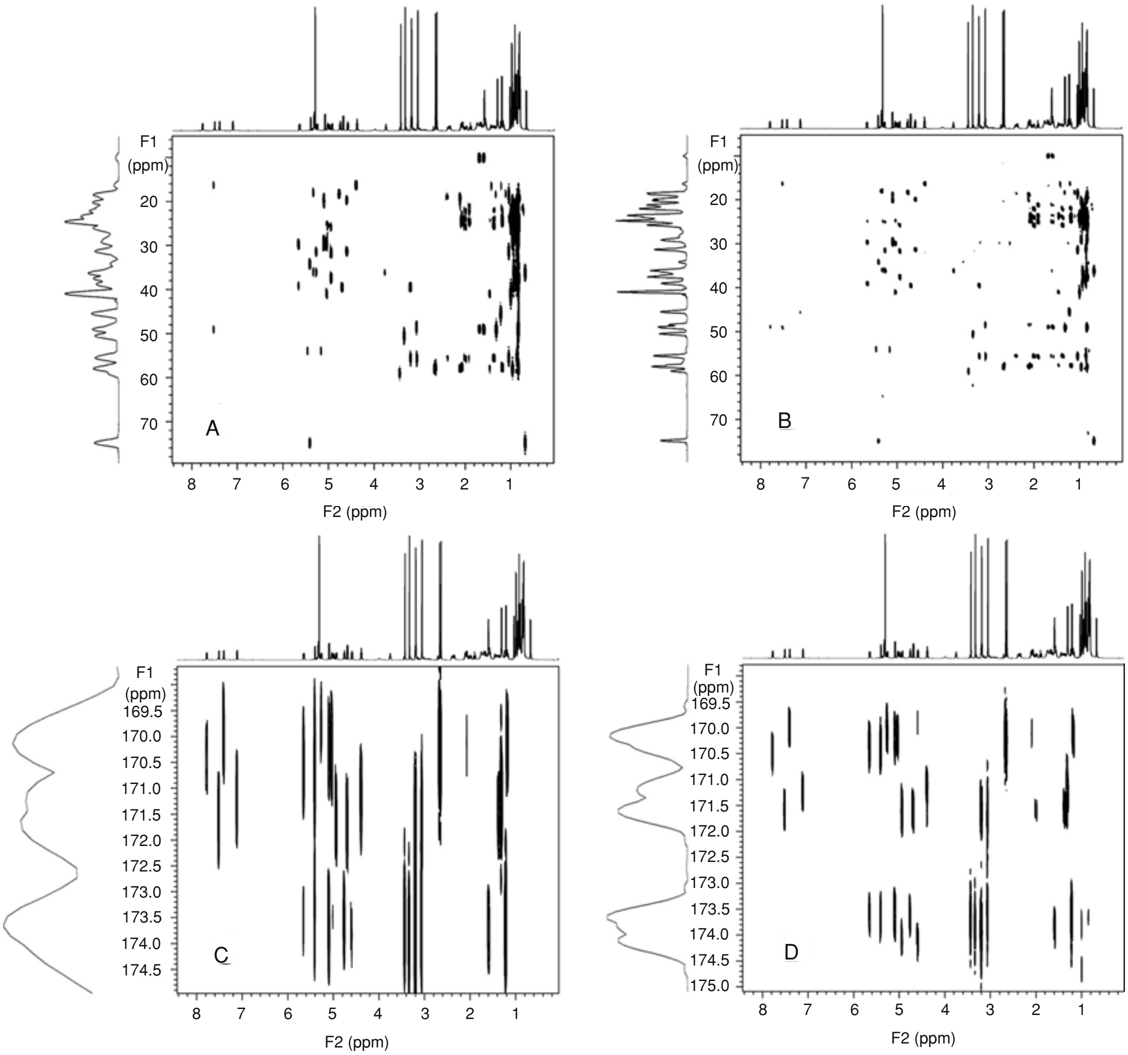

Fig. 3. Panels A–D compare regions from both traditional gHMBC and simultaneous dual-region Hadamard-encoding using the pulse sequence described in Figure 1. Panels A and C are simply expansions from the normal gHMBC depicted in Figure 2, whereas panels B and D are the result of 2DFT sum or difference of Hadamard-encoded data acquired in a single experiment in exactly the same experimental time as the gHMBC data shown in panels A and C. The data in panels A and C (gHMBC) were acquired with four scans/t1 increment. The Hadamard-encoded data in panels B and D were acquired with two scans per increment for both of the region-selected encoding ^{13}C pulses.

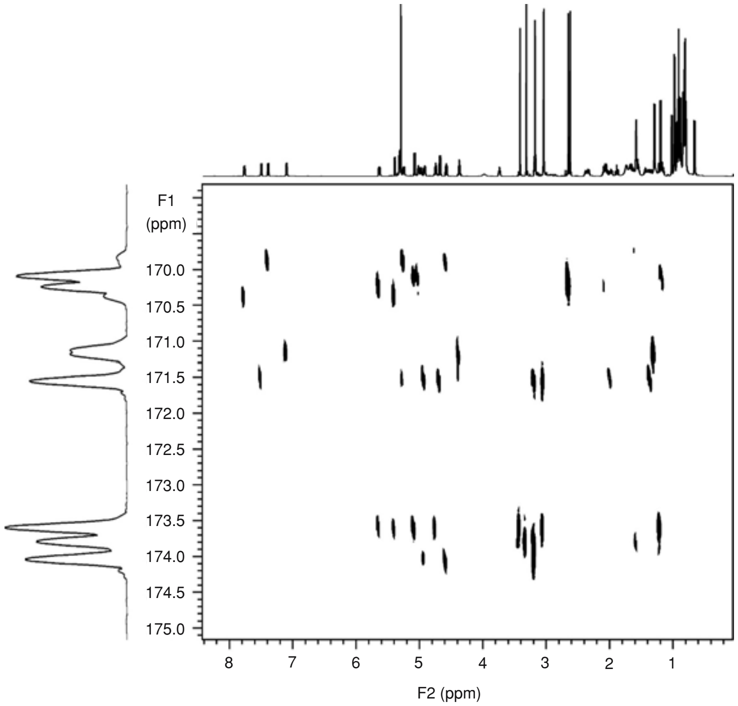

Fig. 4. Single C=O region-selected data acquired with the 2 mg sample of cyclosporine-A in 20 min. Data were acquired with two scans for each of the 256 t1 increments. The data were acquired and processed as a single phase with sine-bell window functions.

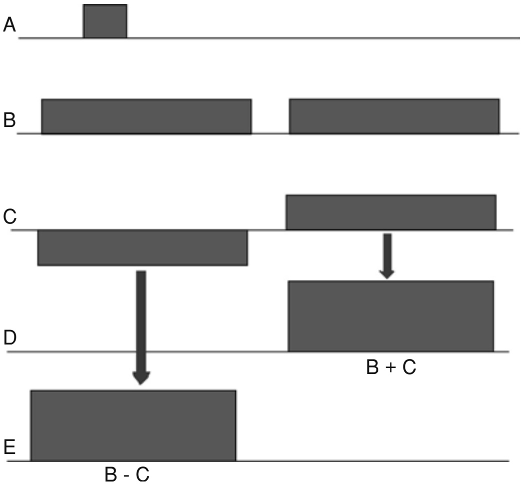

Fig. 5. Graphical representation of band-selection pulses required to acquire data in a two-step Hadamard matrix to generate the results shown in Figure 3. (A) For the single-region band-selection of carbonyl ^{13}C resonances described in Figure 4 only a very narrow refocusing of the ^{13}C carbonyl resonances is required. Figure 5B and C illustrate the pair of band-selected inversion pulses required for Hadamard-encoding. The anti-echo refocusing shown in the inverted portion of Figure 5C is achieved by application of a 90° phase shift for the band-selection of that π pulse portion of the ^{13}C frequency window. In Figure 5D and E the effect of processing the two encoded data sets, respectively, as sum and difference is illustrated. Figure 5D depicts 5B plus 5C, whereas Figure 5E depicts 5B minus 5C.

Abstract

The twin challenges of biomolecular NMR spectroscopy are sensitivity and resolution. Nonuniform sampling, in which data collection is tailored to meet the requirements of sensitivity or resolution, enables new approaches to meet these challenges. We describe the use of nonuniform sampling in biomolecular NMR and the use of maximum entropy reconstruction to process the data. Data collected using nonuniform sampling cannot be processed using conventional methods such as the discrete Fourier transform or linear prediction, because these methods require data sampled at uniform intervals. A two- to three-fold reduction in acquisition time can routinely be realized for each indirect time dimension that employs nonuniform sampling, making this approach a valuable complement to cryogenic probes and high-field magnets for the most demanding biomolecular NMR applications. The approach is especially well suited for high-throughput applications of NMR spectroscopy in drug discovery.

The development of Fourier transform (FT) NMR spectroscopy by Ernst and Anderson [1] in the late 1960s set the stage for the subsequent development of multidimensional experiments [2–4]. By resolving individual nuclear coherences, these experiments enable systematic determination of the structure of biological macromolecules in solution. However, the need to avoid spectral aliasing when using the discrete FT (DFT) to compute frequency spectra from the time domain data imposes substantial data collection requirements; it is not unusual for each additional dimension to increase the amount of data that must be collected, and the time required to complete the experiment, by two orders of magnitude. The Nyquist theorem places a lower bound on the sampling rate, or time between samples (the dwell time), needed to avoid aliasing. This rate is inversely proportional to the width of the spectrum. Frequency resolution comparable to the natural line widths of the resonances is needed to exploit the dispersion of resonances at a given magnetic field, and high-resolution requires data collected at long acquisition times, in essence because the closer two resonances are in frequency, the longer it takes for a detectable difference in their signals to evolve. Since the DFT requires samples collected at uniformly spaced intervals, acquiring data at long acquisition times requires collecting samples at all of the intervening multiples of the dwell time. The data collection requirements increase with increasing magnetic field, because the increased dispersion of resonances necessitates shorter dwell times.

In the 1980s, linear prediction (LP) extrapolation of NMR data beyond the sampled interval was introduced [5,6], and it remains in common use today. LP extrapolation dramatically reduces the need for aggressive apodization when working with short data records, providing improvements in both sensitivity and resolution in favorable situations. However, LP has drawbacks; it has recently been shown that LP extrapolation generates false-positive peaks when applied to noisy data or when used to extrapolate too far beyond the measured interval [7]. A more subtle but insidious defect is that LP extrapolation can cause slight frequency shifts of real signals in these situations. These shifts are not apparent on casual inspection but have potentially serious consequences, such as improper resonance assignments. Furthermore, the extent to which NMR data can be extrapolated using LP depends mainly on the signal-to-noise (S/N) ratio, and consequently additional LP extrapolation is not a general solution to increased data requirements imposed by the increased spectral dispersion at higher magnetic fields.

Conventional approaches employing the DFT, including LP extrapolation, require acquisition times that can be prohibitively long, especially for biomolecules that are fleetingly stable or for data collected at very high magnetic field. Thus, there is considerable impetus for developing alternative methods that can produce high-resolution multidimensional spectra in less time. A wide variety of different approaches are actively being developed. One approach involves multiplexing, resulting in coherence frequencies that encode more than one resonance frequency in a single dimension. These include "reduced dimensionality" experiments such as G-matrix FT (GFT) [8,9] and Hadamard encoding [10]. A drawback of these approaches is that they require special radiofrequency pulse sequences as well as additional post-processing steps to disentangle the multiplexed

Graham A. Webb (ed.), Modern Magnetic Resonance, 1305–1311.
© 2008 Springer.

frequencies. A different approach to multiplexing has been developed by Frydman and colleagues [11], which utilizes orthogonal magnetic field gradients to partition the sample into "subsamples," each reporting a different part of the spin response. This approach is not practical when sensitivity is already a limiting factor for measuring the response of the entire sample, but as advances in probe technology continue to improve sensitivity and gradient strength (which determines the resolution), it will likely find increasing application in biomolecular NMR. Parametric methods that model the NMR signal as a sum of exponentially decaying sinusoids, such as LP singular value decomposition [12], Hankel SVD [13], filter diagonalization method (FDM) [14], maximum likelihood [15], and Bayesian [16] methods are in principle capable of producing high-resolution spectra from very short data records. These methods often exhibit "spontaneous splitting," resulting in multiple sinusoids for a single resonance when applied to noisy or nonideal (non-Lorentzian) data, complicating the parametric interpretation. Indeed the regularized resolvent transform [17], in which an FDM-like approach is used to extrapolate the signal, rather than compute a parametric decomposition, was developed to avoid this problem.

Another class of methods utilizes symmetries or redundancy in multidimensional spectra to avoid acquiring all combinations of the evolution times for the different dimensions. An approach inspired by the methods used in medicine to reconstruct images in computerized axial tomography exploits the relationship between line projections in the frequency domain and linear cross sections in the time domain. Called back-projection reconstruction [18], this approach can, in favorable circumstances recover a complete two-dimensional spectrum from a small number of cross sections through the full time domain data matrix. However, it has been pointed out that in the general case *n* cross sections are needed to unambiguously resolve *n* peaks in multiple dimensions [19], and for complex biomolecules, this may not result in significant time savings. Another approach, called three-way decomposition [20], exploits the fact that line shapes in multiple dimensional spectra can be decomposed into products of one-dimensional line shapes.

Back-projection reconstruction and three-way decomposition are special cases of nonuniform sampling in the time domain. In principle, any method that approaches spectrum reconstruction as an inverse problem, that is, computes spectra and inverts the spectrum to obtain "mock" data that are then compared with the empirical data for consistency, can be used with nonuniformly sampled time domain data. A very general method that makes no assumptions regarding the nature of the signals, and imposes no particular constraints on the subset of the time domain data matrix that must be collected, is maximum entropy (MaxEnt) reconstruction [21]. It has been shown recently to be particularly robust, yielding fewer false positives and more accurate frequencies than LP extrapolation [7]. It is also versatile: it can be used to construct spectra from the same data utilized by back-projection reconstruction, or can be used in combination with other methods, such as GFT (Jim Sun and Gerhard Wagner, personal communication). In principle, it can be used with any pulse sequence, and the computed spectra are compatible with conventional analysis tools developed for Fourier spectra. In this chapter, we describe the use of nonuniform sampling and MaxEnt reconstruction in multidimensional NMR experiments and its application to biomolecules. In practice, factors of two to three savings in data acquisition time per indirect time dimension are readily achieved. The robustness and versatility of MaxEnt reconstruction make it a powerful tool for improving sensitivity and resolution, and saving time in biomolecular NMR experiments.

MaxEnt Reconstruction

The MaxEnt reconstruction of the spectrum of a complex-valued time series **d** is the spectrum **f** which maximizes the entropy $S(\mathbf{f})$, subject to the constraint that the mock data **m**, given by the inverse DFT of the spectrum, is consistent with the time series **d**. Consistency is defined by the condition

$$C(\mathbf{f}, \mathbf{d}) \leq C_0 \tag{1}$$

where $C(\mathbf{f}, \mathbf{d})$ is the unweighted chi-squared statistic,

$$C(\mathbf{f}, \mathbf{d}) = \sum_{i=0}^{M-1} |m_i - d_i|^2 = \sum_{i=0}^{M-1} |\mathrm{IDFT}(\mathbf{f})_i - d_i|^2, \tag{2}$$

and C_0 is an estimate of the noise level; IDFT is the inverse DFT. A definition of the entropy $S(\mathbf{f})$ applicable to complex-valued spectra can be derived from consideration of the entropy of an ensemble of spin-1/2 particles [22] or by extending the Shannon information formula to the complex domain along with suitable differentiability conditions [23]. The two approaches yield equivalent formulations for the entropy of a complex spectrum

$$S(\mathbf{f}) = -\sum_{n=0}^{N-1} \frac{|f_n|}{def} \log\left(\frac{|f_n|/def + \sqrt{4 + |f_n|^2/def^2}}{2}\right) - \sqrt{4 + |f_n|^2/def^2}, \tag{3}$$

where *def* is a scale factor. In principle, the quantum-mechanical derivation prescribes the value of *def* (it depends on the sensitivity of the spectrometer and the number of spins in the sample), but it is more convenient to treat *def* as an adjustable parameter. Essentially, it determines the scale at which the nonlinearity of MaxEnt becomes pronounced. The MaxEnt solution is found by maximizing the objective function

$$O = S(\mathbf{f}) - \lambda C\left(\mathbf{f}, \mathbf{d}\right), \qquad (4)$$

where the value of the Lagrange multiplier λ is adjusted to obtain $C = C_0$. The value of λ depends on the values of the parameters *def* and C_0, and on the data. Practical guidelines for choosing the values of *def* and C_0 are described elsewhere [24].

The formulas for entropy and constraint readily generalize to multidimensional data. However, because MaxEnt reconstruction is nonlinear, MaxEnt must be the last time-to-frequency transformation applied. So if MaxEnt is to be used in t_1, then the t_2 dimension must be transformed to the frequency domain first. And if MaxEnt is to be used for both t_1 and t_2, then it must be applied to both dimensions simultaneously, rather than one at a time. The IDFT operation appearing in Equation (2), and the corresponding sums in Equations (2) and (3), can be applied along as many dimensions as one likes.

Applying MaxEnt to reconstruct separately each t_1 row, or each t_1–t_2 plane, of a three-dimensional spectrum raises another problem. The extent of the nonlinearity of the reconstructions can vary from row to row (or from plane to plane), resulting in distorted peak shapes. One way to avoid this is to process the entire data set as a single unit, extending the sums in Equations (2) and (3) to cover the entire spectrum, rather than working on a single row or plane at a time. Of course, such an approach will entail drastically increased data storage requirements. A simpler solution is to use a fixed value of λ rather than iterating to attain $C = C_0$ [25]. The correct value for λ can be determined by choosing a representative row, then computing the normal MaxEnt reconstruction with an appropriate value for C_0. In quantitative applications, it is important to use one of these methods—full data set MaxEnt reconstruction or constant λ reconstruction—to assure that the nonlinearity is uniform across the spectrum, and thus it can be calibrated in a reliable way.

The nature of the nonlinearity of MaxEnt reconstructions is fairly well understood—in general, MaxEnt reconstruction tends to scale intensities down, compared to the DFT, with small amplitudes scaled down more than large amplitudes [26]. In addition to requiring calibration when used for quantitative applications, such as measuring nuclear Overhauser effects, the nonlinearity of MaxEnt reconstruction heightens the distinction between sensitivity, which is the ability to distinguish peaks from noise, and signal-to-noise ratio (S/N). For MaxEnt reconstruction, S/N is not a reliable indicator of sensitivity.

Nonuniform Sampling

The matched filter is a function that follows the decay envelope of the FID; multiplying the FID by the matched filter results in optimal S/N in the DFT spectrum [27]. In essence, the matched filter places more emphasis on the portion of the data where the S/N (in the time domain) is highest. The same idea can be applied to sampling in the time domain: instead of sampling at uniform intervals, the signal can be sampled more frequently when it is strong, and less frequently when it is weak [28–32]; we call this nonuniform sampling. Nonuniform sampling prevents the use of LP or the DFT, since they require data sampled at uniform intervals, but MaxEnt handles such data because the chi-squared statistic in Equation (2) can be computed from just the collected samples. Nonuniform sampling provides additional flexibility in balancing the trade-offs between acquisition time, resolution, and sensitivity. The potential for time saving accrues in the indirect time dimensions of multidimensional experiments, since the relaxation delay between transients renders the total acquisition time insensitive to the number of samples acquired in the direct time dimension. In contrast, the total experiment time increases in direct proportion to the number of indirect time samples.

A list of evolution times for which data are acquired is called a sampling schedule. Examples of nonuniform sampling schedules are depicted in Figure 1. A uniform grid is used to signify evenly spaced points in the various time dimensions. A large dot indicates a sampled time interval and small dots indicate times not sampled. Panel A illustrates an exponential sampling schedule in one indirect dimension (t_1), and panel B illustrates an exponential sampling schedule in two indirect dimensions. Panel C also illustrates a schedule employing randomly selected points chosen from a two-dimensional exponential distribution; this helps to suppress coherent artifacts that can be introduced by schedules that use exactly the same time values for successive rows or columns (such as the schedule in panel B). Panel D illustrates a schedule appropriate for reduced sampling of constant-time dimensions, where there is no decay. For COSY-type spectra, an optimal sampling schedule can be constructed from a sine-modulated exponential distribution. In principle, it is possible to construct more complex sampling schedules that make explicit consideration of the dimensionality of the experiment or the distribution of expected frequencies, for example, along the lines of the samples used for back-projection reconstruction.

Example Applications

Comparisons of spectra obtained using conventional linear sampling and nonuniform sampling applied to two

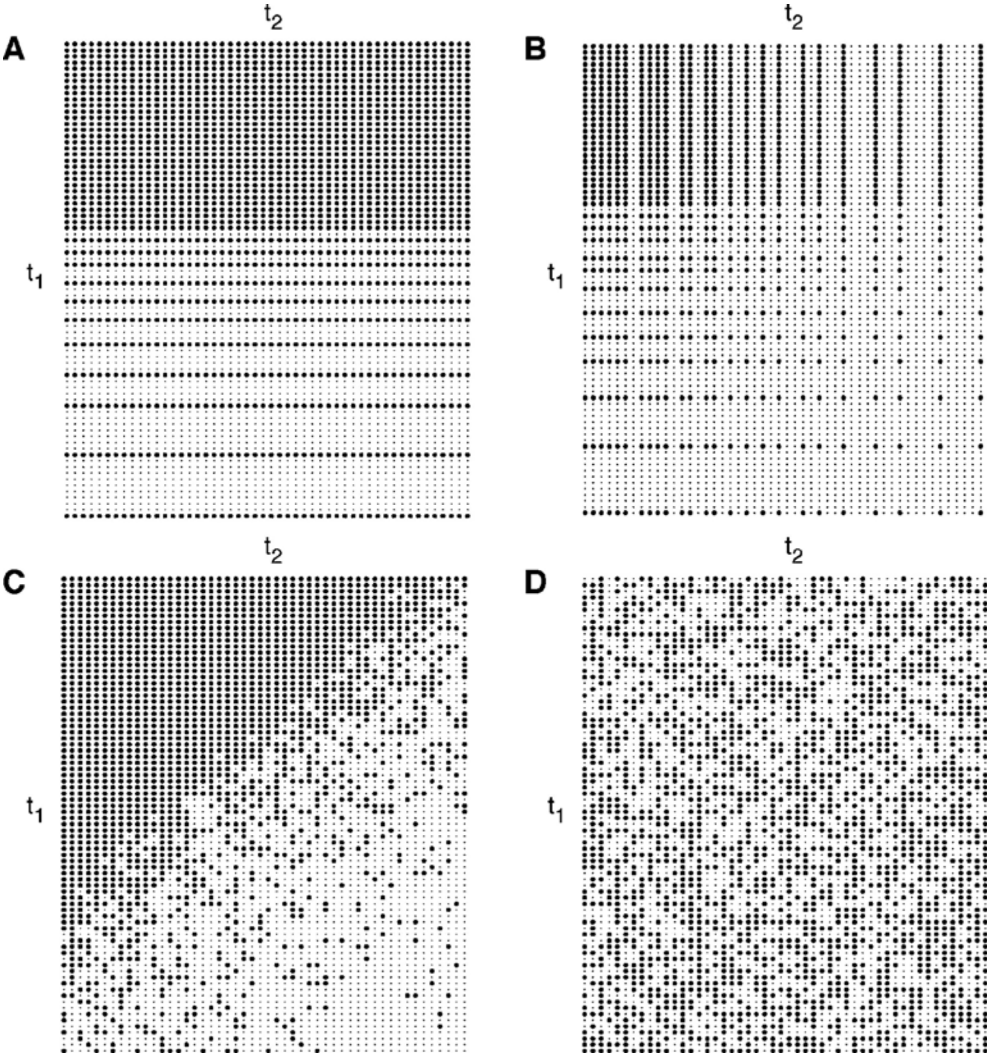

Fig. 1. Nonuniform sampling schedules in one and two indirect time dimensions. Large and small dots indicate times for which samples are collected and not collected, respectively. The schedules depicted are (A) exponential in t_1 and linear in t_2, (B) exponential in both t_1 and t_2, (C) randomly sampled from an exponential distribution in t_1 and t_2, and (D) random in t_1 and t_2.

experiments important for pharmaceutical applications of protein NMR are shown in Figures 2 and 3. Figure 2 shows ^{15}N–^{1}H HSQC spectra of a 42-residue atracotoxin from the Australian funnel-web spider *Hadronyche versuta*. Panel A is the spectrum computed using LP extrapolation, shifted sine-bell windowing, and DFT to produce a 1024-point spectrum in f_1 from 512 uniformly spaced samples in t_1. Panel B was computed in the same fashion and to the same size in f_1, using 64 samples in t_1. The spectrum in panel C was computed using MaxEnt reconstruction, using 64 t_1 samples with exponentially increasing time between samples. Panels D, E, and F show an expanded region of panels A, B, and C, respectively. The resolution obtained from 64 t_1 samples using MaxEnt reconstruction and nonuniform sampling is comparable to that obtained using uniform sampling and conventional processing; however, data acquisition required a factor of eight less time. This time saving can be important for high-throughput applications such as screening compound libraries for molecules that bind to a protein target.

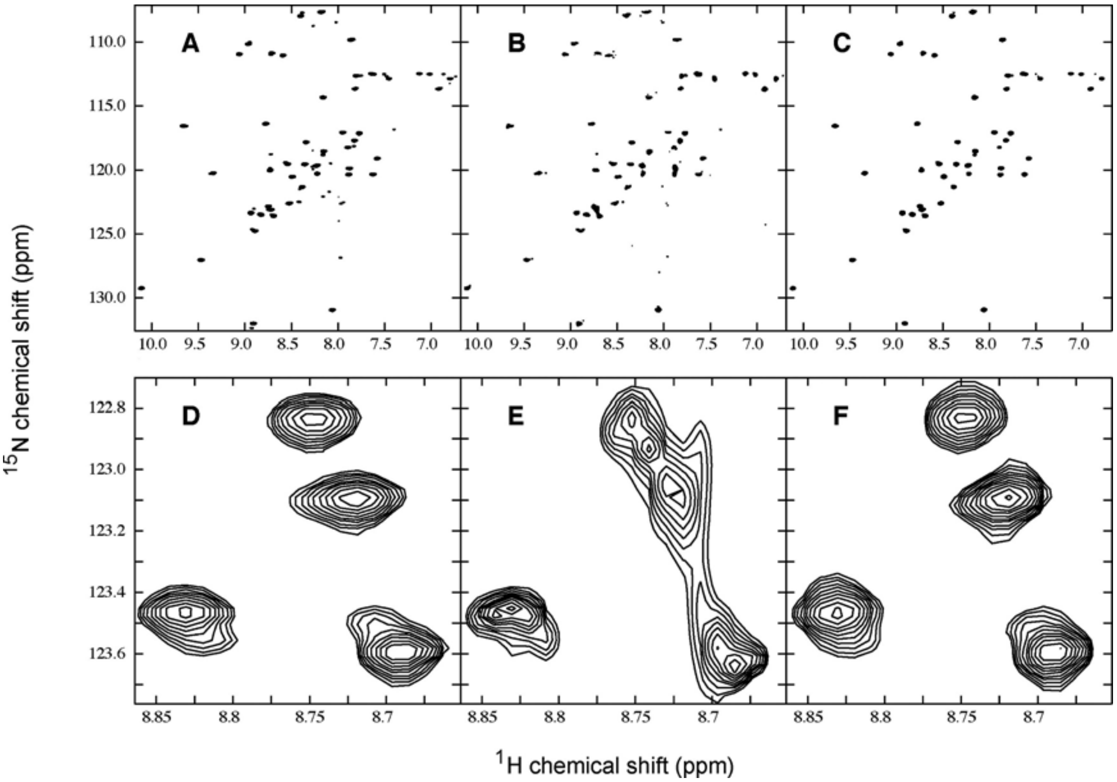

Fig. 2. ^{15}N–^{1}H HSQC spectra for a 42-residue atracotoxin. (A) Computed using LP extrapolation and DFT from 256 linearly spaced samples in t_1, (B) using LP extrapolation and DFT from 64 linearly spaced samples in t_1, and (C) using MaxEnt reconstruction from 64 exponentially spaced samples in t_1. Panels D, E, and F depict an enlarged region from panels A, B, and C, respectively.

Extension of nonuniform sampling and MaxEnt reconstruction to two indirect time dimensions is straightforward, enabling the acquisition of triple resonance spectra for sequential assignment of proteins in 1 day [33]. Experiments in which the signals of interest span a wide range of intensities (such as those involving nuclear Overhauser effects) remain a challenge. The very nature of the nonlinearity of MaxEnt reconstruction, which is to scale down weak signals more than strong signals, makes it more difficult to choose parameters of the reconstruction (*def* and C_0) that enable weak signals to be distinguished from noise. Nonuniform sampling can introduce additional nonlinearities. An example is shown in Figure 3, in which exponential nonuniform sampling and MaxEnt reconstruction have been applied to the two indirect dimensions of a 3D ^{15}N–^{1}H HSQC-NOESY experiment. Panels A and B shows f_1–f_3 cross sections at the f_2 frequency 120.27 ppm, close to the amide ^{15}N chemical shift of residue Cys 21 (120.24 ppm); A is from the linearly sampled DFT spectrum and B is computed using MaxEnt reconstruction from data containing one-eighth fewer samples. Remarkably, the MaxEnt spectrum exhibits resolution superior to the spectrum computed from the larger linearly sampled data set. This is evidenced by the disappearance of resonances at the f_3 frequencies of 8.69 and 8.22 ppm, which correspond to residues with amide ^{15}N chemical shifts of 120.53 and 120.30 ppm, respectively, which have maxima in adjacent f_2 planes. However, the nonlinearity (which depends on the values chosen for *def* and C_0, as well as the sampling schedule) in this instance makes it difficult to observe several weak peaks. Panels C and D are linear cross sections from panels A and B at the f_3 frequency of the amide proton of Cys 21, scaled vertically to the height of the maximum in each panel. While the noise level is greatly reduced, so are the weak peaks, making clear the difficulty caused by high dynamic range.

While careful choice of the nonuniform sampling schedule and parameters of the MaxEnt reconstruction can in principle permit observation of the missing weak

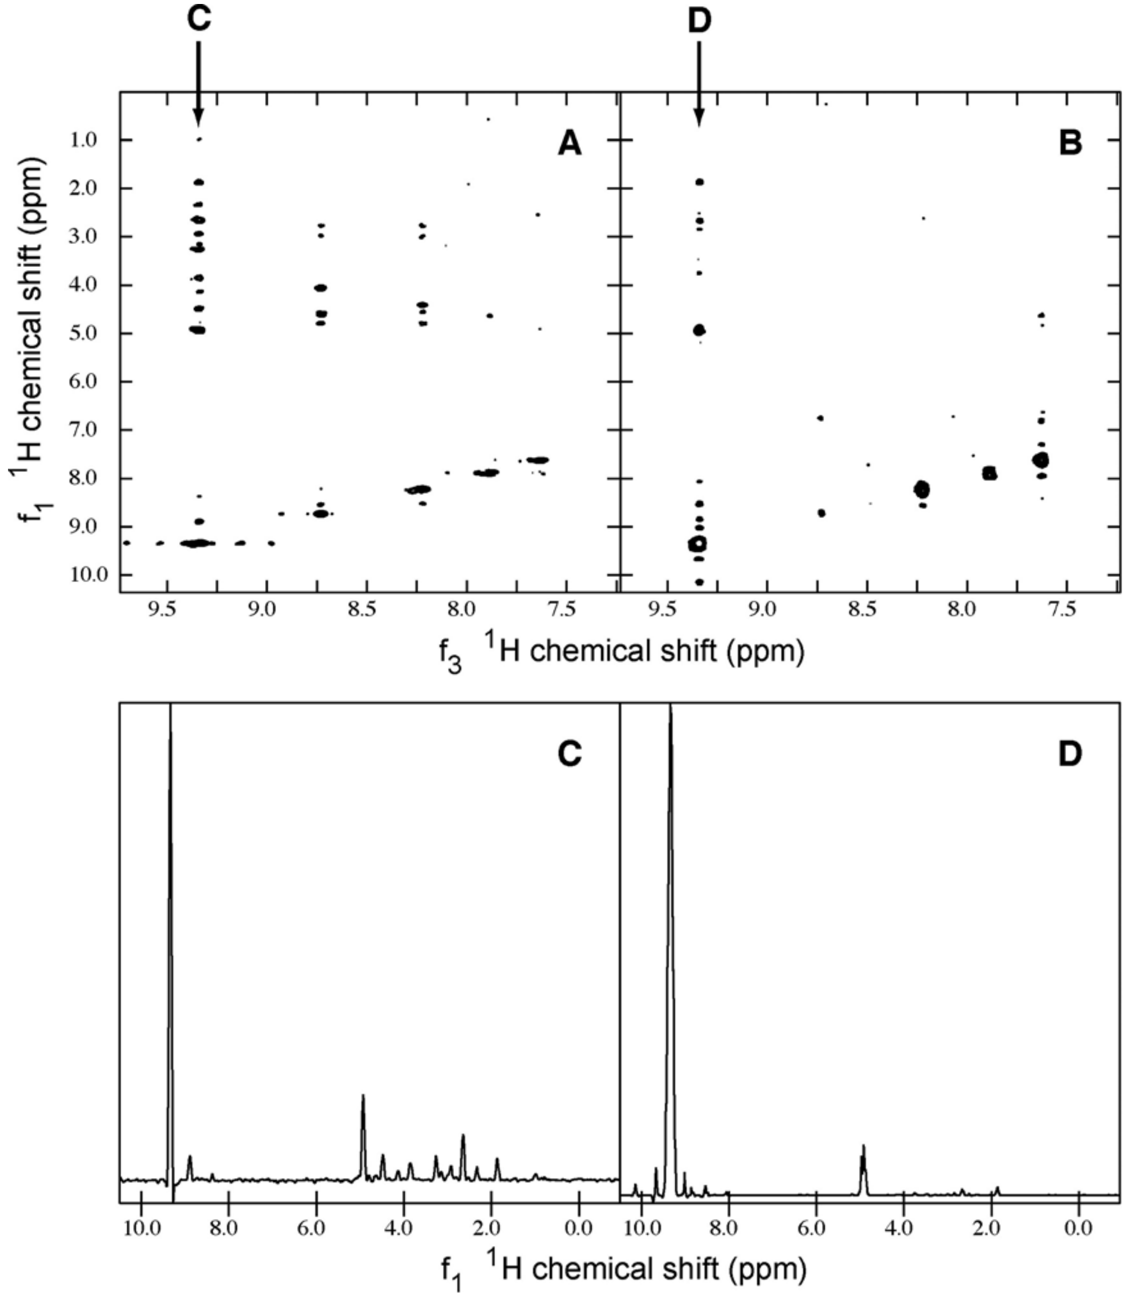

Fig. 3. Two-dimensional cross sections at $f_2 = 120.27$ ppm from 3D ^{15}N–^{1}H HSQC-NOESY spectra of a 42-residue atracotoxin. (A) Computed using LP extrapolation and DFT, (B) using nonuniform sampling in t_1 and t_2 and MaxEnt reconstruction. (C) and (D) are linear cross sections from panels A and B at the f_3 frequency of the amide proton of Cys 21 (9.34 ppm).

peaks (for example, using a small value for C_0 decreases the nonlinearity of the reconstruction), determination of the appropriate values is by no means straightforward, and remains the subject of active research [34]. Regardless of the application, the nonlinearities make error analysis an important adjunct to nonuniform sampling and MaxEnt reconstruction.

Concluding Remarks

MaxEnt reconstruction is a particularly versatile method of spectrum analysis, capable of providing high-resolution spectral estimates from short data records. Its ability to determine spectra from data sampled at arbitrary times enables the use of nonuniform sampling to improve resolution or reduce data acquisition time. Model-based methods, such as Bayesian analysis or FDM, offer many of the same capabilities but are not suited to the computation of spectra containing non-Lorentzian lines. The availability of efficient algorithms and powerful computers has removed what were once perceived as significant barriers to the widespread application of MaxEnt reconstruction in NMR. The ability to collect high-resolution spectra in substantially less time not only enables more efficient use of expensive spectrometers, but also enables investigation of biomolecular systems that are fleetingly stable. These capabilities are particularly well suited to the demands of applications of NMR in drug discovery, including high-throughput screening and rapid assignment of protein spectra.

Applications

Structural Characterization of Antimicrobial Peptides by NMR Spectroscopy

Leonard T. Nguyen, Elmar J. Prenner, and Hans J. Vogel
Structural Biology Research Group, Department of Biological Sciences, University of Calgary Alberta, Canada T2N 1N4

Introduction

Antimicrobial peptides are ubiquitous in nature and they aid in host defenses against bacterial infections. While initial discoveries of bacterial peptides go as far back as the 1950s, the 1990s saw an explosion in research to isolate novel peptides from all kingdoms of life. Out of the more than 800 eukaryotic peptides reported in the Antimicrobial Sequences Database (found at www.bbcm.units.it/∼tossi/pag1.htm), more than 700 entries were reported since 1990. The rapid growth of this field is fueled by the potential of these compounds to be used in a clinical setting [1,2] and replace commonly used antibiotics. The latter are losing potency against disease-causing bacterial strains that are increasingly becoming resistant. The unique qualities of the various antimicrobial peptides make them an incredibly diverse family in terms of sequence, structure and by extension, mechanism of action [3].

Typically shorter than 50 amino acid residues, antimicrobial peptides are prime candidates for structural study by NMR spectroscopy. Cyclic and disulfide cross-linked peptides usually have a stable structure in aqueous solution. However, many of the linear peptides do not form defined structures in aqueous solution and do so only in a membrane mimetic environment [4]; this finding supports the idea that peptide-lipid interactions are critical for antimicrobial action and/or insertion [5]. In addition to solution structures calculated mostly from standard two-dimensional TOCSY and NOESY ^{1}H experiments [6], much progress has been made to characterize the insertion and orientation of the peptides in membrane bilayers through solid-state NMR measurements [7]. This chapter will examine the progress in structural studies of antimicrobial peptides by NMR. Recent reviews have described the solution structures of antimicrobial peptides in an attempt to elucidate general themes and mechanisms [8,9]. Therefore to avoid overlap in this chapter we will highlight the versatility of NMR as a tool to characterize the solution structures of antimicrobial peptides which possess some unique features. In addition, we will describe some solid-state NMR studies which focus on several well known peptides.

Solution Structures of Antimicrobial Peptides

To date, more than 100 unique three-dimensional structures of antimicrobial peptides have been solved by NMR. The complete list consists of more than 80 parent peptides and roughly 20 synthetic peptide derivatives, resulting in great variability. Table 1 summarizes the information for selected solution structures of peptides that have been studied because of their potential as bactericidal agents. In order to be useful, such peptides cannot have high toxicity toward mammalian cells. Some representative structures are shown in Figures 1 and 2. Well-characterized antimicrobial peptides include magainin 2 from the skin of the African clawed frog (Figure 1A) [10], protegrin-1 from mice (Figure 1B) [11], and several members of the defensin family (Figure 2). Some rather distinct antimicrobial peptides have been included in Table 1 as well: These are human hepcidin (Figure 1C) [12], which is better known as a peptide involved in the regulation of iron absorption [13], three gramicidin S derivatives [14], which are listed in spite of the fact that the parent gramicidin S compound, which is secreted from a Bacillus species [15], possesses significant hemolytic activity, and a completely synthetic peptide, combi-1 [16], that was obtained by screening from a library of hexa-peptides produced by combinatorial chemistry.

Various structural classification schemes have been used in the past ([8] for example). However, given the wide diversity of the peptides, a satisfactory organization scheme can misrepresent the properties of certain peptides. Nevertheless, the eukaryotic cationic peptides are often classified into broad groups according to the secondary structure of the parent peptide. As such researchers often talk about helical, β-sheet, turn or extended peptides. This nomenclature can be somewhat misleading at times as some of the larger peptides should really be considered as mini-proteins with various types of secondary structure. For example, insect defensin A [17], as a defensin, is grouped as a β-sheet peptide even though there is an α-helix present in the structure in addition to several β-strands. It should also be noted that sometimes the structure of a synthetic derivative deviates from that of the parent peptide. This is seen for a shortened derivative of

Table 1: Examples of NMR derived high-resolution solution structures of antimicrobial peptides

Peptide	Class	Membrane Mimetic[a]	Source	Ref.
Cecropin A	α-helix	HFIP	*Hyalophora cecropia*	[87]
Cecropin A-Magainin 2 hybrid (CA-MA) (4)[b]	α-helix	DPC, None	Synthetic	[88]([89])c
Cecropin A-Melittin hybrid (CA-ME)	α-helix	DPC	Synthetic	[88]
Magainin 2 (1)	α-helix	DPC, SDS,TFE	*Xenopus laevis*	[10]([90])
Ovispirin-1 (2)	α-helix	TFE	Synthetic (from *Ovis aries*)	[91]([91])
PGLa	α-helix	DPC	*Xenopus laevis*	[92]
Sheep myeloid antimicrobial peptide (SMAP-29)	α-helix	TFE	*Ovis aries*	[93]
Bovine lactoferricin (1)	β-sheet	None	*Bos taurus*	[19]([18])
Drosomysin	β-sheet	None	*Drosophila melanogaster*	[41]
γ-1-H thionin	β-sheet	None	*Hordeum vulgare*	[42]
Hepcidin-20 and -25	β-sheet	None	*Homo sapiens*	[12]
Human β defensin-3 (HBD-3)	β-sheet	None	*Homo sapiens*	[44]
Human neutrophil protein-1 (HNP-1)	β-sheet	None	*Homo sapiens*	[39]
Insect defensin A/Phormicin	β-sheet	None	*Protophormia terraenovae*	[17]
NaD1 floral defensin	β-sheet	None	*Nicotiana alata*	[94]
Protegrin-1 (2)	β-sheet	None, DMSO	*Sus scrofa*	[11]([95,96])
Rabbit kidney defensin 1 (RK-1)	β-sheet	None	*Oryctolagus cuniculus*	[97]
Rhesus θ defensin-1 (RTD-1)	β-sheet	Acetonitrile	*Macaca mulatta*	[47]
Tachyplesin I (3)	β-sheet	None	*Tachypleus tridentatus*	[98]([98])
Tachystatin A	β-sheet	None	*Tachypleus tridentatus*	[99]
Ac-RRWWRF-NH2 (Combi-1)	Extended	SDS	Synthetic	[16]
Indolicidin (1)	Extended	SDS, DPC	*Bos taurus*	[21]([20])
Tritrpticin	Turn	SDS	Synthetic (from *Sus scrofa*)	[100]
NK-lysin	Loop	None	*Homo sapiens*	[101]
Thanatin	Loop	None	*Podisus maculiventris*	[102]
Bacteriocins				
Carnobacteriocin B2	α-helix	TFE	*Carnobacterium piscicola*	[103]
Gramicidin S derivatives (3)	Loop	None	Synthetic (from *Bacillus brevis*)	([14])
Microcin J25	Loop	None	*Escherichia coli*	[36,61,62]
Nisin A	Turn	DPC, SDS	*Lactococcus lactis*	[30]

[a] Abbreviations used for membrane mimetic present are as follows: TFE, trifluoroethanol; DPC, dodecylphosphocholine micelles; HFIP, hexafluoroisopropanol; SDS, sodium dodecyl sulfate micelles, and DMSO, dimethyl sulfoxide.

[b] Number in parentheses denotes the number of derivatives from a parent peptide for which structures are available.

[c] Number in parentheses in the reference column refers to the structures of the derivatives.

bovine lactoferricin [18] which forms an extended peptide structure even though intact bovine lactoferricin itself [19] adopts a β-sheet conformation. Also, a cyclized derivative [20] of indolicidin [21] has quite a different structure than its parent compound.

The prevalent theme among all eukaryotic cationic peptides is a structure with an amphipathic character. Thus the vast majority of the peptides have a preponderance of basic and hydrophobic amino acids, yet they have no sequence homology. The cationic side of the structure is responsible for electrostatic interactions with the bacterial membranes, which have a high abundance of negatively charged phosphatidylglycerol phospholipids head groups. The charge-charge interactions are thought to be an important factor in providing long-range attraction between the peptide and bacterial membranes [3]. This mechanism allows for broad specificity in target cells while retaining low toxicity to eukaryotic membranes, which mostly have

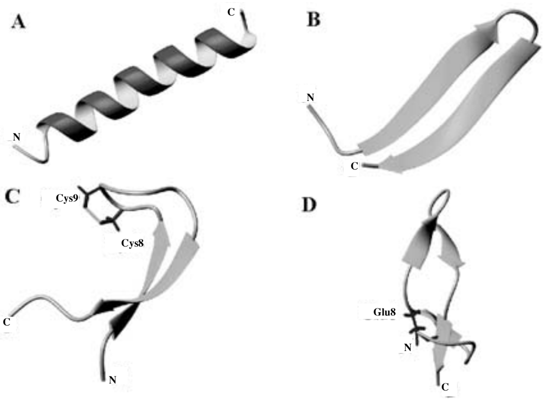

Fig. 1. Representative solution structures of antimicrobial peptides presented as ribbon diagrams: (A) magainin 2 (PDB ID 2MAG) in TFE solution, (B) protegrin-1 (PDB ID 1PG1), (C) hepcidin-20 showing the vicinal disulfide link between Cys8 and Cys9 (PDB ID 1M4E), and (D) microcin J25 showing the amide link between the sidechain of Glu8 and the N-terminal amino group (PDB ID 1Q71). These figures were prepared using MOLMOL [104]. (See also Plate 100 on page XX in the Color Plate Section.)

zwitterionic phosphatidylcholine head groups. However, a few anionic peptides from eukaryotic sources have been identified, for example in human lungs where Zn^{2+} chelation is required for activity [22], or from the toad *Bombina maxima* where the activity does not require the presence of cations [23]. The hydrophobic portion of the antimicrobial peptides allows them to interact with the acyl chain region of membrane bilayers. The amphipathicity that balances both facets of the peptides plays a key role in target selectivity, as peptides that have greater hydrophobicity usually act as general toxins, such as the bee venom melittin [24].

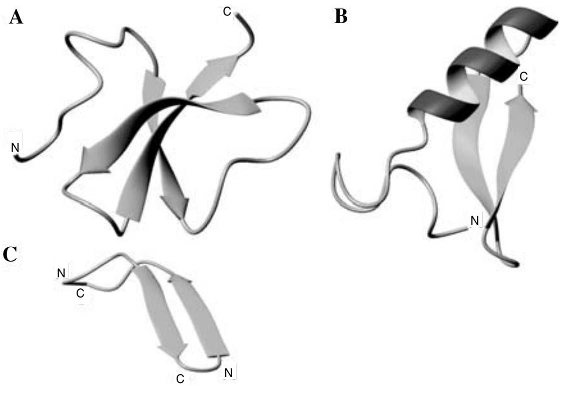

Fig. 2. Solution structures of some defensin peptides in ribbon diagram: (A) bovine neutrophil β-defensin-12 (BNBD-12) (PDB ID 1BNB), (B) insect defensin A (PDB ID 1ICA), and (C) rhesus θ-defensin (RTD-1) (PDB ID 1HVZ). These figures were prepared using MOLMOL [104]. (See also Plate 101 on page XX in the Color Plate Section.)

Almost all α-helical linear peptide structures were solved using either a micelle suspension or an organic co-solvent environment because the vast majority does not form a defined structure in aqueous solution. Highly represented in this category are the peptides obtained from the skins of frog or toad species. β-sheet peptides meanwhile, which encompass the mini-protein defensin family, come from a variety of plants and animals and are known for their characteristic disulfide linkages between cysteine residues [25,26]. Highly disulfide bridged peptides quite frequently act as antimicrobial peptides because the crosslinking would reduce their flexibility and promote stability against proteolytic enzymes. In contrast to the α-helical peptides, structures of the β-sheet peptides have mostly been solved in an aqueous environment and in fact, binding of protegrin-1 to lipid bilayers resulted in aggregation, which prevented detailed structural analysis [27,28]. Highly oligomerized peptides on membrane-mimetic surfaces, while possibly more representative of *in vivo* behavior, unfortunately pose difficulties in structure elucidation.

Also included in Table 1 are a few antimicrobial peptides from bacterial origin. Bacteria use these to protect themselves from unrelated microbes in their ecological niche. These “biological warfare” peptides contain many unusual amino acids which are either the result of extensive post-translational modifications of ribosomally synthesized peptides (e.g. lantibiotics and microcins) or they are synthesized non-ribosomally on large peptide synthesis complexes (e.g. peptaibols). These peptides, often referred to as bacteriocins [29], have been the focus of many studies and nisin A [30] from *Lactococcus lactis* particularly has received a lot of attention to date, because this peptide is currently widely used as a food preservative [32]. Moreover, it is active at lower concentrations than the cationic antimicrobial peptides. The more potent activity could be explained when it was discovered that nisin, and related lantibiotics, form a specific complex with phospholipid II, a precursor for bacterial cell wall biosynthesis [33,34]. Very recently, an NMR paper was published showing the complex structure of nisin with lipid II (Figure 3) [35]. This is a unique contribution as lipid/peptide interactions are usually too transient to experimentally capture their complex structures. The reader is encouraged to read this intriguing paper describing the “pyrophosphate cage” structure for the nisin/lipid II complex. The solution structure of microcin J25 (Figure 1D) [36], another bacterial peptide with uncommon biochemical properties, will be discussed later in this chapter.

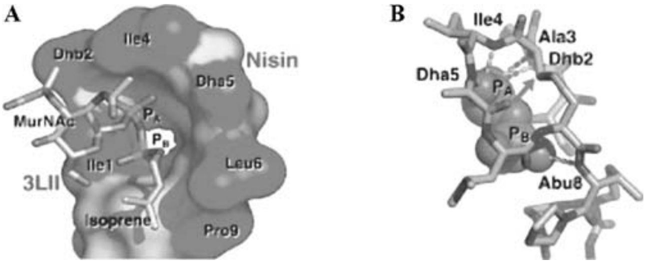

Fig. 3. The contact region between nisin and 3LII, a lipid II variant, as determined from the NMR solution structure of the complex in dimethyl sulfoxide. (A) The N-terminal part of nisin (shown in van der Waals surface) encages the two phosphate groups (P_A and P_B) of 3LII, which also contains the amino sugar N-acetylmuramic acid (MurNAc) and an isoprene tail. The side chains of nisin are labeled, with the dehydrated residues dehydroalanine, Dha, and dehydrobutyrine, Dhb. (B) The intermolecular hydrogen bond network between the nisin backbone and the 3LII pyrophosphate group (in spheres). Hydrogen bonds with high occurrence in the ensemble of structures are indicated by dashed lines, with corresponding residues labeled (with Abu representing α-aminobutyric acid). An arrow indicates the position of Ala3-Cβ, at which bioactivity is disrupted by the addition of a methyl group. The figures were taken with permission from Hsu *et al.* [35]. (See also Plate 102 on page XXI in the Color Plate Section.)

Defensins; Structure Determination and Dimerization Properties

The defensins (Figure 2) are cationic antimicrobial miniproteins that play a key role in the innate immune defense of organisms. Major families are found in plants, insects, and vertebrates including humans. They are distinguished by the position and cross-linking patterns of six disulfide-bonded cysteine residues. A three-stranded β-sheet structure is found in most of the defensins. Plant and insect defensins have their own distinct disulfide connectivity patterns while the disulfides of the mammalian defensins [26] are separated into three major classes: the α- and β-defensins and the more recently discovered θ-defensins. Along with the cathelicidins [37], the defensins make up the major family of antimicrobial peptides produced in humans. They are of great biological importance as they can also play a key role in stimulating the adaptive immune response, substituting for chemokines [28]. They are found on the skin and other epithelial linings and in phagocytic neutrophils [26].

Defensins are of a small enough size (30–50 amino acids) that their proton NMR spectra can be fully assigned by regular TOCSY and NOESY NMR spectroscopy [6]. The first structures solved were those of rabbit neutrophil defensin-5 (NP-5) [38], NP-2 [39], and human neutrophil protein-1 (HNP-1) [38]. These early studies revealed a typical monomeric defensin structure with an amphipathic triple stranded antiparallel β-sheet. The structure was further characterized by hairpin formation and several other tight turns which appear to be stabilized by the disulfide bonds. The structure of the bovine neutrophil β-defensin-12 (Figure 2A) was also shown to be similar to the previously studied α-defensins [40]. While the structure of insect defensin A (Figure 2B) has similar features to the mammalian defensins, it contains an additional "cysteine-stabilized α-helix" (CSH) motif where the α-helix is stabilized by disulfide bridging to the nearby antiparallel β-sheet [17]. This CSH motif is also found in other insect defensins such as in drosomycin from *Drosophila melanogaster* [41] as well as in a few plant defensins such as the γ-1-H and γ-1-P thionins from *Hordeum vulgare* and *Triticum turgidum*, respectively [42].

While the majority of the structures of the defensins show monomeric molecules, a few human peptides are thought to dimerize at low concentrations in aqueous solution. The rationale for this is unclear but it may be a first-step toward oligomerization which is required for pore formation in membranes. For example, the crystal structure of human neutrophil protein-3 (HNP-3) [43] showed an amphipathic symmetrical dimer of peptides. Diffusion NMR and dynamic light scattering, which were used to estimate the approximate size of human β-defensin-3 (HBD-3) in solution, also suggest the presence of a dimeric complex for this peptide, but not for other β-defensins [44]. Distinct chemical shifts for a region within the first β-strand of HBD-3 indicate that it is likely involved in intermolecular β-sheet formation. However, unambiguous NOE crosspeaks in the spectra could not be found to identify the exact dimerization contacts between the two β-defensin molecules in the dimer. Diffusion NMR, using the PG-SLED approach [45], is a facile technique to study the dimerization and multimerization properties of peptides and small proteins in solution [12,44,46].

A recently solved structure of interest is that of the cyclic θ defensin-1 (RTD-1) [47] from rhesus macaque leukocytes. The biosynthesis of RTD-1 involves the translation of two α-defensin-related nonapeptides which are combined by head-to-tail backbone ligation of the peptides and the formation of three disulfide bridges between these two molecules [48]. The resulting NMR-derived structure (Figure 2C), determined in 10% acetonitrile, shows an antiparallel β-sheet with very well defined turns but an overall flexible structure as judged from the poor superposition of the final 10 structures. The lack of a well-defined structure was attributed to bending motions at the center of the cyclic peptide [47].

Hepcidin; Identification of Disulfide Cross-Linking

The structure determination of the liver-synthesized peptide hepcidin presented a challenge in establishing the correct disulfide bond connectivities. Hepcidin was originally discovered in human urine [49] and plasma ultrafiltrate [50] in two forms of 20 and 25 amino acid residues long. The peptide plays an important role in the control and regulation of iron uptake; in addition, hepcidin has also been found to have antimicrobial and antifungal properties [50]. As observed with several antimicrobial peptides, there is a high proportion of Cys in hepcidin. All eight of its Cys residues are involved in disulfide bonds [50], but the specific connectivities between the residues could not be determined by conventional proteolysis methods [51]. Therefore, the solution structure determination of the two peptides by 2D ^{1}H NMR was used to establish the connectivities [12]. As done previously for the 51-residue pheromone Er-23, where the disulfide bond pattern could also not be determined by chemical methods [52], initial structure calculations incorporated only NOE restraints and bond angle constraints, without the disulfide bonds or the hydrogen bonds being included. The initial NOE patterns of the hepcidins themselves only clarified two out of the four unambiguous disulfide links. Hydrogen exchange experiments in D_2O helped to establish the position of some hydrogen bonds, and once these were introduced all the disulfide cross-links could be assigned in further rounds of the structure calculations. This approach resulted in a highly unusual vicinal cysteine bridge between the adjacent Cys residues 8 and 9. Support for this unexpected connectivity was obtained from other NMR parameters, such as a lack of amide proton correlations in the fingerprint regions for these two residues in the TOCSY and NOESY spectra, as well as broad peaks for their α and β-protons, indicating a conformational exchange process on the NMR timescale. The role of this unique structural feature in the hepcidins is still unclear. Vicinal disulfides have been observed in a few enzymes where they were found to be critical for enzyme function [53]. They have not yet been found in any other antimicrobial peptide. The overall structure of the hepcidins is a distorted two-stranded β-sheet where the vicinal disulfide bridge is found at the turn of the hairpin. In a similar manner, disulfide connectivities have been determined on the basis of NMR experiments alone for other peptides such as the antifungal Alo-3 [54] and the insecticidal pea albumin 1, subunit b [55]. These authors used ambiguous disulfide restraints and reduced charges on the sulfur groups in the early stages of the structure calculation, with the ARIA software [56] to establish the correct connectivities.

Microcin J25; Characterization of Unusual Linkages

The bacteriocin microcin J25 is secreted by certain strains of *Escherichia coli*; its antibacterial mechanism of action has been suggested to involve cell membrane disruption [57]. However, several bacterial strains with specific mutations in the β-subunit of RNA polymerase have been found to be resistant to the peptide [58], suggesting another mode of action. The original solution structure determined for the peptide [59] revealed a distorted, highly compact β-sheet structure with the main chain N- and C-termini joined together by an amide bond.Unexpectedly, microcins with their circular backbone cleaved by thermolysin retained their antimicrobial activity as well as the core structure [60]. Subsequent NMR analysis of chemically synthesized linear and head-to-tail cyclic peptides revealed that the spectra of these synthetic peptides were different from those of the natural compound [36]. A reanalysis of the original NMR data for native microcin J25 revealed that the expected sequential NOEs linking the glycines of both termini were absent. Nevertheless, mass spectrometry of the native peptide showed that there was one extra link present in the peptide, which had been formed through a dehydration reaction. A careful NMR analysis of microcin J25 revealed that the compact peptide did not have a head-to-tail cyclized backbone, but rather a novel side chain-to-backbone ring structure (Figure 1D). This linkage involves an amide link between the amino terminus of the peptide and the carboxyl side chain of Glu 8, with an overall knot structure where the C-terminal end is threaded through the ring in a rigid conformation. In fact, this noose-shaped structure was simultaneously reported in two other independent NMR studies [61,62]. The internal cross-link found in microcin J25 has been found in other bacterial proteins, such as small peptide inhibitors [63], where it is believed to contribute to a greater resistance to proteolytic degradation.

Solid-State NMR Experiments: Peptide Orientation in Bilayers

Magainin 2

As a classical example of amphipathic α-helical antimicrobial peptides, magainin, and its natural and synthetic analogues have been intensively studied [64]. Membrane pore formation is thought to be at the center of its mechanism of action, given that magainin has been shown to disrupt the electrochemical gradient across cell membranes [65]. Hence, recent NMR studies have focused on characterizing its interactions with membrane bilayers. Residue-specific ^{15}N labeling of a series of synthetic magainin 2 peptides has been used in solid-state NMR measurements of oriented membrane samples. This work conclusively showed that the helix formed by magainin, and the related PGLa peptide, lie in an orientation that is parallel to the membrane surface of oriented bilayer samples [66], in agreement with fluorescence quenching experiments [67]. The cationic side of the magainin helix is exposed to the aqueous environment and interacts with the surrounding polar lipid head groups, while the hydrophobic half of the peptide is embedded into the membrane and interacts with the fatty acyl chains in the bilayer. Additionally, a recent hydrogen/deuterium exchange NMR experiment confirms this parallel arrangement in SDS micelles [68], with lower exchange factors associated with the hydrophobic residues and higher exchange rates seen for the polar residues.

These findings have helped in explaining the mechanism of pore formation for these peptides by excluding the “barrel-stave” model of pore formation in favor of the “toroidal” pore model [5] (shown in a schematic in Figure 4). In the barrel-stave model, lytic peptides oligomerize at very low peptide:lipid ratios on the membrane and then form peptide-lined pores by orienting perpendicularly to the membrane plane. A good example of such a barrel-stave pore is provided by alamethicin [9], a peptide that is inhibitory of prokaryotic as well as eukaryotic cells. In the toroidal pore model, after reaching a high peptide:lipid threshold, the peptides associate loosely with each other to form transmembrane pores that are lined with peptides separated by lipid head groups. This lipid-peptide rearrangement has been supported in the case of magainin 2 through fluorescence experiments showing rapid flip-flop of the lipids from one side of the bilayer leaflet to the other upon addition of the peptide [70]. Solid-state ^{31}P NMR studies of lipid bilayers showed that upon addition of MSI-78, a synthetic analogue of magainin, the temperature-dependent transition from the fluid lamellar to the hexagonal phase was inhibited [71]. This means that the peptide induced a positive curvature strain in the membrane which is consistant with toroidal pore formation.

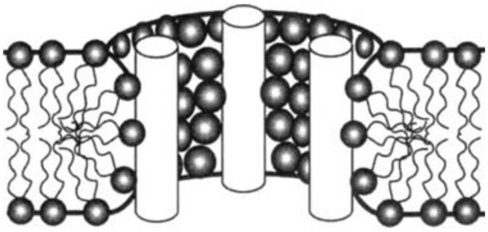

Fig. 4. The toroidal pore model as originally proposed for magainin 2. After a threshold concentration is reached, the peptides change their conformation from a parallel orientation on the bilayer plane. The peptides transiently cross the membrane to adopt a conformation perpendicular to the bilayer plane. Contacts with the phospholipid head groups remain because the pore is lined with peptides intercalated with lipids.

Recently, TRNOE experiments [72] of magainin 2 transiently bound to dilaurylphosphatidylcholine (DLPC) vesicles suggested that the peptide formed an antiparallel dimer structure; this interpretation was based on numerous long-range NOE crosspeaks that were not compatible with the peptide being in a monomeric state [73]. This study contests that solid-state NMR studies of magainin 2 missed this dimer formation because the ^{15}N labeling only provides information for the main chain conformation. Meanwhile, side chain conformations and therefore oligomerization contacts are harder to determine. The impact of this dimer formation on the currently accepted model of pore formation by magainin is presently unclear.

Protegrin-1

Solid-state NMR measurements with protegrin-1, a β-sheet peptide, showed different results compared to magainin 2. Chemical shifts of ^{13}CO and ^{15}N labels on Val-16 of the peptide were measured, and the two-stranded hairpin was calculated to be rotated by 48 ± 5° from the bilayer normal of the DLPC bilayers [74]. This orientation and the length of the peptide still allow for the positively charged arginine side chains to protrude out of the hydrophobic core of the membrane and interact with the lipid head groups. Three of the six Arg’s are near the termini of the peptide and the other three are adjacent to each other near the hairpin turn, while the residues on the strands are hydrophobic to allow for favorable interactions with the acyl portion of the membrane. In a related solid-state NMR experiment, relatively low concentrations of paramagnetic Mn^{2+} were used to induce distance-dependent dipolar relaxation to investigate the depth of insertion of specific residues of protegrin-1 bound to DLPC bilayers [75]. This was accomplished through specific labeling of four selected residues with

^{13}C, and the order of penetration of the residues was in agreement with the tilted model for protegrin-1 insertion. While these experiments shed an interesting light on the arrangement of protegrin-1 in bilayers, it should be recognized that the DLPC lipids used have shorter acyl chains by 4–6 carbons than physiologically relevant phospholipids.

Solid-state NMR studies making use of the magic-angle-spinning (MAS) technique to obtain higher resolution have also been reported. These allowed the study of protegrin-1 bound to palmitoyloleoylphosphatidylcholine (POPC) bilayers, a more relevant membrane system [27]. However, the ^{13}C signals of the isotopically labeled protegrin-1 indicated a high level of aggregation in these bilayers; therefore proper characterization of the bound peptides could not be achieved. Be that as it may, information about the lipid arrangement could be obtained by studying ^{2}H NMR spectra of deuterium-labeled POPC with increasing concentrations of protegrin-1. The results clearly showed a greater proportion of unordered lipids in the lamellar phase [74]. These findings support the toroidal pore mechanism in the case of the protegrin-1 peptide where the membrane is under positive curvature stress and the lipids can move between the inner and outer leaflets.

Conclusions and Future Directions

Standard 2D proton NMR spectroscopy remains the primary method to obtain reliable and detailed structural information about antimicrobial peptides in solution or bound to micelles. As we have discussed, when performing structure calculations based on NMR data alone, one must carefully consider at what stage of the process it is justified to include hydrogen bonding, disulfide bridging or special features such as the knot motif in microcin J25 [36,61,62] as a constraint in the calculations. As the population of easily solvable peptide structures decreases, new NMR strategies will be necessary to fully characterize antimicrobial peptides in a more realistic membrane environment, where many are thought to exert their antimicrobial effects [3]. To this end solid-state NMR has already started to provide a snapshot of such peptides in a membrane bilayer. In the future, it should be possible to use fully isotope-labeled and deuterated peptides and TROSY NMR approaches to study these antimicrobial peptide in small vesicles, as is already being done for some membrane proteins [76,77,78]. Vesicles are a better membrane mimetic than the frequently used micelles.

The development of lipid bicelles, bilayers composed of lipids with different chain lengths forming small discoidal shapes [79], could also prove useful in determining more accurate membrane-bound solution structures. Multimerization of the peptides presents difficulties in data analysis and yet, the oligomerization states could be more reflective of biologically relevant conditions. Also, the structural data coming from solution NMR studies should be supplemented by dynamic information to gain further insights. Novel approaches using homonuclear NMR are now available [80].

Additionally, a multitude of other aspects of the mechanism of action of antimicrobial peptides remain to be characterized. In particular, studies of their interactions with the lipopolysaccharides of the outer membrane of Gram negative bacteria need to be done. Although many peptides exert their cytotoxicity through membrane disruption, in the case of peptides that do not act on the membrane, interaction studies with their intracellular targets will need to be pursued.

In addition to being bactericidal, other useful properties are starting to emerge for many of these peptides [81]. A fair number of them also selectively exhibit toxicity toward tumor cells [82], fungi [83], and viruses [84]. Interaction studies with relevant receptors can lead to an understanding of a peptide's role in the anti-inflammatory response [85], cell signaling pathways [86], or its capacity to stimulate the adaptive immune response [28]. These alternate properties present further directions in which research in this field can go.

Great strides have been made in the characterization of the solution structures of antimicrobial peptides by high-resolution NMR. In addition, solid-state NMR is beginning to provide valuable insights into the positioning of these peptides in membrane environments. Such information will be crucial for the design and development of novel classes of powerful pharmaceuticals to combat bacterial infections.

Acknowledgments

The authors would like to thank Drs. David Schibli, Howard Hunter, and Weiguo Jing for many insightful discussions. This research is supported by the Canadian Institute for Health Research and the Alberta Heritage Foundation for Medical Research.

Pharmaceutical Applications of Ion Channel Blockers: Use of NMR to Determine the Structure of Scorpion Toxins

Muriel Delepierre[1] and Lourival D. Possani[2]
[1] *Unité de Résonance Magnétique Nucléaire des Biomolécules, CNRS URA 2185, 75 724 Paris Cedex 15, France*

Introduction

Animal venoms, such as those from snakes, scorpions, cone snails, sea anemones, spiders and honeybees, are rich sources of different classes of ligands that affect the function of eukaryotic cells and tissues by blocking ion channels [1]. These ligands recognize membrane bound proteins with different specificities and affinities, thus providing scientists with unique tools to investigate diverse areas of neuroscience, protein chemistry and evolution, including the ionic channels of excitable membranes, the phylogeny of proteins and structure–function relationships of proteins [2,3]. It is unclear why toxins with similar structures display such different functions, for example why do they show specific affinities for ion channels from a particular animal? Specific recognition of a wide range of ion channel types allows the use of their pharmacological properties.

A given toxin can act on several different channels, of which only one may be of therapeutic interest [4], rendering its use as a therapeutic agent dangerous [5]. Nevertheless, successful approaches have been developed for the production of immunosuppressive agents from toxins and structural analogs [4] for the treatment of chronic pain [6] and for the treatment of various human disorders such as multiple sclerosis [7], cancer, diabetes, cardiovascular, and neurological diseases [1,8]. The fact that animal toxins are built around limited disulfide bonded frameworks, makes them resistant to degradation and permissive to mutations, meaning that they can be used as templates for protein engineering [9,10]. Before the detailed structure of a potassium channel was solved by X-ray crystallography [11], animal toxins were mainly used to map the channel-binding site and to identify the structural attributes that make a channel unique [12]. With present knowledge, the use of these toxins can be switched to the design or identification of new compounds that compete or interfere with their action upon ion channels. Unfortunately, for Na^+ channels no high-resolution structural model is yet available [13]. Therefore, further structure–activity relationship studies are required on animal toxins to determine the molecular basis of the toxin–ion channel interaction in order to engineer molecules with novel biological functions and/or therapeutic potential [1].

This chapter will focus on toxins extracted from scorpion venoms that are active on sodium and potassium channels. Sodium channel toxins are much more abundant in scorpion venom than potassium channel toxins, which account for less than 0.1% of total venom. In addition, toxins affecting potassium channels usually make only a minor contribution to the effects of envenomation on humans. It is therefore not surprising that the first toxin structure to be solved was that of a sodium channel-specific toxin, the *Centruroides sculpturatus* variant-3 toxin [14].

Use of NMR to Determine the Structure of Rare Components

It is essential to solve the three-dimensional structure of a toxin to determine how it interacts with its receptors. NMR and X-ray crystallography are the two most powerful tools available for structural determination and have been extensively used to obtain structural information on toxins. X-ray crystallography is limited by the necessity to obtain crystals, whereas NMR is limited by the size of the molecule and the low sensitivity of the method, making these two techniques complementary. NMR, which is particularly useful for determining the structure of small molecules, can also be used to obtain information on the dynamics of macromolecules over a wide timescale range and to study molecular interactions [15,16]. However, NMR is inherently less sensitive than almost all other analytical methods as a result of the small energy gap between ground and excited states. Indeed, the minimal quantity that can be analyzed by NMR is usually in the

Graham A. Webb (ed.), Modern Magnetic Resonance, 1325–1330.
© 2008 *Springer.*

nanomolar range or higher, precluding its routine use in trace analysis.

Nevertheless, the sensitivity of NMR has been improved considerably in the last decade by increasing the field strength—900 MHz is now available—and by increasing probe performance [17]. The use of cryogenic probes increases the coil quality factor, improving sensitivity by four- or fivefold compared to conventional 5 mm probes [18]. Sensitivity can be also improved by optimizing the sample volume as a function of the specific availability or solubility of a given sample.

Three types of small sample volume probes have been developed:

(i) Microprobes that use small diameter (3 mm) vertical sample tubes with volumes ranging from 120 to 150 µl. These probes, designed to couple HPLC with NMR, use saddle-type radio frequency (RF) coils. They were initially used in the pharmaceutical industry and are now becoming more widely used in academic laboratories for the characterization of small volumes of natural products and other rare samples [19]. The sample volume can be further reduced to 70–80 µl by using 3 mm Shigemi tubes. In this case, the bottom of the tube that is not in the receiver coil is filled with glass with the same dielectric properties as the solvent used. The amount of material necessary and/or the experimental time can be decreased further by using a 3-mm cryogenic probe [20]. Finally, 1.7 mm submicro inverse-detection gradient NMR probes first described in 1998 are compatible with sample volumes of just 20–30 µl [21].

(ii) The nano-NMR probe was first developed to characterize molecules covalently attached to solid-phase synthesis beads [22]. It uses a 40 µl observable volume that does not need to be filled without compromising the line widths [23] and identical concentrations to standard probes. High detection efficiency is achieved by placing the entire sample in the receiver coil. Magnetic susceptibility contributions to the line width around or within the sample are removed by spinning samples very rapidly (1–4 kHz) at the magic angle. This produces a very narrow water lineshape even at the base of the water signal (Figure 1). However, the spinning of samples in the presence of both RF and magnetic field inhomogeneities modulates the effective field, dramatically reducing the performance of isotropic mixing in TOCSY experiments when conventional composite-pulse mixing sequences are used. Adiabatic mixing sequences are less susceptible to such modulations [24] and perform considerably better in TOCSY experiments at the magic angle [25].

(iii) Microcoil NMR probes were first described in 1994 [26]. Their capillaries can contain nanoliter to microliter volumes and the probes are built with a solenoid coil of about 1 mm. They were developed to couple capillary HPLC or electrophoresis to NMR [27]. Although impressive results have been obtained [28], most of these microprobes are still in the prototype phase.

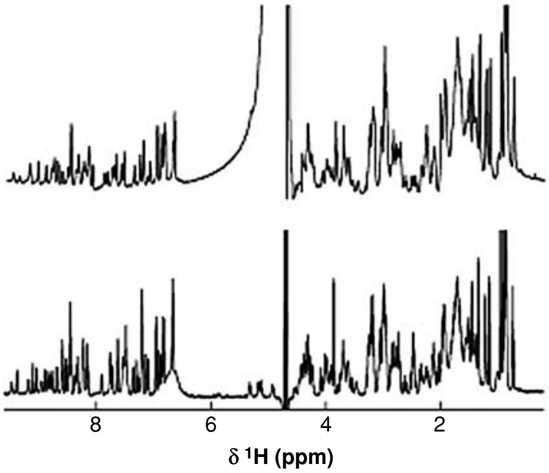

Fig. 1. One-dimensional spectra of the Pi4 toxin [56]. The lower spectrum corresponds to natural ($CONH_2$) Pi4 toxin at 380 µM 15% D_2O obtained at 500 MHz with a nano-NMR probe (Varian INNOVA) while top spectrum corresponds to synthetic (COO^-) Pi4 toxin at 100 µM 15% D_2O, 3 mm Shigemi tube obtained at 600 MHz with a cryoprobe (Varian INNOVA). In both cases 80 µg of protein was dissolved in 5 mM pH 4.0 CD_3COONa buffer. The water was suppressed with presaturation (courtesy of Inaki Guijarro).

The small volume probes make it possible to collect spectra with excellent resolution, sensitivity, and lineshape with small amounts of product, making this technique a promising option when sample size is a real limitation. The combined use of small volume probes—3 mm and below—cryogenic technology, and Shigemi tubes makes it possible to determine chemical structures at unprecedented low concentrations. The use of these technological improvements has allowed the reduction of sample amounts to less than 2% of the initial quantity required. This is evidenced by the fact that for the first scorpion toxin solved by NMR, the sodium channel-specific insect toxin AaHIT, about 12 mg was needed [29], whereas for the first potassium channel-specific scorpion toxin, charybdotoxin (ChTX) 8 mg was required [30]. Nowadays, as little as 200 µg is necessary to obtain structure of potassium channel-specific toxin with a reasonable precision, i.e. with an average of 8–14 constraints per residue [31,32].

NMR Structures of Toxins Active on Sodium Channels

Sodium channel toxins typically contain 60–70 amino acid residues. Two classes of toxin were initially described based on their pharmacological properties and their ability to bind to two different sites on the extracellular surface of the sodium channel [33,34]. Alpha scorpion toxins (α-ScTxs) slow down sodium channel inactivation by binding to receptor site 3 in a voltage-dependent manner. These have been mostly found in the venom of Asian and African scorpions. Beta scorpion toxins (β-ScTxs) bind to receptor site 4 of sodium channels and alter the mechanism of activation of the channel. They were initially found in the New World scorpion (North and South America). This rule is not absolute, because α-ScTxs have been found in the New World and conversely β-ScTxs in the Old World. Displacement experiments on excitable tissues have shown that the two binding sites are not related.

In addition to channel specificity, the sodium channel toxins also display species specificity, for example some α-like toxins are active on insects and mammals [33]. Based on toxicity tests, binding experiments and electrophysiological experiments, sodium channel toxins can be divided into peptides that are specifically toxic to either one or combinations of groups of animals. In this context, the term specific does not mean “exclusively effective” but refers to low toxicity or affinity in one group and/or higher toxicity or affinity in another.

The three-dimensional structures of several sodium channel toxins have been determined by NMR or X-ray crystallography. All toxins (α, β, and α-like) have the same overall structure based on a conserved scaffold with different insertions, deletions, and mutations. Inserted fragments are named loops J, M, B, and F and correspond, respectively, to loop 1 between β strand 1 and the α-helix, loop 2 between the α-helix and the β strand 2, loop 3 between β strands 2 and 3 and finally the C-terminal end. The α-ScTxs have a short J loop and a long B loop, while the β-ScTxs have a long J loop and a short B loop. Excitatory toxins have short J and B loops. An example of such insertion is the excitatory insect toxin from *Buthotus judaicus* (BjxtrIT) in which a five-amino acid insertion occurs just before the α-helix in loop 1 and a short α-helix is inserted in the C-terminal part of the molecule [35]. The α-ScTxs contain an insertion at around residue 42 of the B loop that is believed to play a key role in the modulation of toxic activity [36].

Based on experimental evidence, three criteria appear to be important for sodium channel specificity, namely: (i) the presence of a positively charged residue at the N-terminus (usually lysine and sometimes arginine), immediately followed by a negatively charged residue such as glutamic acid or aspartic acid at position 2; (ii) a conserved aromatic cluster; and (iii) a positively charged group (e.g. lysine or arginine) at position 13 in β-type toxins or position 58 in α-type toxins.

Most of the scorpion toxin structures that have been reported so far have been assigned to the α-type group or are weakly toxic to mammals. In North and South America, two of the most dangerous scorpions for mammals are *Centruroides noxius* and *Tityus serrulatus*, respectively. In each case, the most toxic components for mammals are β-type toxins active on sodium channels, respectively Ts1 and Cn2. Ts1 is a β-ScTxs and is the major component of the venom of *T. serrulatus*. The structure of Ts1, also known as Ts-γ or toxin VII, has been determined by X-ray diffraction to a resolution of 1.7 Å [37] while the structure of Cn2 has been determined by NMR [38]. Cn2 is composed of one α-helix and three β strands. It contains 10 aromatic residues, several of which are located on the same face of the molecule, face A, as is generally observed for sodium channel toxins. This face was thought to be the determinant for the sodium channel specificity. The orientation of the C-terminal region differs between α- and β-toxins as do the sizes of the J loop and B loop regions. The unique orientation of the Cn2 C-terminal region stems from a proline in a *cis* conformation. Interestingly Ts1 C-terminal orientation is similar to that of Cn2 but here the *cis*-proline is replaced by a helix turn. Whereas binding of β toxins to a common site on the sodium channel may be explained by the same recognition pattern on face A (i.e. the face containing the hydrophobic cluster), the difference in their toxicities may be related to the distribution of residues on the opposite face (face B). In Cn2 and Ts1, this face, formed by loop 1 and the C-terminal end, displays a large number of basic amino acid residues, whereas in weakly active toxins these residues are replaced by neutral amino acids.

The fact that the first crustacean-specific toxin for which a structure was solved came from a scorpion of the same genus as Cn2 (*Centruroides limpidus limpidus*) revealed structural features that might be responsible for the species specificity: mammals versus crustaceans. Whether a particular toxin of the genus *Centruroides* is specific towards mammals or arthropods depends on the nature of a few residues clustered in two well-defined regions (mainly loops between secondary structure elements). Mutational analyses in which the two regions are exchanged or point mutations introduced at these residues are required to corroborate these results.

NMR Structures of Toxins Active on Potassium Channels

Potassium channel toxins also vary considerably in terms of sequence and specificity, and can act on a wide range of potassium channels. Although potassium channel toxins from scorpions of the family Buthidae are mostly present as minor components of the venom, the increasing interest in venom constituents has led to efforts to improve the separation and identification of all venom compounds. So far, more than 120 different K^+ channel toxins have been found in scorpion venoms [39,40]. They have been divided into three subfamilies based on their primary structures and functions: α-, β- and γ-KTxs. The α-KTx family is the largest one, containing more than 80 members in 18 subfamilies active on Kv, BK_{Ca}, or SK_{Ca} channels. They are short-chain toxins, consisting of 23–41 amino acids and three or four disulfide bridges [41]. The four members of the β-Ktxs family identified so far are long-chain toxins composed of 60–64 amino acids and containing only three disulfide bridges [42]. Twenty-six members of the γ-Ktxs family have been identified. Members of this family are HERG channel blockers consisting of 36–47 amino acids and three or four disulfide bridges [43].

With the exception of the κ-Hefutoxins [44], all the K^+ channel-specific toxins isolated from scorpion venoms are structurally related. They are characterized by the cysteine-stabilized α/β motif (CS-αβ) in which Ci–Cj and $Ci+4$–$Cj+2$ disulfide bridges link the α-helix to the second strand of the β-sheet. κ-Hefutoxin 1 adopts a unique three-dimensional fold, consisting of two parallel helices linked by two disulfide bridges and without any β-sheets [44].

The first potassium channel toxin to be identified was noxiustoxin in 1982 [45]. Its three-dimensional structure was solved in 1995 [46]. The first potassium channel for which the structure was solved was charybdotoxin [47] discovered in 1985 [48]. The structures of several potassium channel toxins have been elucidated in the last 15 years either by X-ray or by NMR. This was made possible by following developments including: (i) chemical synthesis associated with efficient refolding, (ii) recombinant methods allowing uniform ^{15}N and ^{13}C labeling of these toxins, (iii) advances in methods for the extraction and purification, and (iv) recent developments in highly sensitive NMR methodology allowing structure determination with just a few hundred micrograms of compound [49, and references therein].

Among the 120 K^+ channel toxins the α-Ktx6 subfamily, which now comprises five different members, is characterized by the presence of an additional disulfide bridge that, in most members, fixes the C-terminus to the turn following the α-helix. Two different arrangements of disulfide bonds have been described for members of this subfamily. Pi1 [50], Pi4 [51], Pi7 [32,51] and HsTX1 [52] show half-cystine pairing of C1–C5, C2–C6, C3–C7, C4–C8, whereas MTX displays a different S–S bond topology C1–C5, C2–C6, C3–C4, C7–C8 [53]. The different S–S bonds in MTX link contiguous regions in the sequence; however MTX displays the characteristic structure of a small scorpion toxin [54]. Interestingly, no target has yet been found for toxin Pi7 despite it having a similar overall fold to all potassium channel toxins [32]. Another toxin containing four disulfide bridges has also been purified from *T. serrulatus*, TXT α-KTx17, but the additional disulfide is on the N-terminal end and the structure of this toxin has not yet been solved [55].

The three-dimensional structures of the three *Pandinus imperator* toxins have been determined using nanomolar amounts of the natural compounds and the nano-NMR probe approach and/or 3 mm Shigemi tubes [31–32,56]. The structures of HsTX1 [57] and MTX [54] were determined using synthetic molecules. The structure of Pi4 was determined using both the natural and synthetic toxins, showing that both have the same fold and disulfide pairing [56].

Disulfide bridges can be identified from the spatial interactions observed between Hα and Hβ and between Hβ and Hβ of cysteines involved in the disulfide bridge. However, in cysteine-rich proteins, such as scorpion venom toxins, it is not always possible to obtain conclusive results, as connections between Hβ protons can involve more than two cysteines. S–S bonds have been successfully assigned by NMR and modeled using different methodologies for several proteins [57,58]. Structures are calculated using NMR data only, with no disulfide bridges, to propose topologies compatible with NMR restraints for all possible combinations of disulfide bridges. Given that the bond between the sulfur atoms can only be formed if the distance between the two sulfur atoms is 2.03 Å, the structures with lowest experimental energies are analyzed in terms of the statistical distribution of distances between cystine sulfur atoms [32]. Even when other experimental data are available, NMR and structure calculations offer the possibility of testing the disulfide bridge pattern determined by other techniques and can be routinely used to locate the S–S bonds of proteins of unknown structures.

The structures of only two members of the γ-KTx family have been solved: BeKm-1 [59] and CnErg1 [60]. They have different disulfide bridging patterns and do not share any significant homology in primary structure, but both block the turret region of the HERG channel [61,62]. Their structure was solved using the recombinant toxin [59], the synthetic toxin [63] and the native toxin in the case of CnErg1 [64]. They adopt the α-KTx CS-αβmotif; however the turn of helix observed in the N-terminal part of CnErg1 is unique to the family of potassium channel toxins [63,64]. BeKm-1 and CnErg1 share similar interaction surfaces with the HERG channel. Evolutionary [65] and structural analyses demonstrated the presence of two important functional residues that are mainly located in two patches—one hydrophobic and the other hydrophilic—located at the two opposite heads of the toxin molecules [40,54,61,62]. Therefore, scorpion γ-KTx toxins seem to share the same interaction mode regardless of their primary structures.

Conclusion

The structures determined so far for scorpion toxin acting on ion channels seem to converge to a unique global fold CS-αβmotif even though they exert a wide range of biological functions. It is therefore reasonable to expect that molecular modeling will be enough to establish reasonable structural models. However, it is probably the unique fine details of structure (i.e. subtle changes in secondary structure elements and/or the relative orientation of side chains and/or the dynamic properties of the molecule) that are important for channel recognition and species specificity. Two recent findings emphasize how fine structure can help to elucidate the structure–function relationships of scorpion toxins. The first one concerns the finding that a α-KTx toxin, BmTx3, isolated from the venom of the scorpion *Buthus martensi* Karsch, can display dual activity, blocking HERG activity and A-type potassium currents [66]. The second is the finding of the inhibitor cystine knot (ICK) [67] fold among scorpion toxins [68]. Furthermore, preliminary results on venom proteomics [39] seem to suggest that a large number of toxins from the venom of various animal species remain to be structurally characterized, thus it is reasonable to expect that new folds and new potent molecules will be discovered.

Structure and Dynamics of Inhibitor and Metal Binding to Metallo-β-Lactamases

Christian Damblon and Gordon C.K. Roberts

Biological NMR Centre, Department of Biochemistry, University of Leicester, Leicester LE1 7RH, UK

Introduction

The β-lactam antibiotics are among the most useful antibacterial chemotherapeutic agents, for both human and animal use, but their efficiency is continuously being challenged by the emergence of resistant strains of pathogenic bacteria. Production of β-lactamases, which inactivate these antibiotics by hydrolyzing their endocyclic amide bond, is the most important resistance mechanism [1]. β-Lactamases have been divided into four classes on the basis of their amino acid sequences and catalytic mechanisms [2]. Class B enzymes, the metallo-β-lactamases (MBLs), are ∼30 kDa metallo-proteins which require one or two zinc ion(s) for their activity [3]. In the last 20 years, MBL-mediated resistance has appeared in several pathogenic strains including *Bacteroides fragilis*, *Aeromonas hydrophila, Stenotrophomonas maltophilia*, and *Serratia marcescens* [4], and some MBL genes are being disseminated rapidly by horizontal transfer, involving both plasmid and integron-borne genetic elements [5–9]. The spread of MBL-mediated bacterial resistance to β-lactams is thus a matter of concern, particularly in view of the very wide substrate profile displayed by many MBLs, which can hydrolyze almost all the known β-lactam antibiotics, including the carbapenems such as imipenem [10].

The MBLs share a small number of conserved motifs, but otherwise show significant sequence diversity. Crystal structures have been determined for the MBLs from *B. cereus* [11,12], *B. fragilis* [13–15], *Chryseobacterium meningosepticum* [16] and *S. maltophilia* [17], and for the IMP-1 enzyme from *Pseudomonas aeruginosa* [18]. These structures reveal a unique “αββα sandwich” characteristic of this family of enzymes and distinct from other zinc-dependent amide hydrolases such as thermolysin and carboxypeptidase A. It has subsequently become apparent that the metallo-β-lactamase fold is a widespread one [19–21]. Two zinc cations are present in the active site of the MBLs for which crystal structures are available. For example, in site I of the *B. cereus* enzyme, the zinc is co-ordinated by the imidazole rings of three histidine residues, H86, H88, and H149 (H116, H118, and H196 according to the standard numbering of MBLs [22]) and one water molecule. This water (or hydroxide) bridges to the zinc in site II, which is also co-ordinated by a histidine (H210 in *B. cereus*), a cysteine, an aspartate and a second water (or a carbonate ion). The zinc ligands are not absolutely conserved among MBLs, some enzymes having an Asn in place of a His in position 116 (site I ligand) and others having an Asp in place of the Cys in site II. These differences may contribute to some of the observed differences in substrate profiles and zinc affinities between different MBLs.

The precise role of the two metals in catalysis is still unclear (e.g. [3,23–26]); mechanisms have been proposed in which only the zinc in site I is involved in catalysis [23], and in which both zinc cations play essential catalytic roles [3,26]. In fact, it remains unclear whether the mononuclear or binuclear enzyme is the more physiologically relevant; recent measurements suggest that at physiological metal ion concentrations most MBLs may exist as the apoenzyme, and that the presence of substrate leads to enhanced zinc binding in the mononuclear form of the enzyme [27]. It is notable that, while the presence of the second zinc does seem to be necessary for obtaining the maximum catalytic efficiency in MBLs, most of them can catalyze substrate hydrolysis with only one zinc cation bound [28–30]. Indeed, catalytic activity of the *A. hydrophila* MBL is actually inhibited by the binding of a second zinc cation [30]. It has been proposed that the observed conservation of the ligating residues at site II may be explained if a translocation of the metal ion between the two metal sites is involved in catalysis, and that this might explain the observation of catalytic activity with only one zinc per molecule of enzyme.

The range of active site architectures for the MBLs makes the discovery of useful broad-spectrum inhibitors a challenging task, although compounds of several different chemical classes which inhibit the enzyme *in vitro* have been described [15,18,23,31–44]. Structural information, from crystallography or NMR, is available for the binding of a biphenyl tetrazole, which binds to the zinc in site II [31], and for a number of mercaptocarboxylates [18,41,44,45]. We recently demonstrated that a simple mercaptocarboxylate, thiomandelic acid

Graham A. Webb (ed.), Modern Magnetic Resonance, 1331–1337.
© 2008 *Springer.*

(β-mercapto phenylacetic acid), is a reasonably potent (sub-micromolar) inhibitor for most MBLs, except for the enzyme from *A. hydrophila* [45]. The kinetic data for thiomandelic acid fitted a competitive pattern of inhibition, and no evidence was obtained for irreversible binding of thiomandelic acid, at least to the *B. cereus* enzyme. Such a wide spectrum of activity against MBLs is unprecedented in previously published data concerning MBL inhibitors. For instance, thiomandelic acid is only about 25-fold less potent as an inhibitor of the enzyme from *B. fragilis* than of the IMP-1 enzyme from *P. aeruginosa*. This is in marked contrast to the reported thioester inhibitors, which are very much poorer inhibitors of the *B. fragilis* enzyme [37,38,43].

To obtain structural information to guide the design of improved broad-spectrum MBL inhibitors, we have used NMR to study the interaction of thiomandelic acid with the *B. cereus* MBL, BcII, particularly with its metal ions. The approaches we have used are described below.

Effect of Inhibitor Binding on the Backbone Amide Resonances

A two-dimensional proton–nitrogen correlation spectrum (^{1}H-^{15}N HSQC) of ^{15}N-labelled BcII allows the rapid observation of most of the backbone amide ^{1}H and ^{15}N resonances. We have assigned these resonances to individual residues in the free protein [45], and monitoring changes in these resonances thus provides a convenient method for identifying the regions of the enzyme affected by inhibitor binding—the "chemical shift mapping" approach has become a widely used method for the initial characterization of protein–ligand and protein–protein interactions.

Figure 1 shows a comparison of the ^{1}H-^{15}N HSQC spectra of the free enzyme and of the enzyme in the presence of *R*-thiomandelic acid (*R*-TM). Most of the spectrum remains essentially unaffected, but some significant changes are observed, generally involving residues which are close to the zinc binding sites. Only very few residues in the secondary structure elements of the core of the protein are affected by the inhibitor; some 90 residues in this part of the structure which give well-resolved resonance signals are unaffected by the addition of inhibitors. While the resonance assignment for the free enzyme is complete, the resonances in the complex are not yet assigned, so that the magnitude of the shifts of individual resonances cannot be accurately determined. We have thus used the "minimum chemical shift" approach [46–48], in which the chemical shift difference from a given cross-peak in the free protein to the closest cross-peak in the complex is calculated, to identify the residues most affected by inhibitor binding; these are indicated on the structure in Figure 1. As would be expected for a competitive inhibitor, many of the residues showing significant changes in chemical shift are in the active-site region of the structure, near the zinc ions. Only two or three residues in the structural core of the enzyme show significant changes.

Substantial amide chemical shift perturbations are, however, observed for residues in the "flexible-flap" region (the β_3–β_4 loop, residues 30–40), which in the absence of inhibitor is some distance from the active site (Figure 1). Shift changes are seen for E30, L31, F34, and V39 in this loop. (A significant shift perturbation is also observed for W59, which is located at the beginning of a loop on the top of the cavity; since the side-chain of W59 extends towards the β_3–β_4 loop, this could result from a movement of the loop.) There is good evidence that this loop plays a role in ligand binding and catalytic activity [18,41,44,45,49,50]. Loop deletion and loop swapping experiments with the *B. fragilis, B. cereus* and IMP-1 MBLs [49,50] have shown that the loop influences not only the K_i of inhibitors but also both the K_M and k_{cat} of substrates, suggesting that it plays a role in the catalytic mechanism. In the structure of the complex of IMP-1 MBL with a large mercaptocarboxylate inhibitor [18], there are clear hydrophobic contacts between the inhibitor and residues of the β3–β4 loop. These interactions might stabilize the loop, which is flexible in the absence of the inhibitor [44], in a "closed" position. However, our own studies with the *B. cereus* enzyme have shown that the residues of this loop are affected by the binding of much smaller inhibitors, not only thiomandelic acid [45] but even the simple mercaptoacetic acid [Kumar, S. unpublished work]. This clearly shows that hydrophobic interactions with the bound ligand cannot be the origin of the loop movement; there must be a "trigger" mechanism related to the coordination of the metal ions.

Effect of Inhibitor Binding on the Imidazole Resonances of the Metal Ligands

In examining the effect of inhibitor binding on the active site of the *B. cereus* enzyme, the imidazole resonances of the metal-binding histidine residues (H86, H88, and H149 in site I, H210 in site II) provide valuable probes. The imidazole N*H* resonances appear between 12 and 15 ppm (Figure 2). They have been assigned to individual residues by using ^{1}H-^{15}N HMQC spectra optimized for observation of the long-range ^{1}H-^{15}N couplings in the imidazole ring [29], which allow one to connect the N*H* resonances to those of the two nitrogens and the two C*H* protons in each imidazole. At pH 6.4, 298K, in the absence of inhibitors, relatively sharp resonances are observed for H86 and H88, and a broad resonance for H210, but no signal is apparent for H149. At lower pH or temperature, the H210 resonance sharpens and a signal for H149 appears. These differences in linewidth reflect the

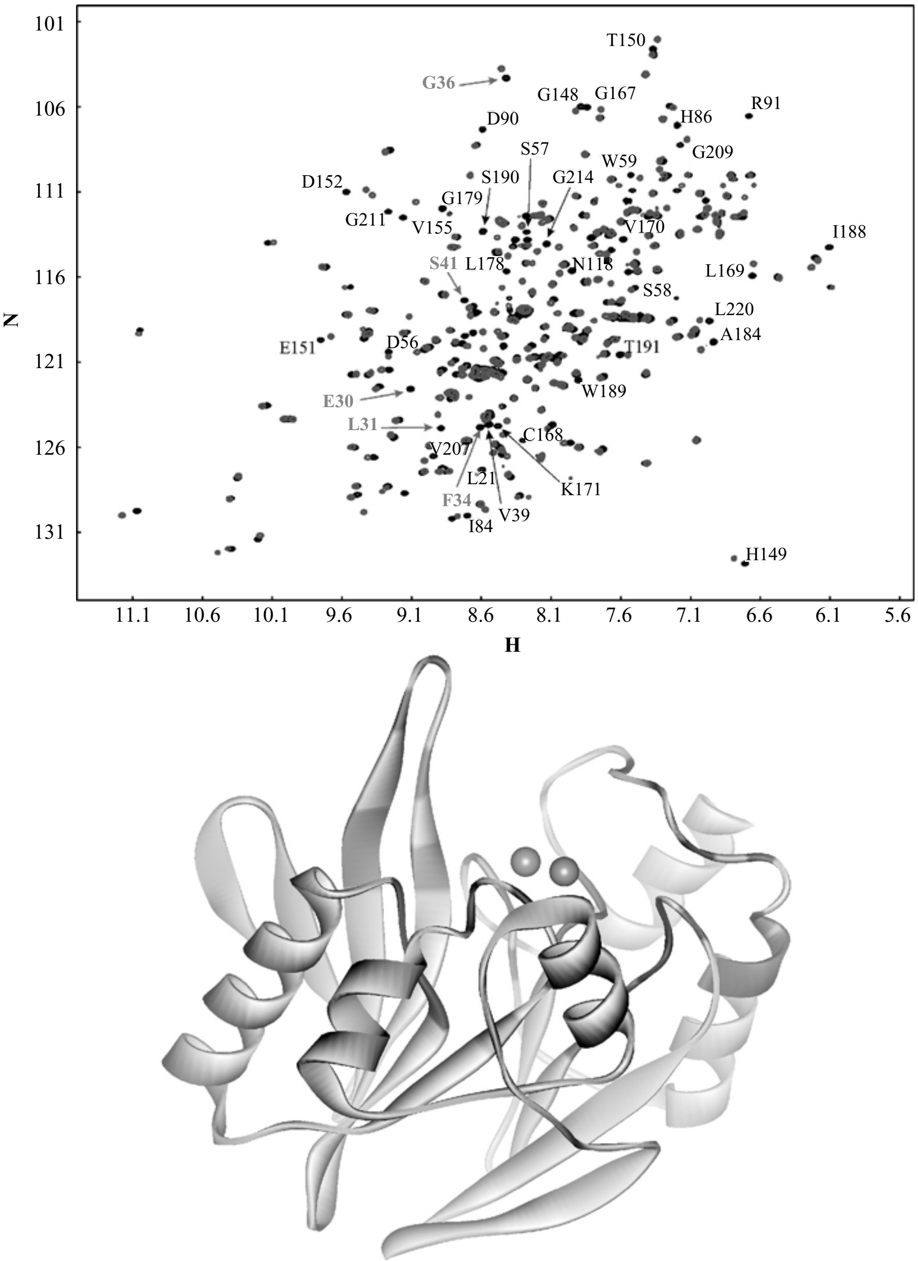

Fig. 1. ^{1}H-^{15}N HSQC spectra of *B. cereus* MBL BcII alone in black, and in its complex with *R*-TM in red. Assignments of residues affected by ligand binding are labelled on the HSQC spectra and are displayed on the X-ray structure of the free BcII. Residues affected in the flexible β3-β4 loop are labelled in blue on the HSQC and on the structure. Other residues affected by the presence of the inhibitor are coloured in green on the structure. (See also Plate 103 on page XXI in the Color Plate Section.)

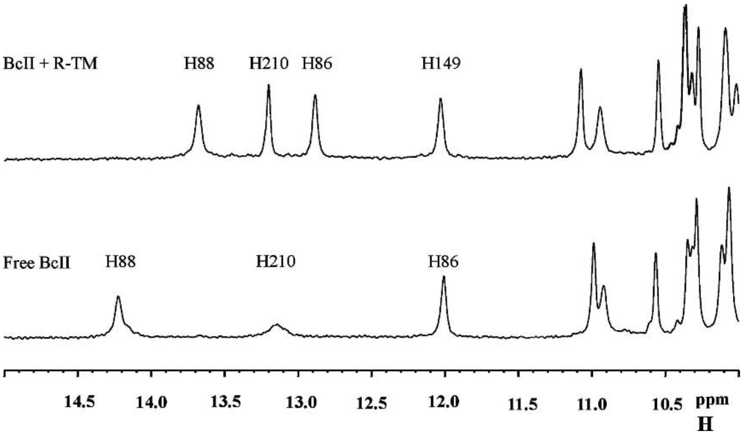
Fig. 2. Part of the ^{1}H NMR spectrum of *B. cereus* MBL BcII in the presence and absence of *R*-TM, showing the imidazole N*H* resonances of the metal-binding histidine residues.



differences in accessibility of the histidine imidazole N*H*s for exchange with the solvent. Gradual addition of *R*-thiomandelic acid to the enzyme results in a progressive decrease in the intensity of the imidazole N*H* signals from the free enzyme, and a progressive increase in a new set of signals attributable to the enzyme-inhibitor complex. The changes are complete at a 1:1 ratio of inhibitor to enzyme, and the spectrum of the fully formed complex is shown in Figure 2. It is clear that the imidazoles in both metal binding sites are markedly affected by inhibitor binding. In site I, both H86 and H88 show large (>0.5 ppm) changes in N*H* chemical shift on inhibitor binding. In addition, inhibitor binding clearly tends to decrease the rate of exchange with water of the imidazole N*H*s of the metal-binding histidines, thus sharpening their resonances, although the magnitude of this effect varies significantly from one residue to another. Thus, the resonances of H86 and H88 are reasonably sharp in the spectrum of the free enzyme, and their linewidths are little affected by inhibitor binding, while the resonance of H210 is broad in the spectrum of the free enzyme and is markedly sharpened by the binding of *R*-thiomandelic acid so that in the complex it has approximately the same linewidth as H86 and H88. The N*H* resonance of H149, on the other hand, is too broad to see in the spectrum of the free enzyme; only the binding of the inhibitor decreases the imidazole N*H* exchange rate of this residue sufficiently to yield an observable resonance—in fact one as sharp as those of the other three active site histidines in this complex. The binding of *R*-thiomandelic acid thus changes not only the time-average environment of the zinc-ligating residues, as reflected in their chemical shifts, but also their dynamics, as reflected in the rate of exchange of their N*H* protons with water.

Direct Observation of the Active-Site Metals

In the majority of MBLs, zinc can be exchanged with cadmium to yield catalytically active enzymes [51], and in the case of CcrA, the structure of the cadmium-substituted enzyme has been shown to be essentially identical to that of the zinc enzyme [52]. Isotopes of cadmium provide very convenient spectroscopic probes, allowing direct studies of the co-ordination and dynamics of the metal ion. We have used NMR and, in collaboration with Prof. R. Bauer (Copenhagen), perturbed angular correlation of γ-rays (PAC) spectroscopy [29,45,53,54] to make detailed studies of metal binding to the *B. cereus* MBL. The enzyme with two cadmium ions bound gives a ^{113}Cd NMR spectrum containing two distinct resonances at ~140 and ~260 ppm [29]. We have assigned these two signals to the two metal binding sites of the enzyme by using a variety of multinuclear NMR experiments, particularly ^{113}Cd-edited ^{1}H and ^{1}H-^{15}N HSQC experiments, which allow us to connect the ^{113}Cd signals to assigned ^{1}H and ^{15}N resonances from the metal ligands (see Figure 3; [29,45,53,54]).

Analysis of the ^{1}H-^{15}N HSQC spectra of the *B. cereus* MBL enzyme with only one cadmium ion bound demonstrates the existence of a mononuclear cadmium enzyme, which is distinct from the apoenzyme, and from the species with two cadmiums bound. This mononuclear enzyme shows one single broad ^{113}Cd NMR signal at ~175 ppm, suggesting at first sight that cadmium occupies only one of the two sites under these conditions; however, two well defined cadmium PAC signals are observed [53]. The only explanation for these observations comes from considering the dynamics of metal binding and the different time regimes monitored by the two methods.

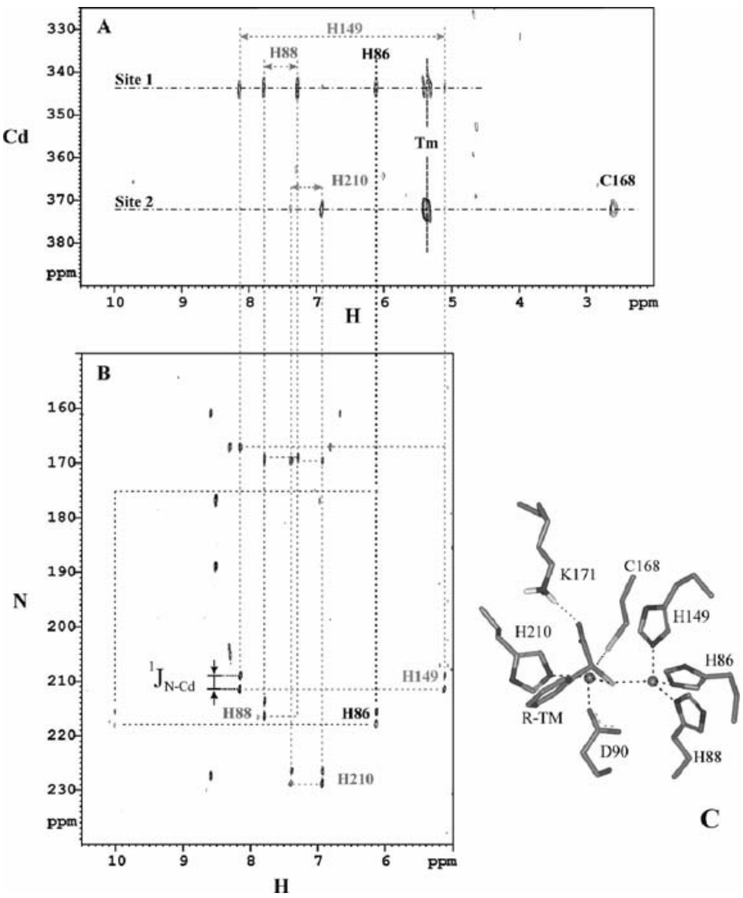


Fig. 3. NMR spectra of di-cadmium BcII in the presence of one equivalent of *R*-TM. (A) ^{1}H-^{113}Cd HMQC spectrum; (B) ^{1}H-^{15}N HMQC spectrum of the imidazole resonances, allowing assignment of the imidazole cross-peaks in A. Signal splittings in the nitrogen dimension due to the N-Cd coupling are observed for the four active site histidines. (C), Model of the binding of *R*-TM to the active site of BcII [49].

The timescales to which the two methods are sensitive are quite different: ^{111m}Cd-PAC experiments can monitor dynamics in a time regime from about 0.1 ns to 100 ns, whereas chemical exchange effects in ^{113}Cd NMR, with large chemical shift differences arising from differences in coordination, can typically monitor dynamics from 0.01 to 10 ms. The most straightforward explanation consistent with both the NMR data and the PAC data at [Cd(II)]/[E] ratios ≤ 1, is that a single cadmium bound to the enzyme jumps between the two binding sites on a time scale between 100 ns and 0.01 ms. Thus, the long-held assumption that the two different macroscopic dissociation constants for metal ion binding to the enzyme, reflecting a higher affinity of the metal for site I was shown to be wrong; they in fact reflect negative co-operativity in metal binding [53]. Recent studies of the wild-type and mutant enzyme by optical spectroscopy and EXAFS experiments indicated that there is a similar negative co-operativity in the binding of zinc and cobalt [55].

Effects of Thiomandelate Binding on the ^{113}Cd Spectrum

The BcII gives a ^{113}Cd NMR spectrum containing two distinct resonances at ~140 and ~260 ppm [29,53]. Addition of one molar equivalent of *R*-thiomandelic acid to the *B. cereus* MBL with two cadmium ions bound leads to a substantial downfield shift of both the ^{113}Cd resonances, to ~343 and ~372 ppm (Figure 3). Addition of 0.5 molar equivalent of thiomandelate leads to a spectrum containing both resonances corresponding to the free enzyme, and those corresponding to the complex, with approximately equal intensities, indicating that thiomandelate binding is in slow exchange on the ^{113}Cd NMR timescale. Further addition of the inhibitor from one to two molar equivalents does not change the NMR spectra. The direction and magnitude of the inhibitor-induced change in chemical shift is consistent with that expected for the co-ordination of a sulphur atom to each of the cadmium ions, and hence with the idea that the inhibitor binds directly to both metal sites.

Direct evidence for this, and the assignment of the two ^{113}Cd resonances in the inhibitor complexes, can be obtained from the combination of ^{1}H-^{113}Cd HMQC spectra and ^{1}H-^{15}N HSQC spectrum optimized for observation of imidazole resonances [29], shown in Figure 3. In the ^{1}H-^{113}Cd HMQC spectrum, cross-peaks are observed from the 343 ppm ^{113}Cd resonance for three imidazoles, His88, His86, and His149. The His88 can easily be assigned because it is the only metal-bound histidine which is in the N_{ε}H tautomeric form, and thus readily recognized in the ^{1}H-^{15}N HSQC spectrum[1]. The 343 ppm ^{113}Cd resonance can thus be unambiguously assigned to the cadmium in site I. There is also a strong cross-peak to a signal at 5.36 ppm, which can be assigned to the CαH (benzylic proton) of the bound *R*-thiomandelate (*R*-TM). This inhibitor resonance also gives a strong cross-peak to the low-field ^{113}Cd resonance (Figure 3), which in turn shows cross-peaks to the imidazole protons of His210 and the β-proton(s) of Cys168, and can thus be assigned to the metal in site II. The observation that, in a complex containing one molar equivalent of inhibitor, the *R*-TM resonance at 5.36 ppm gives a cross-peak in the ^{1}H-^{113}Cd HMQC spectrum to both ^{113}Cd resonances, is clear evidence that *R*-TM co-ordinates through its sulphur atom to both cadmium ions.

As described above, the ^{113}Cd spectrum of the enzyme having one cadmium equivalent bound contains a single resonance, reflecting a rapid intramolecular exchange of the single metal between the two sites. Addition of one molar equivalent of *R*-TM to the mono-cadmium enzyme led to a ^{113}Cd spectrum having two resonances at the same chemical shifts as those observed for the complex of the di-cadmium enzyme. Furthermore, the ^{113}Cd-edited ^{1}H spectra of the *R*-TM complex demonstrated that the thiomandelate CαH resonance at 5.35 ppm showed ^{1}H-^{113}Cd scalar coupling to two cadmium nuclei, just as observed for the di-cadmium enzyme, demonstrating that the thiomandelate-enzyme complex contains two cadmium ions. These observations clearly demonstrate that addition of thiomandelate to a sample of enzyme containing cadmium at a [Cd]/[E] ratio of one, leads to the formation of the *R*-TM complex of the di-cadmium enzyme together with a corresponding amount of apoenzyme [54]. This was confirmed by analysis of the backbone amide ^{1}H-^{15}N HSQC spectrum. The presence of the inhibitor, which binds to both metal ions, thus induces positive co-operativity in metal binding, in marked contrast to the negative co-operativity in cadmium binding observed in the absence of inhibitor [29].

Conclusion

The power of NMR in determining the three-dimensional structure of proteins and their complexes in solution is well-established. Full structure determination of course provides the most detailed picture of a drug–protein complex, and in the present case the determination of the structure of the complex of *R*-thiomandelic acid with the *B. cereus* MBL is in progress. However the experiments described here demonstrate some of the range of NMR experiments which can provide very valuable structural and dynamic information on ligand binding short of a full structure; others are reviewed elsewhere [56,57]. Experiments of this kind, which can be carried out rapidly, have considerable value in understanding drug–protein interactions and in comparing the binding of related compounds to a target, and promise to have a continuing place in structure-based drug design.

NMR Spectroscopy in the Analysis of Protein–Protein Interactions

David A. Gell and Joel P. Mackay
School of Molecular and Microbial Biosciences, University of Sydney, Sydney, NSW 2006, Australia

Introduction

Specific interactions between pairs or larger sets of proteins are central to all processes that take place within an organism, and many of these interactions may prove to be suitable targets for therapeutic intervention. In order to target such complexes effectively, detailed structural information is highly desirable, and NMR spectroscopy is one of the methods of choice for providing this information.

Recent methodological advances have enabled full structure determination for increasingly large proteins and protein complexes. These methods include TROSY pulse sequences, sample deuteration, and the use of additional long-range structural restraints derived from residual dipolar couplings (RDCs) and paramagnetic effects to complement traditional NOE-based methods. For protein–protein complexes, filtered/edited NOE experiments with differentially labeled samples greatly reduce spectral complexity through selecting only intra- or intermolecular NOEs.

While NMR cannot currently compete with X-ray crystallography in the determination of the structures of huge macromolecular machines such as the ribosome, it has many advantages for the study of more transient protein complexes, for which crystals are less likely to form. Relatively weak or transient interactions (high μM–mM dissociation constants) allow cells to respond dynamically to rapidly changing conditions; for example, many cell surface receptor interactions [1] and electron transport processes [2] rely on transient interactions. Likewise, transcription factor complexes are often formed from combinations of low-affinity interactions [3], facilitating exchange of factors that alter the transcriptional activity of the complex [4]. For weak protein complexes full structure determination by NMR may be prevented by exchange processes, but protein–protein interfaces and association constants may still be determined using chemical shift perturbation experiments. In such cases, shift perturbation data or long-range conformational restraints can be used to drive the docking of a complex, based on known structures of subunit components.

This chapter will outline the approaches mentioned above, together with experimental difficulties that are likely to be encountered. Examples both from our own work and from that of others will be used for illustration.

Tackling the Size Issue for Larger Protein Complexes

In general, the study of protein complexes involves dealing with larger species. Unfortunately, the slower tumbling (measured by τ_c, the molecular correlation time) of larger species leads to increased transverse relaxation rates. Faster transverse relaxation reduces the efficiency with which magnetization can be transferred through scalar couplings. As a consequence, the experiments used to make resonance assignments perform more poorly as τ_c increases. This has effectively placed a rough upper limit of ~30 kDa on the size of a system that can be solved using standard triple resonance methods [5]. However, several recently developed approaches have opened the door to the analysis of much larger proteins and protein complexes.

Deuteration

The first strategy involves the preparation of protein samples in which some percentage of protons is substituted by deuterons. This can be achieved by protein over-expression in cells grown on deuterated media [6]. Two advantages are conferred by the incorporation of ^{2}H. Firstly, the relaxation of ^{13}C nuclei is brought about primarily through the dipolar interaction with their attached proton(s). Because the magnitude of the dipolar interaction is directly proportional to the gyromagnetic ratios of the nuclei involved, substitution of ^{1}H for ^{2}H ($\gamma_H/\gamma_D = 6.5$) reduces the magnitude of this interaction significantly. With the addition of ^{2}H decoupling that removes the line broadening effects that arise from scalar coupling to a quadrupolar nucleus, ^{13}C line widths are dramatically reduced. Secondly, the general reduction in

© 2008 *Springer.*

proton density reduces spin diffusion significantly, resulting in narrower ^1H line widths.

Growth medium for protein deuteration is made up in ^2H_2O, and cells often require acclimatization on this media to grow well [7]. To achieve complete deuteration (perdeuteration), labeled carbon sources are required in addition to ^2H_2O (e.g. ^2H, ^{13}C-glucose or acetate). The extent of deuteration aimed for will depend on the goal of the study. Perdeuteration, followed by back exchange of labile backbone and side chain amide deuterons for protons, as will generally occur during protein purification in ^1H_2O, will yield the greatest improvements in sensitivity and resolution for backbone triple resonance experiments and chemical shift perturbation experiments (see below). However, lower levels of deuteration, down to ~50% [8], are required if side chain NOEs are to be detected. Alternatively, several groups have pioneered the use of biosynthetically directed labeling strategies that can be used to produce, for example, ^2H-, ^{13}C-, and ^{15}N-labeled proteins that bear protonated methyl groups on Leu, Val, and the $\delta 1$ methyl of Ile [9]. Such protein samples allow NOEs to be detected between methyl groups, which often lie in the protein core and provide a substantial number of structural constraints. Indeed, H^N–H^N, H^N–methyl, and methyl–methyl NOEs alone may be sufficient to define the global fold of a large protein [6].

TROSY

The other recent breakthrough that is revolutionizing the analysis of large systems is transverse relaxation optimized spectroscopy (TROSY) [10]. Transverse relaxation of amide ^1H and ^{15}N spins at high field strengths is dominated by two main mechanisms: dipole–dipole (DD) interactions and chemical shift anisotropy (CSA). Amide protons additionally experience significant relaxation (~40% of T_2 [11]) from remote ^1H spins, but this latter term can be largely eliminated by perdeuteration, as described above. Interference between DD and CSA relaxation (cross-correlation) has the effect of enhancing the relaxation of one component of the H^N doublet while slowing the relaxation of the other; the two doublet components thus display different line widths. The same is true for the ^{15}N doublet, and an undecoupled 2×2 multiplet in an HSQC has one component that is considerably narrower in both dimensions. The degree of relaxation interference changes with field strength, because CSA but not DD relaxation is field dependent, and at ~1 GHz the two relaxation mechanisms essentially cancel each other in the narrow component. The line width of this component consequently becomes relatively insensitive to the rotational correlation time of the protein, and the TROSY pulse sequence element (a simple modification of the HSQC pulse sequence) selects this signal. TROSY promises a great deal for the analysis of large systems and high-quality TROSY-HSQC spectra have already been recorded of systems up to ~900 kDa (a GroEL–GroES complex [12]). The TROSY element has been incorporated into a number of triple resonance experiments, and in combination with deuteration these sequences have been used to make massive strides in the size of systems that are amenable to solution NMR analysis. Backbone assignments of malate synthase, a 723-residue monomer [13], and aldolase, a 110-kDa octamer [14], have been reported recently. Perhaps even more excitingly, the structures of several integral membrane proteins solubilized in lipid micelles have been determined [15–17]. These latter studies hold substantial promise for the analysis of interactions between receptors and effector proteins.

The benefits of TROSY and deuteration have already been applied to map the interaction surfaces of large protein complexes using chemical shift perturbation experiments. Complexes formed between Ras and Byr2 [18], calreticulin and Erp57 [19], p53 and Hsp90 [20], and FimC and FimH [21] have all been characterized in this fashion.

Reducing Complexity: Differential Isotope Labeling

An additional issue that arises in NMR studies of protein complexes is the increase in the number of resonances. A simple method to alleviate this problem involves preparing complexes in which individual subunits carry different isotope labeling patterns. Most commonly, one protein will be ^{15}N- and ^{13}C-labeled, while its partner will be unlabeled. This arrangement has two advantages. First, HSQC spectra show signals from only the labeled partner, simplifying chemical shift titration experiments. Second, heteronuclear filters can be incorporated into pulse programs to either select or filter out magnetization from protons attached to specific nuclides, and hence select specific subsets of inter- or intramolecular resonances. The double half-filtered NOESY spectrum comprises four sub-spectra that are created by the linear combination of four data sets recorded with different phase cycles [22]. The most useful of these sub-spectra contain only NOEs between protons attached to different nuclides. For example, the $^{13}C(\omega_1)$-filtered/$^{13}C(\omega_2)$-selected sub-spectrum of a $^{13}C(\omega_1, \omega_2)$ double half-filtered NOESY will display NOEs between protons not bound to ^{13}C in ω_1 and protons exclusively bound to ^{13}C in ω_2. Figure 1 shows such a sub-spectrum from a data set recorded on a complex of two zinc finger domains [23] in our laboratory, and many other studies have utilized this technique to gather NOE constraints for structure determination.

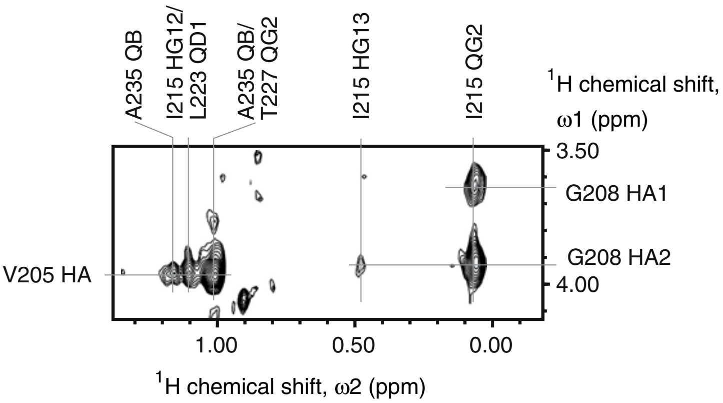

Fig. 1. Heteronuclear filtered/selected NOESY data. A portion of a two-dimensional ^{13}C-filtered, ^{13}C-edited NOESY spectrum of a 1:1 complex formed from ^{15}N and ^{13}C-labeled GATA-1 N-finger and unlabeled U-shaped finger 1, highlighting a number of intermolecular NOEs (Liew *et al.* (2005) PNAS 102, 583–8). This sub-spectrum contains only NOEs between protons attached to ^{12}C (ω2) and protons attached to ^{13}C (ω1).

Obtaining Long-Range Structural Information

A recent innovation has been the use of long-range structural information to supplement the conventional NOE data. Two methods for deriving long-range structure calculation restraints are described below; these methods have particular significance for protein complexes as they provide information about the relative orientation of subunits.

Line ‘em Up—Residual Dipolar Couplings

In NMR spectra of species that do not undergo rotational motion, resonances are split not only by scalar couplings (J), but also by dipolar couplings (D) involving nuclei that are nearby in space. These dipolar couplings can be extremely large (thousands of Hz), but average to zero if the molecule tumbles rapidly in solution. Because the magnitude of a dipolar coupling is dependent on the orientation of each internuclear vector relative to the static field, couplings between different pairs of nuclei reveal the orientation of those vectors relative to a common frame of reference (and therefore relative to each other). This represents valuable structural information, not least because it reports on the relative orientations of distant parts of a molecule or complex, in contrast to the more usual NOEs and scalar coupling constants [24].

The trick in creating a useful structural tool from this concept has been to create a physical environment where a protein exhibits a small degree of preferential alignment. Too much alignment results in the observation of many dipolar couplings that render spectra un-interpretable, but a small amount yields RDCs of up to ~10–20 Hz that are observed only for spin pairs that are strongly coupled: generally one-bond interactions. Solutions containing low concentrations of a highly aligned and asymmetric component provide suitable environments for these experiments. Bacteriophage, disc-shaped lipid bicelles (both of which align completely in a magnetic field) and compressed polyacrylamide gels have all been used [24], and in such media, the reorientation of a protein becomes slightly non-isotropic. The magnitudes of the RDCs can be tuned by altering the concentration of the alignment medium.

These splittings (e.g. $^1D_{\mathrm{HNN}}$, $^1D_{\mathrm{H}\alpha\mathrm{C}\alpha}$) can be measured directly in simple 2D and 3D NMR experiments such as undecoupled HSQC and HNCO spectra, and methodologies have been developed to incorporate these data into standard structure calculation programs [25]. It should be noted that there is some degeneracy in the derived data, with more than one possible relative orientation of a vector leading to the same RDC. This fact, together with issues with the energy landscapes generated by dipolar couplings in simulated annealing protocols, have somewhat hindered the widespread use of such data to date [24].

Dipolar coupling data have been demonstrated to be beneficial in a number of scenarios, including validation of NMR structures [26] and DNA structure determination [27]. One of their most powerful uses may prove to be in defining the relative orientations of domains in a multi-domain proteins [28–30] or of protein subunits in a complex [31,32].

Paramagnetic Nuclei

Paramagnetic species cause a multitude of effects on the relaxation and chemical shifts of neighboring nuclei [33]. Paramagnetics induce both T_1 and T_2 relaxation in nearby nuclei through a number of mechanisms, and traditionally cause problems in the structure determination of metalloproteins such as copper(II) plastocyanin. However, these effects show predictable distance and angle dependence, and can therefore provide useful structural information [33,34]. Pseudocontact shifts (PCSs) are chemical shift changes induced through the interaction of nuclei with the anisotropic susceptibility tensor χ of the paramagnetic center. These changes are dependent on the position of the nucleus relative to the χ tensor and fall off with the third power of distance, thereby providing useful long-range structural information [35]. Furthermore, interaction between the χ tensor and the strong static magnetic field can lead to preferential orientation of the protein, generating RDCs.

Because PCSs are long-range effects, chemical shift changes can be induced across protein–protein interfaces and the information can therefore be used to orient protein complexes. This approach has been successful for complexes containing cytochromes [36–38] as well as for a DNA polymerase III complex [34]. Many proteins contain metal sites that can accommodate paramagnetic ions. For example many Ca^{2+} binding sites can bind paramagnetic lanthanide ions, which due to their highly anisotropic paramagnetic susceptibilities are good choices for PCS and RDC studies [39]. In the absence of natural metal binding sites, spin-labels, such as gadolinium-EDTA [40], cobalt-EDTA [35], and TEMPO (which contains a stable nitroxide radical [41]), can be attached to proteins by chemical cross-linking.

Mapping Protein–Protein Interfaces

Chemical Shift Perturbation Experiments

The chemical shift of a nuclear spin is extremely sensitive to the physical and chemical environment of the spin, and has been used extensively to map the amino acids in a protein that directly contact a binding partner. Figure 2A shows ^1H, ^{15}N HSQC data from the titration of a solution of unlabeled α-hemoglobin into uniformly ^{15}N-labeled alpha hemoglobin stabilizing protein (AHSP [42]). ^1H, ^{15}N HSQC spectra are generally used in such titrations because of their high sensitivity and excellent resonance dispersion. It can be seen that a subset of the signals shift significantly upon the addition of α-hemoglobin, and it can be inferred that the amino acids that correspond to these signals (Figure 2B) either reside on the α-hemoglobin binding surface of AHSP, or are involved in a conformational change upon α-hemoglobin binding Feng *et al.* (2004) CELL 119, 629–40. Because of this latter possibility, care must be taken in interpreting the results of chemical shift titrations; complementary data from mutagenesis studies are often extremely useful [23,43]. Identification of binding surfaces is potentially an

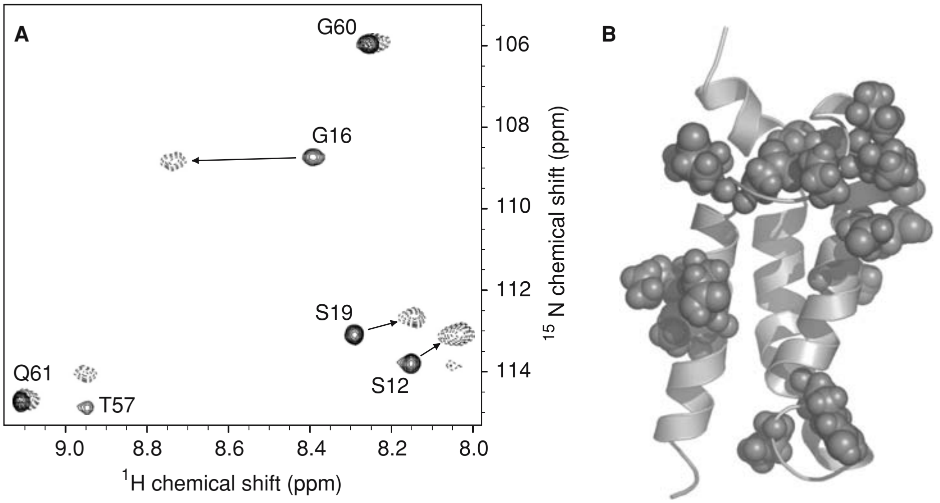

Fig. 2. Chemical shift perturbation experiment. (A) Sections of ^1H, ^{15}N HSQC spectra of ^{15}N-labeled AHSP are shown in the absence (solid lines) and the presence (dashed line) of 1.2 molar equivalents of unlabeled α-hemoglobin. Resonance assignments are indicated for several residues that undergo significant chemical shift changes (indicated by arrows), as well as several that remain unperturbed. (B) A ribbon representation of the AHSP NMR structure, highlighting the residues that undergo significant chemical shift changes upon titration with α-hemoglobin (space-fill). These residues constitute the major portion of the α-hemoglobin binding surface of AHSP (Feng *et al.* (2004) CELL 119, 629–40).

important early step in the design of targeted therapeutics, and chemical shift titrations have been used extensively in the screening of small molecule libraries to find lead compounds that bind a target protein [44]. Chemical shift titration data can also be used to determine equilibrium constants (for $K_A \sim 10^3$–10^6 M^{-1}).

Cross-saturation

Recently, a new method for mapping protein interfaces, called cross-saturation [45], has been employed to map interaction interfaces of a number of protein complexes [46–48]. In this approach, the protein whose interaction surface is to be mapped is ^{2}H- and ^{15}N-labeled and mixed with its unlabeled partner. Saturation of high-density ^{1}H nuclei of the unlabeled protein spreads to the back-exchanged amide protons on the interaction surface of the double-labeled protein by spin diffusion and can be detected through quenching of signals in a ^{1}H, ^{15}N TROSY-HSQC. Because this technique relies on through-space proximity of the interaction surfaces, conformational changes would not be expected to affect the results as they do with chemical shift mapping studies.

Protein–Protein Interactions and Chemical Exchange

The phenomenon of chemical exchange is observed in many different guises in NMR spectra. In the examination of protein–protein interactions, the rate of exchange between free and bound protein forms can lead to poor NMR spectra if the timescale of the binding process compared to the chemical shift timescale is inappropriate.

As is well known, slow and fast exchange regimes exist [49]. Consider a single proton at a protein–protein interface. In slow exchange, the lifetimes of both the bound and free states are sufficiently long ($>\sim$1 s) that a separate signal is observed for each. In fast exchange ($\sim$µs or shorter lifetimes), a single signal at an averaged chemical shift (determined by the populations of the bound and free states) is observed. At the extremes of these regimes, no signal broadening occurs. However, in between lies the intermediate exchange regime, where substantial line broadening and non-Lorentzian lineshapes can occur.

In the situation where two species with equal populations interconvert in a unimolecular reaction ($A \leftrightarrow B$), the maximum amount of line broadening occurs when the rate of exchange (k_{ex}) is given by:

$$k_{ex} = \frac{\pi \Delta \nu}{\sqrt{2}} \tag{1}$$

where $\Delta \nu$ is the frequency difference for a spin between two states. For bimolecular reactions ($A + B \leftrightarrow C$), the mathematics is more complex, but analogous expressions, albeit approximate, can be derived. In cases of intermediate exchange, the degree of line broadening depends on several parameters, namely the off-rate for the complex (k_d), the equilibrium constant (K_A), the line widths of the free and bound species, and the concentrations of each component. For typical frequency changes that might be observed in the formation of a protein complex ($\sim$10–600 Hz for ^{1}H), and assuming diffusion controlled on-rates for complex formation, equilibrium constants in the range 10^3–10^6 M^{-1} are most likely to give rise to NMR spectra exhibiting intermediate exchange. As noted above, regulatory interactions of this strength are common in cells.

Chemical shift titration data can be used to determine interaction affinities. For systems in fast exchange, non-linear least squares fitting of the population averaged chemical shift to a simple hyperbolic binding function can be carried out. For slow exchange, disappearance and/or reappearance of signals from the free or bound protein states can be used to generate a binding curve. In the case of intermediate exchange, where significant line broadening occurs, the analysis is more complex, but binding constants may still be calculated [50] (Figure 3).

Line widths often increase substantially during the course of such a titration as a result of exchange broadening, but then decrease toward the end as the fraction of labeled protein in the complexed state nears one. If the

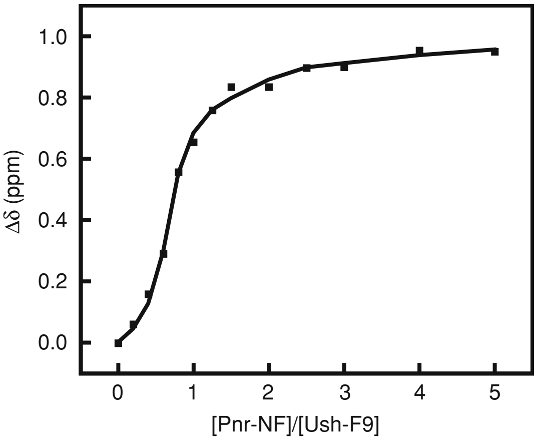

Fig. 3. Deriving binding affinity from NMR data. Plot of the change of ^{15}N chemical shift ($\Delta\delta$) for residue V21 of U-Shaped finger 9 (Ush-F9) upon binding to the N-finger of Pannier (Pnr-NF). The analysis [62] was based using a model of intermediate exchange [50] and reveals an association constant of 2.5×10^4 M^{-1}.

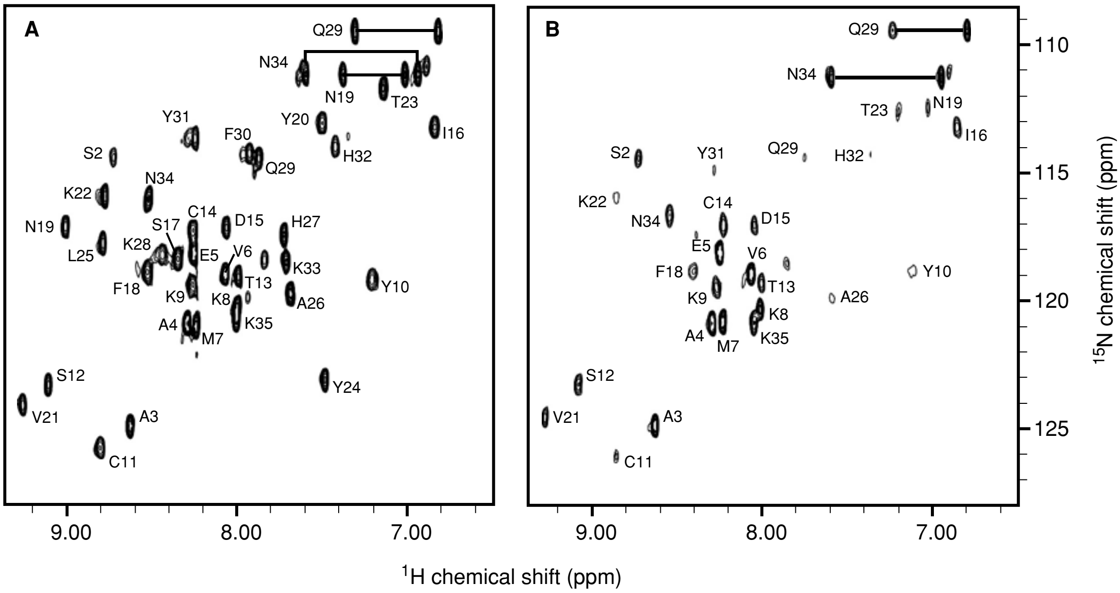

Fig. 4. The effect of intermediate chemical exchange on NMR spectra. ^{1}H, ^{15}N HSQC spectra of a point mutant (C32H) of zinc finger 9 from U-shaped, in the absence (left) and presence (right) of 5 molar equivalents of its binding partner, the N-terminal zinc finger from GATA-1 [62].

binding is relatively weak, however, it may be impractical to reach this point, preventing assignment of the complex and determination of a structure. In the titration shown in Figure 4, the signals that disappear correspond to residues that are known to lie at the protein–protein interface from mutagenesis studies [23], but it can be seen that they do not reappear even following the addition of 5 molar equivalents of unlabeled binding partner.

In principle, manipulation of solution conditions might allow one to move from intermediate to fast or slow exchange; however, in practice, the narrow range of conditions under which protein structural studies can be carried out often precludes this possibility. Protein complexes that exhibit unfavorable chemical exchange properties therefore often remain difficult to characterize by NMR.

Stitching Up Proteins for Improved Stability

In many cases, the preparation of protein complexes for structural studies is hindered by the instability of one or both components. In such cases, it may prove advantageous to either co-express the two partners [51] or to express engineered fusions of the interacting proteins. For example, the LIM domain proteins LMO2 and LMO4 are extremely unstable in isolation, which hampered studies in our laboratory of their structures and their interaction with the co-regulator ldb1. In contrast, single-chain LMO2-ldb1 and LMO4-ldb1 fusion proteins [52] could be readily purified and their structures determined [53]. Volkman *et al.* used an identical strategy in their analysis of the N-WASP:WIP complex [11]: the EVH1 domain from N-WASP was poorly expressed and insoluble, but these problems were alleviated in a N-WASP:WIP fusion protein.

A similar approach may hold promise for the analysis of weak protein complexes in which chemical exchange prevents the acquisition of high-quality data. By constraining diffusion of the two components, it may be possible to shift the system to a more favorable exchange regime. Indeed, covalent end-to-end ligation of two individually expressed recombinant proteins could potentially be achieved using intein technology (self-splicing protein modules [54]), thus permitting differential labeling of the two components as described above.

Docking Protein Complexes

An interesting new development is the use of NMR data to guide docking of protein–protein complexes, given the known 3D structures of the subunits. The *in silico* docking of two proteins in the absence of direct experimental data has generally been unsuccessful because of the large

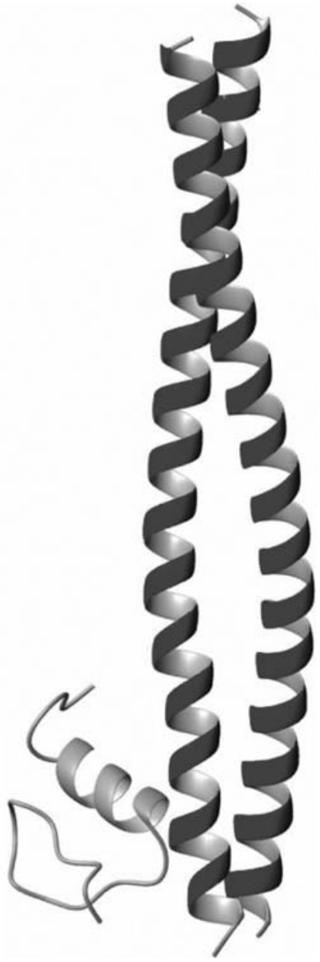

Fig. 5. HADDOCK derived structure of a complex formed between TACC3 and the third zinc finger of FOG. The TACC3 dimeric coiled-coil (dark) and the FOG zinc finger (light). The model was generated using the known structure of FOG finger 3, a homology model of the TACC3 coiled-coil, and a combination of alanine scanning mutagenesis and chemical shift perturbation data (Simpson *et al.* (2004) J Biol Chem 279, 39789–97).

number of degrees of freedom presented by two protein surfaces. However, long-range structural information derived from RDCs or paramagnetic effects, along with limited intermolecular NOEs, can be used to orient protein subunits in docking routines. For example, the N-terminal domain of enzyme I (EIN) and the histidine phosphocarrier, HPr were successfully docked using 231 ${}^{1}D_{\mathrm{HNN}}$ RDC restraints and only nine intermolecular NOEs. The final docked complex was within 1.3 Å of the previously solved NMR structure of the complex [55]. Such approaches can equally be employed to determine the domain packing of multi-domain proteins [56].

The identification of intermolecular NOEs requires the time-consuming assignment of side chain resonances. A number of approaches have been recently described for docking protocols that do not rely on NOE data [57–59]. These methods utilize chemical shift perturbation, mutagenesis and RDC data, which require only backbone assignments. HADDOCK [58] docks two proteins of known structure in the CNS-based ARIA protocol [60,61]. The use of ARIA allows the introduction of ambiguous interaction restraints (AIRs) derived from a wide range of NMR and other biophysical data. Chemical shift titration data are introduced by defining AIRs between each amino acid on the identified interaction surface of one protein and all of the residues on the surface of the partner protein. Mutagenesis data can be included in a similar fashion. We recently used this procedure to generate a model of the complex formed between a zinc finger from the transcriptional regulator FOG and a coiled-coil domain from TACC3 (Figure 5). One limitation of docking approaches is that they rely on the assumption that the structures of the bound and complexed proteins remain unchanged.

Summary

In this chapter, we have outlined the major approaches to characterizing protein–protein complexes using solution NMR spectroscopy, with a particular emphasis on recently developed experimental techniques. Essentially all of these approaches are applicable to other macromolecular complexes, and it is likely that we will see a substantial increase in both the number and the complexity of the systems analyzed over the next 5 years.

Identification and Characterization of Ternary Complexes Using NMR Spectroscopy

Robert E. London

Laboratory of Structural Biology, National Institute of Environmental Health Sciences, Research Triangle Park, NC 27709, USA

Introduction

The complex macromolecules that have evolved to serve a broad range of biological functions present surfaces with highly variable topological, electrostatic, and hydrogen bonding properties. These surfaces provide the basis for interactions that play critical roles in catalysis and signal transduction, and offer a limitless landscape of potential targets for chemical agents designed to interfere with these functions. A broad range of analytical techniques has been developed to exploit this topological information when it is available, but it is clear that flexible ligands can interact in unanticipated ways with their theoretical targets, and often with unintended targets as well. Substitution of an amino group for a single oxygen substituent to convert folate to aminopterin results in a potent antifolate drug which, unexpectedly, adopts a dramatically different conformation in the complex with the target enzyme, dihydrofolate reductase [1,2]. Studies of the inhibition of alpha-chymotrypsin by a series of 1-acetamidoboronic acids unexpectedly revealed that when the side chain of the inhibitor was altered from a *p*-chlorophenyl to a 1-naphthyl group, the enzyme reversed its usual preference for L-enantiomers, which more closely resemble the natural substrates, and bound more tightly to the D-enantiomer [3].

The sensitivity of NMR spectroscopy to ligand–macromolecule interactions makes it of considerable value for the process of ligand identification and modification, and a broad range of approaches have been described that involve direct observations of either the target macromolecule [4] or the ligand [5]. The use of any particular approach is generally strongly dependent on the particular problem under study, however direct NMR studies of biologically important macromolecules are limited by the size and complexity of the macromolecule, its solubility, the general requirement for isotopic labeling, and the more extensive analysis which may be required. Alternatively, observations of ligands have been demonstrated to be useful for selecting lead compounds from complex mixtures [6] and for obtaining insight into the conformation of bound ligands [7], and are often more straightforward to interpret.

One approach for the analysis of ligand–macromolecule interactions involves the identification of ternary complexes formed from pairs of ligands in the presence of a macromolecule. In some cases, biologically interesting complexes have formed from adventitious inorganic ions such as aluminum or beryllium fluorides [8]. The presence of adventitious zinc ions led to the identification of a trypsin-Zn^{2+}-bis(5-amidino-2-benzimidazolyl)methane ternary complex, which formed a basis for the further development of serine protease inhibitors [9]. Arsenate and borate complexes have been identified due to the use of cacodylate and borate buffers [10,11]. Vanadate complexes have been identified in toxicological and bioinorganic studies [12–14]. These complexes have been detected based on their biochemical effects, or by structural methods including X-ray crystallography and NMR spectroscopy. Arsenate complexes often mimic phosphate complexes, both structural and biochemically, while vanadate complexes often form pentavalent structures that mimic the transition state involved in nuclease and phosphatase biochemistry [12–15]. Vanadate, and aluminum and beryllium fluorides are all capable of mimicking the terminal phosphate group of nucleotides, e.g. turning ADP into the ADP-VO_4 analog of ATP [16–18]. Boronate and borate complexes most frequently mimic the tetrahedral transition state of serine proteases and mechanistically related enzymes [19–21]. Alternatively, enzymatic catalysis frequently involves the formation of ternary complexes that include two, and occasionally more, organic ligands. For example, many enzyme-catalyzed redox reactions involve ternary enzyme-substrate–cofactor complexes. Formation of transient complexes involving macromolecules and organic ligands can be studied using transferred interligand Overhauser effects (ILOEs) [22–27]. A brief outline of NMR approaches used to study ternary complexes is described in the present article.

Borate Complexes and Their Study by NMR Spectroscopy

Studies of ternary and higher order complexes formed from inorganic ions have provided insights into the

Graham A. Webb (ed.), Modern Magnetic Resonance, 1347–1356.
© 2008 *Springer.*

toxicological properties of these ions, valuable structural information, insight into catalytic mechanisms, as well as fundamental information of use for the design of inhibitors. In some cases, these ions interact with active site residues of enzymes in ways that mimic transition state structures. A comprehensive review of this area is beyond the scope of the present article, but our recent studies of borate complexes illustrate many of the features of these studies.

Boric acid (pK = 9.0) is a convenient buffer for high pH assays of enzymes or other biochemical phenomena. The use of borate buffers has led to a number of unanticipated observations that resulted from the presence of borate–ligand complexes. For example, borate has been found to inhibit pyridine nucleotide and flavin-requiring enzymes as a result of complex formation with these cofactors [28,29]. A more dramatic effect is observed in studies of the membrane protein γ-glutamyl transpeptidase (γ-GT), an enzyme important for glutathione metabolism that transfers γ-linked glutamyl groups between peptides, amino acids, or other acceptors. For this enzyme, serine and borate, which individually exert little effect on the enzyme, exhibit a dramatic inhibitory synergy [11]. This inhibitory synergy apparently results from the stabilization of a ternary γ-GT–serine–borate complex, in which the borate adopts a tetrahedral, anionic form that is esterified to both an enzyme threonine hydroxyl group, as well as to the hydroxyl group of the serine ligand [20,21]. This ternary complex thus mimics a putative transition state in which the threonine hydroxyl group of the active site binds to the γ-carbon of the glutamyl group in glutathione or another substrate, creating a transition state with tetrahedral geometry.

Although direct NMR observations of membrane associated enzymes such as γ-GT are difficult, the general features of such ternary complexes have been observed for the serine protease trypsin [30–32]. In these studies, several cationic alcohols with presumed affinity for the trypsin S1 specificity binding pocket were studied. The molecules were selected so that the alcohol function would be appropriately positioned to interact with a borate bound to the active site serine-195. Boron-11 spectra of samples containing borate, trypsin, and 4-aminobutanol (4AB) are characterized by a resonance with a chemical shift that corresponds to the boric acid–borate equilibrium at the pH used for the study, as well as an upfield shifted resonance corresponding to a tetrahedral borate which is now in slow exchange with the free boric acid/borate species (Figure 1). Binary mixtures of borate–trypsin or borate–4AB, or a ternary mixture of borate, trypsin, and 3-aminobutanol do not show the upfield shifted resonance. The resonance observed at −17.3 ppm can therefore be assigned to a ternary trypsin–borate–4AB complex.

Analogous complexes have now been observed in the crystalline state [31,32]. Interestingly, the crystallographic studies demonstrate that the nature of the borate complex formed at the active site is significantly influenced by lattice contacts, so that a ternary trypsin–borate–4AB complex analogous to that observed in solution could be observed in $P3_121$ crystals [32], while only quaternary trypsin–borate–4AB–ethylene glycol complexes were observed in $P2_12_12_1$ crystals [31]. In the $P2_12_12_1$ crystals, formation of the active site borate complex was found to be correlated with a 4% expansion of the crystal along the *b*-axis. These results were interpreted to indicate that the additional stability of the quaternary complex was required to overcome crystal packing effects. This study therefore illustrates the significant effect that lattice contacts can have on crystallographic screening for enzyme ligands.

Most of the inorganic complexes which have been studied by NMR, involve nuclei with spin >1/2, and hence are subject to quadrupolar relaxation. For quadrupolar nuclei bound to very large molecules such that $\omega\tau \gg 1$, where ω is the Larmor frequency of the nucleus and τ its rotational correlation time, the relaxation behavior is multiexponential. For nuclei with half-integral spin in this limit, the central $1/2 \leftrightarrow -1/2$ transition can give rise to a relatively narrow signal, while the remaining transitions are very broad and generally unobserved [33–36]. Subject to the above assumptions, the linewidth of the central transition is then inversely related to $\omega^2\tau$, i.e. the linewidth actually narrows as the rotational correlation time of the complex τ increases:

$$\Delta\nu_{1/2} = \frac{1}{\pi T_2} = \frac{2s+3}{\pi s^2(2s-1)}\Big(2J_1^Q(\omega_S) + ((s+3/2) \times (s-1/2)-1)\Big(J_2^Q(2\omega_S)\Big)\Big) \quad (1)$$

where

$$J^Q(\omega) = \frac{3\chi^2}{160}\left(\frac{\tau}{1+\omega^2\tau^2}\right) \quad (2)$$

χ is the quadrupole coupling constant, nucleus S has spin s and Larmor frequency ω_S, τ is the rotational correlation time, and isotropic motion is assumed. In the limit $\omega\tau \gg 1$, we obtain:

$$\Delta\nu_{1/2} = \frac{1}{\pi T_2} \approx \left(\frac{2(2s+3)}{\pi s^2(2s-1)}\right)\left(1+\frac{1}{8}((s+3/2) \times (s-1/2)-1)\right)\frac{3\chi^2}{160}\frac{1}{\omega^2\tau} \quad (3)$$

This inverse dependence on τ contrasts with the linewidth predictions based on other relaxation mechanisms such as the dipolar interaction and chemical shift anisotropy, which predict $\Delta\nu_{1/2} \sim J(0) \sim \tau_c$. Exchange

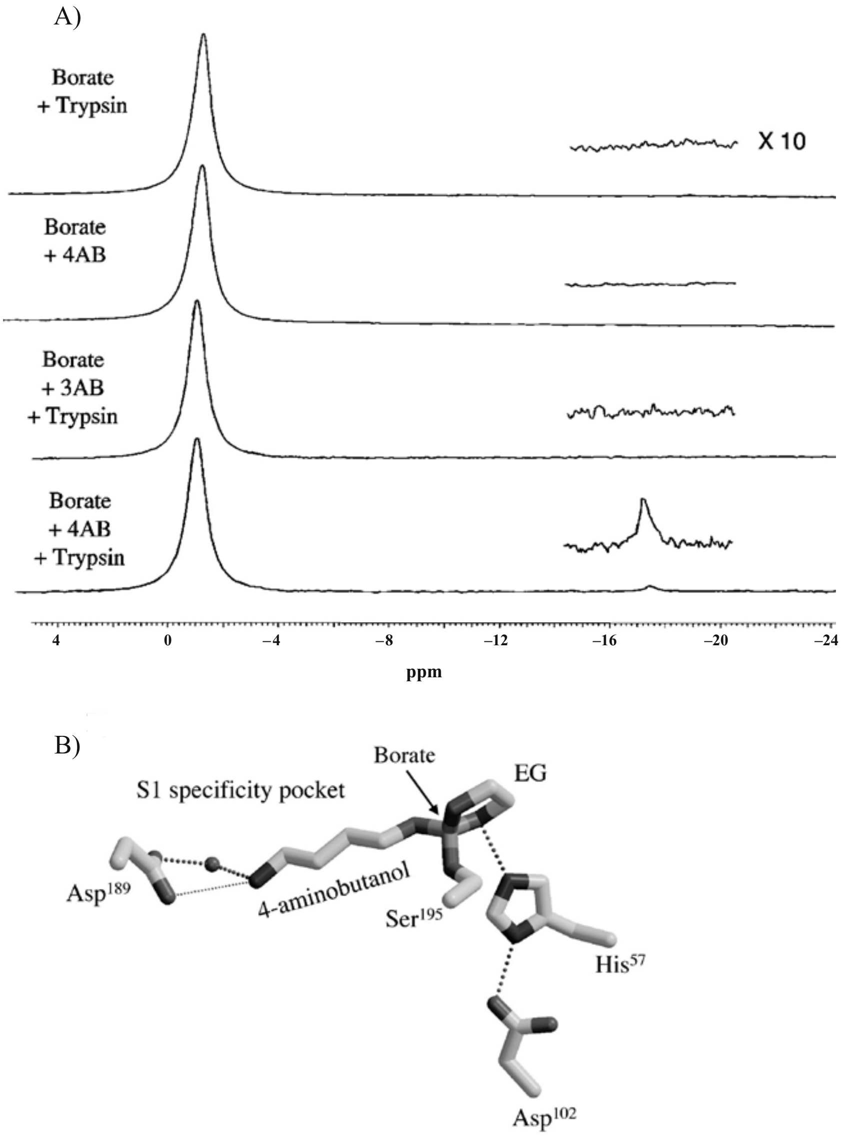

Fig. 1. (A) Boron-11 NMR spectra obtained at 160.6 MHz, 25°C on samples containing (top to bottom) 5 mM borate and 2 mM porcine pancreatic trypsin; 25 mM borate and 250 mM 4-aminobutanol; 5.0 mM borate, 50 mM 3-aminopropanol, and 2 mM trypsin; 5.0 mM borate, 50 mM 4-aminobutanol, and 2 mM trypsin. Insets show a 10-fold vertical expansion. All samples contained 20 mM HEPES, pH 8.0 (based on Figure 1 of Ref. [30]). (B) Active site of trypsin showing complex formed with borate, 4-aminobutanol, and ethylene glycol (EG) (based on Figure 1F of Ref. [31]). A similar ternary complex without the EG has also been observed for crystals in the $P3_{1}21$ space group [32].

broadening due to the chemical exchange between uncomplexed and variously complexed forms of the ion also can make significant contributions. The observation of narrow resonances for quadrupolar nuclei in macromolecules is illustrated by the ^{11}B NMR spectrum of 4-fluorobenzeneboronic acid (FBBA) in the presence of a small ligand, sorbitol, and the enzyme subtilisin Carlsberg (MW = 27.3 kD), shown in Figure 2. As

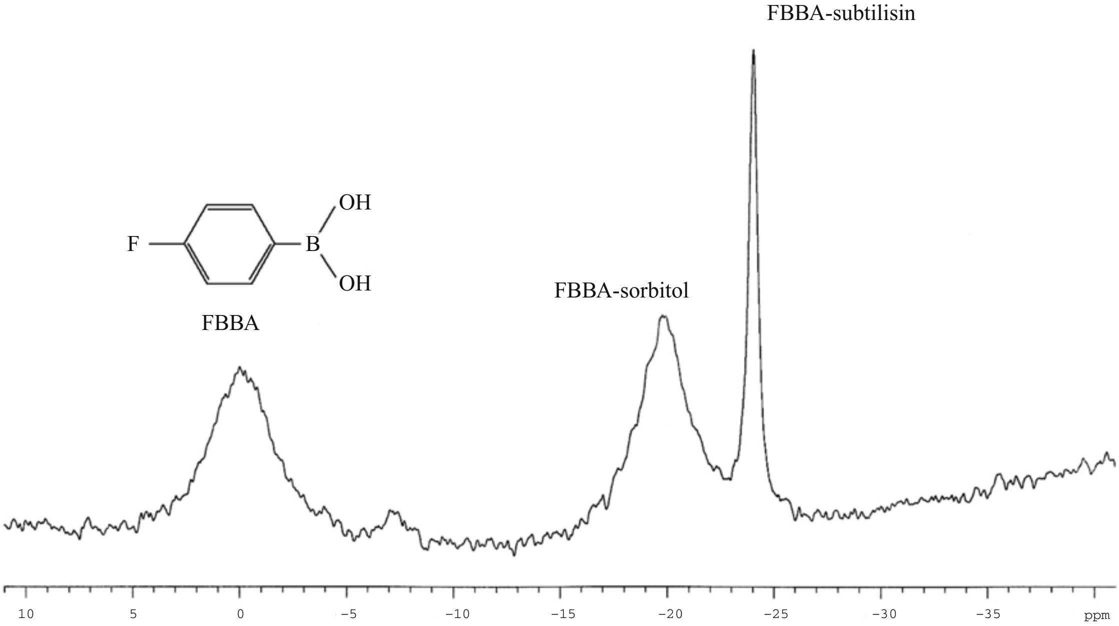

Fig. 2. Boron-11 NMR spectrum of 5 mM 4-fluorobenzeneboronic acid, 1.5 mM sorbitol, 2 mM subtilisin Carlsberg (MW = 27.3 kD) in 50 mM HEPES, pH 7.5 obtained at 11.75 T (160.6 MHz ^{11}B frequency), 5°C.

predicted above, the resonance arising from the boronate–subtilisin complex is significantly narrower than the resonances for either free boronate or for the boronate–sorbitol complex. The ^{11}B linewidth of the uncomplexed FBBA is determined by quadrupolar relaxation of the ^{11}B nucleus (spin = 3/2) and by boronic acid–boronate exchange, while the linewidths of the FBBA–sorbitol and FBBA–subtilisin complexes are probably determined primarily by quadrupolar ^{11}B relaxation. In addition to this unintuitive dependence of linewidth on rotational correlation time, the quadrupolar nuclei are also subject to a second-order dynamic frequency shift which is also inversely correlated with ω (i.e. B_0) [35,36]:

$$\delta = \frac{8s(s+1)-6}{s^2(2s-1)^2}\Big(L_1^Q(\omega_S) - L_2^Q(2\omega_S)\Big) \qquad (4)$$

where

$$L^Q(\omega) = \frac{3\chi^2}{160}\left(\frac{\omega\tau^2}{1+\omega^2\tau^2}\right) \qquad (5)$$

so that

$$\delta \approx \frac{4s(s+1)-3}{s^2(2s-1)^2}\left(\frac{3\chi^2}{160}\right)\left(\frac{1}{\omega}\right) \quad \text{for } \omega\tau \gg 1 \qquad (6)$$

Expression of the shift in ppm results in a ω^{-2} dependence. Observations on the relaxation behavior of various metal ion complexes with transferrin have verified the predicted linewidth and shift behavior [37–39].

In summary, ^{11}B NMR studies provide a useful way of characterizing transient complexes that may form involving borate esters. The exchange behavior among various complexes is often sufficiently slow on the NMR time scale to allow observation of separate resonances. Similar complexes can be observed in the crystalline state, however in this case, lattice contacts can significantly alter the observation of these weak complexes. The observation of such complexes can provide useful insight into the development of boronated as well as non-boronated ligands.

Ternary Complexes Involving Organic Molecules

Although ternary complexes formed from inorganic ions can provide a useful basis for the development of high affinity ligands, it is desirable to generalize this approach by removing the restriction to inorganic ions. The observation of ILOEs provides one basis for obtaining information on the spatial proximity and relative orientation of two (or potentially more) ligands that form a relatively weak complex with a macromolecular binding site. Nuclear Overhauser effect (NOE) interactions involving

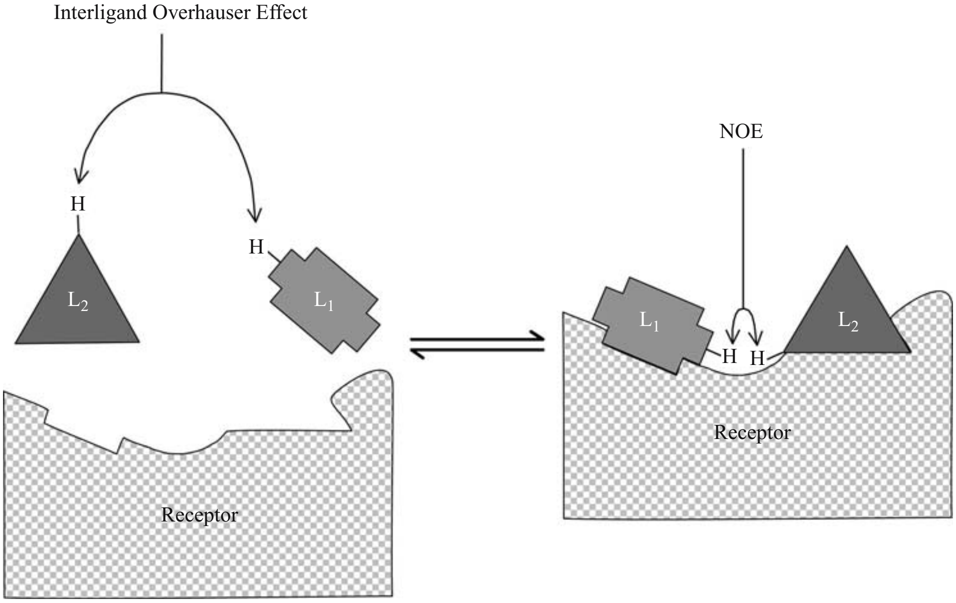

Fig. 3. Schematic illustration of the interaction of two ligands, L$_1$ and L$_2$, with a macromolecule. NOE interactions between the protons on the two different ligands can be transferred to the free ligands due to dissociation of the complex.

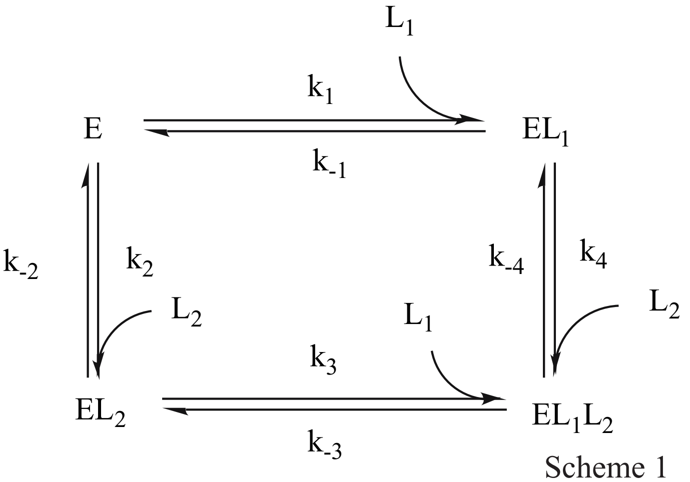
protons on the two ligands are transferred to the pair of uncomplexed ligands much as the intramolecular NOE information is transferred to the free ligand in a transferred NOE experiment (Figure 3). As in the transferred NOE experiment, these experiments are typically performed using a significant excess of ligand concentration, i.e. [L$_1$], [L$_2$] $\gg$ [E], where L$_1$ and L$_2$ are the two ligands and E is the enzyme or other macromolecule forming the complex. Since this approach involves direct observation of the ligand resonances, but not the resonances of the macromolecule, it does not require complex resonance assignment strategies. Further, as with the transferred NOE experiment, it works well on macromolecules that are too large for direct structural determination using currently available NMR methodology. However, in contrast with the transferred NOE experiment, this experiment is considerably less subject to misinterpretation resulting from non-specific binding, ligand aggregation, or ligand misbinding. The latter effect arises because ligand binding is essentially an exploratory process in which a ligand may become transiently lodged in an enzyme cleft in a non-productive conformation such that the structural constraints will not allow it to readily adopt a productive conformation. It then becomes most probable for the ligand to dissociate, and subsequently it may reassociate in a conformation which can lead to a productive complex. If the misbound ligand remains associated with the macromolecule for a time that is on the order of the rotational correlation time, it is then able to develop an NOE characteristic of the bound state, and this NOE information characteristic of the misbound complex will be transferred to the free ligand, along with the NOE information from the correctly bound ligand.

For both transferred NOE and interligand NOE studies to provide useful information, the exchange rates for both ligands must be reasonably fast compared with the T_1 time scale of the protons that are under observation. This allows NOE interactions characteristic of the bound ligand(s) to be observed regardless of whether the exchange is fast or slow on the chemical shift time scale, although in general, slow exchange on the shift time scale is less likely to satisfy the T_1 time scale constraint noted above, and leads to non-linear NOE build-up curves. The long T_1 values for the uncomplexed ligand allow it to be used as a "magnetic storage device" for NOE information that is formed in the macromolecular complex. The kinetic behavior of such a system is described using eight rate constants, seven of which are independent, as shown in Scheme 1. The fractional populations of the uncomplexed enzyme/macromolecule, pE, the two binary complexes pEL$_1$ and pEL$_2$, and the ternary complex pEL$_1$L$_2$, can be expressed as a function of the concentrations and rate constants, as described previously [24]. From a practical standpoint, we have generally found that

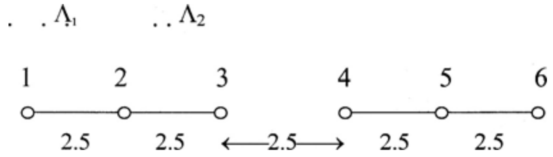


Scheme 1

association rate constants of ~10^8/M/s and dissociation rate constants of 10^3/s that correspond to equilibrium dissociation constants of ~10 μM produce strong effects that are readily observed under typical sample conditions.

An illustrative 2D NOESY spectrum for a system with two spins is shown in Figure 4. The 1D spectrum for this system consists of two sets of three resonances: for spin 1 on L_1, the shift will generally be dependent on whether the ligand is free, in a binary complex with E, or in a ternary complex with E and L_2. The diagonal peaks are shown as open circles. The exchange cross peaks which connect specific spins interconverting among the free, binary, and ternary complexed forms are in black. The NOE cross peaks connecting spins 1 and 2 on the ternary complex are shown in light gray. Of course, since the spins are postulated to be on different ligands, the values for the binary complexes and the free ligands will be zero in the absence of exchange. Finally, the dark gray cross peaks are exchange-mediated NOE interactions which become non-zero when both chemical exchange and NOE interactions are present. For example, such cross peaks can connect spin 1 in a ternary complex with spin 2 in the free state. When the exchange is sufficiently rapid compared with the relevant spin lattice relaxation rates, the sets of nine cross peaks in each of the four boxes shown in the figure exhibit the same time dependence, differing only in a magnitude. When this condition is not met, the elements in each box can exhibit different dependences on the mixing time. In a typical experiment of this type, one observes only a single resonance for each spin due to the fact that the concentrations of the binary and ternary complexes are much lower than the free ligand concentrations, or, more typically, due to fast exchange on the chemical shift time scale. If the latter condition is met, it is appropriate to sum the NOE build-up curves for the nine peaks in each of the indicated boxes. This represents the optimal condition for the transferred NOE and interligand NOE observations. In this case, the sum of the nine NOE cross peaks, A_{ij}, can be represented by another matrix, C_{ij} [24].

Simulations of the dependence of the interligand NOE (ILOE) on mixing time have been performed for a range of geometric structures and kinetic rate constants [24]. In general, the ILOE curves exhibit a dependence on mixing time which is similar to the transferred NOE curves, characterized by an initial build up and a subsequent decay as relaxation effects become dominant. Calculations corresponding to the intensities of the NOESY cross peaks, A_{ij}, and to the sums of elements, C_{ij}, have been performed for a model system that contains two ligands with three spins arranged linearly and separated by 2.5 Å. A ternary complex was modeled in which all six nuclei of both ligands are also arranged in a line, with nucleus 3 on ligand 1 and nucleus 4 on ligand 2 also separated by 2.5 Å, as shown below:



Using parameters: [E] = 0.4 mM, $[L_1] = [L_2] = 5$ mM, $\tau_{1F} = \tau_{2F} = 10^{-10}$ s; $\tau_B = 10^{-7}$ s, $k_1 = k_2 = k_3 = k_4 = 10^8$/M/s, $k_{-1} = k_{-2} = k_{-3} = k_{-4} = 10^{-3}$/s, and other parameters as given in Ref. [24], curves showing

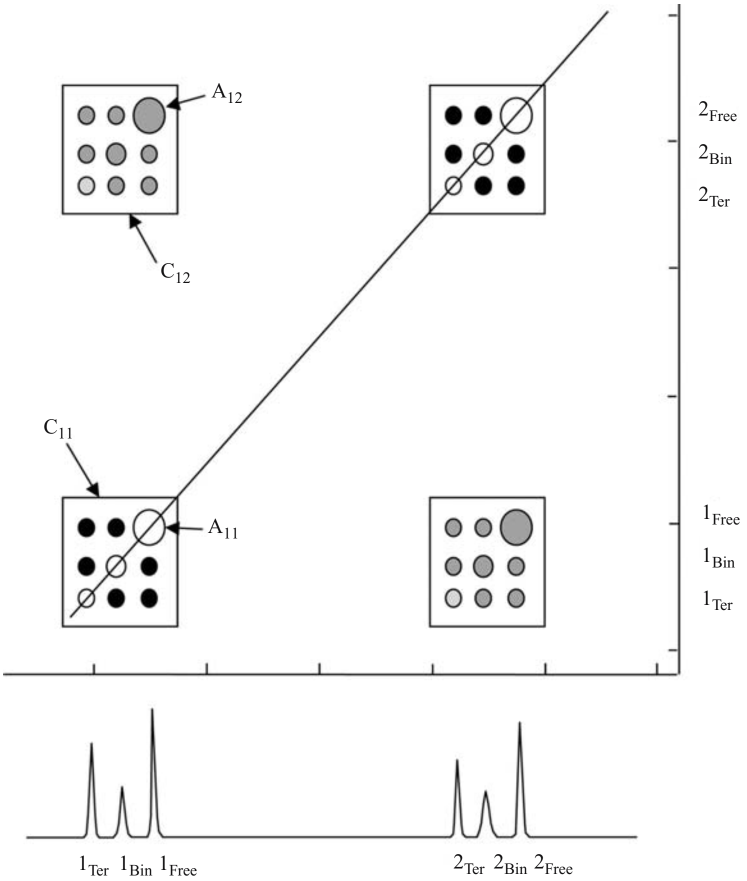


Fig. 4. Schematic representation of a 2D NOESY spectrum for a system containing a macromolecule, E, and two ligands, L_1 and L_2, which can form binary or ternary complexes with E. Nucleus 1 is assumed to be positioned on L_1, and nucleus 2 on L_2. The observation of separate resonances for each spin in the free, binary, and ternary complexes would only be possible under slow exchange conditions on the chemical shift time scale, but is useful for illustrative purposes. The exchange peaks which interconvert nucleus 1 (or 2) between free, binary, and ternary complexes are shown in black. Cross peaks arising from NOE interactions between nuclei 1 and 2 in the ternary complex are shown in light gray. Note that if spins 1 and 2 are on different ligands, there will be no cross peaks for the uncomplexed ligands and for either binary complex. Cross peaks that arise due to a combination of exchange and NOE interactions are shown in dark gray. Under conditions of fast exchange, only the sums of the peaks in each square, i.e. the C_{ij} matrix elements, are observed (based on Figure 1 of Ref. [24]).

the dependence of C_{12}, C_{56}, and C_{34} on the mixing time are shown in Figure 5A. Note that the initial slopes of the C_{12}, C_{56}, and C_{34} curves are identical, consistent with the equal r_{12}, r_{56}, and r_{34} internuclear distances in the model ternary complex which, based on the above parameters, corresponds to 0.996 of the total enzyme concentration available. Most of the difference that can be observed between C_{12} and C_{34} arises due to the faster decay of the C_{34} NOESY interaction, which arises primarily from the presence of two nearest neighbor spins in the ternary complex, compared with one nearest neighbor spin for nucleus 1. Thus, a comparison of the C_{23} with C_{34} curves shows greater similarity (not shown).

In a typical transferred NOE experiment, the internuclear distances of the complexed ligand can be calibrated by comparing the initial slope of the NOE build-up curves with that obtained for a pair of nuclei that have a fixed internuclear distance. For example, in a study involving NADPH, the calibration curve could correspond to the H5–H6 protons on the nicotinamide ring. For the interligand NOE, the analysis becomes more complex if the two ligands have significantly different kinetic parameters. If the fraction of the ternary complex pEL_1L_2 becomes significantly less than one and the fraction of one binary complex, e.g. pEL_1 becomes significant, ligand 1 will be subject to greater transferred NOE effect than ligand 2. In general, the ILOE will scale with the weaker binding ligand. As shown in Figure 5B, increasing the off rates for L_2 to 10^5/s results in a relatively modest increase in pEL_1 and decreased initial slopes for the C_{56} and C_{34} build-up curves. Further increasing the off rate of L_2 to 10^6/s lowers the fraction of E in the ternary complex to 1/3, resulting in a significantly greater initial slope for C_{12} than for C_{56} or C_{34}, which exhibit similar values (Figure 5C). Increasing $k_{-2} = k_{-4}$ to 10^7/s largely eliminates the binding of ligand 2, giving $pEL_1 = 0.95$ (Figure 5D). Interestingly, the initial slope calculated

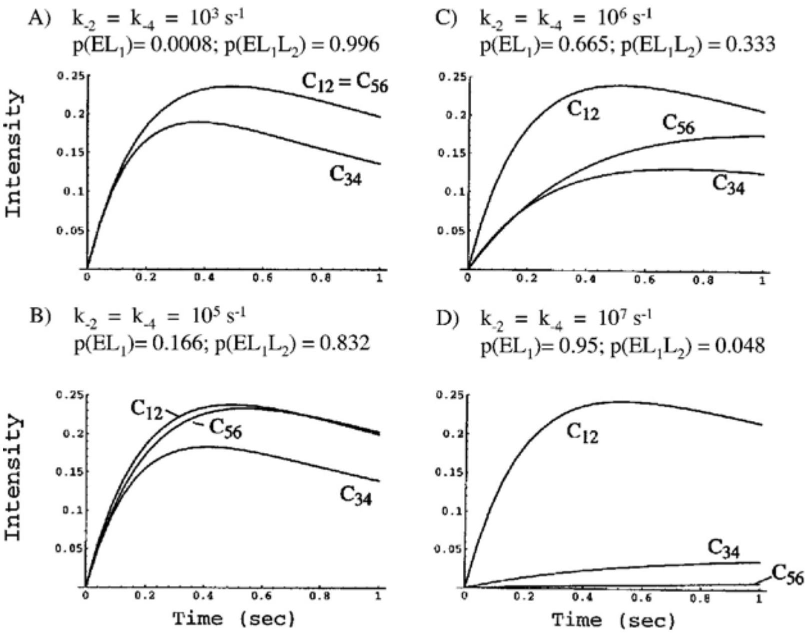

Fig. 5. Sensitivity of interligand Overhauser effects to weaker binding. The set of simulations shown above illustrates the effect of increasing the dissociation rate constant of L$_2$, while leaving that of L$_1$ fixed, with $k_{-1} = k_{-3} = 10^3$/s. All association rate constants are set at 10^5/M/s. The calculated fractions of E involved in the ternary (pEL$_1$L$_2$) and binary (pEL$_1$) complexes are shown for the corresponding dissociation rate constants above each figure. (A) $k_{-1} = k_{-2} = k_{-3} = k_{-4} = 10^3$/s; (B) $k_{-2} = k_{-4} = 10^5$/s; (C) $k_{-2} = k_{-4} = 10^6$/s; (D) $k_{-2} = k_{-4} = 10^7$/s. Other parameters as given in Ref. [24] (based on Figure 6 in Ref. [24]).

for C_{34} is greater than that calculated for C_{56}, and no significant transferred NOEs are predicted for ligand 2. This results because for these parameters, L$_2$ is largely free, and free L$_2$ experiences an NOE of opposite sign to the bound ligand. Hence, the presence of free L$_2$ reduces the observed build-up. However, no such subtraction effect arises for the interaction between nuclei 3 and 4, since these do not interact when L$_2$ is not bound to E.

ILOE Observations—Type II Dihydrofolate Reductase

Interligand Overhauser effects have been observed in several systems of interest [22,23,25–27]. In general, such effects can be observed in non-productive ternary enzyme complexes that involve inhibitors or other molecules that are not substrates for the enzyme under study. Ternary complexes involving enzyme substrates can be observed if the enzyme has been inactivated by mutagenesis. Alternatively, enzymes involved in redox chemistry can be studied if the pair of ligands are both in the oxidized or reduced state, rather than the reduced–oxidized combination that functions as a substrate–cofactor pair. Of course, binding to other types of macromolecules can also be studied, and in this case, there are no concerns about ligand tur over.

Dihydrofolate reductase catalyzes the NADPH-dependent reduction of dihydrofolate to tetrahydrofolate. Type II dihydrofolate reductase is a plasmid-encoded enzyme that is structurally unrelated to the extensively studied type I enzyme, and confers antifolate drug resistance on bacteria containing the plasmid. The enzyme is a symmetric tetramer that binds the substrate and cofactor in a central pore [27]. Figure 6 illustrates portions of a NOESY experiment for a sample containing 0.1 mM R67 DHFR, 5 mM folate, and 5 mM NADP [25]. The region of the spectrum including the CH$_2$ protons of folate (at the F9 position) are shown in Figure 6. Transferred NOE cross peaks to the folate F7, proton, and to the folate F12/16 and F13/15 protons on the *p*-aminobenzoyl group are readily observed. ILOE peaks connecting the folate F9 protons to the nicotinamide NH-4 and NH-5 protons on the NADP also can be observed in the spectra. All of these peaks exhibit time-dependent build-up curves expected for the

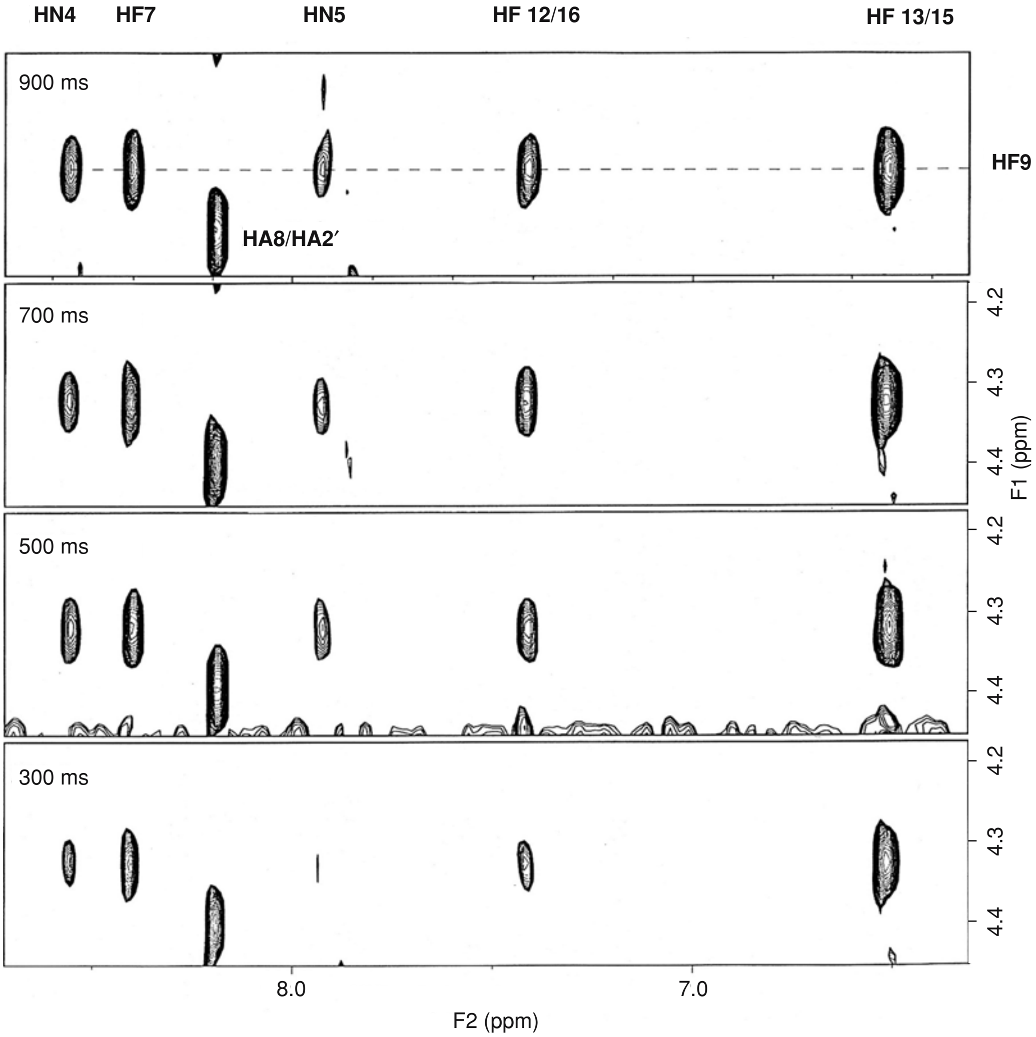

Fig. 6. A portion of the NOESY spectrum illustrating the cross peaks connecting the folate H-9 protons with the aromatic protons of folate and NADP$^+$, obtained on a sample containing 0.1 mM R67 DHFR, 5 mM folate, and 5 mM NADP$^+$ in 100 mM Tris-d11, pH 8.0 in D_2O. The spectra correspond to mixing times of 300, 500, 700, and 900 ms, as indicated (based on Figure 2 of Ref. [25]).

NOE experiment. The results obtained in this study are intuitive since the ILOE peaks are observed near the positions (NH-4 on NADPH, C-6 on folate) at which redox chemistry occurs. The very weak ILOE peaks involving the folate F-7 were also useful for determining the relative positions of the two ligands.

The potential application of ILOE studies for ligand discovery has been demonstrated in experiments on alcohol dehydrogenase, in which a sample contained NADH and an inhibitor, *m*-methylbenzamide, as well as a reducing agent, sodium cyanoborohydride, included in order to maintain the NADH in the reduced state [26]. In this study, unanticipated cross peaks were observed between the BH_3 protons on the cyanoborohydride and the methylbenzamide protons. It was concluded that the methylbenzamide binds primarily to a hydrophobic pocket in the active site that is involved in binding larger substrates, such as benzyl alcohol, while the cyanoborohydride formed a transient complex with the active site Zn^{2+} ion [26].

Summary

The identification and characterization of ternary complexes involving organic molecules and inorganic ions should provide a useful basis for the further development of targeted ligands. Although the example of borate discussed above involved the serine protease trypsin, recent structural data indicate that borate complexes can form outside of the active site, supporting the possibility of targeting protein–protein interactions in a more general way. Comparisons with crystallographic analyses of the same complexes indicate that crystal screening approaches, while generally very useful, are subject to potentially significant influences that result from lattice contacts. ILOEs can provide useful insight into the relative binding and orientation of ligands that reversibly form ternary complexes. The presence of unanticipated complexes has been observed in some studies, supporting the potential application of this approach to the design of novel ligands.

The Transferred NOE

Mike P Williamson

Firth Court, Western Bank, Sheffield S10 2TN, UK

Abstract

The transferred NOE allows NOE information to be obtained on a bound ligand, but appearing on the resonances of the free ligand. It is thus a very useful method for gaining information on the bound ligand. Its major limitation is that it only works well in a range of dissociation constants between 1 mM and 10 nM. A key negative control experiment is to demonstrate the absence of NOEs arising from nonspecific binding, by addition of competitor ligands. A second is to measure NOEs in the absence of protein. For quantitative work, it is also necessary to minimize spin diffusion, by using relatively short mixing times. Recent work has shown that spin diffusion in TR-NOE is no worse than spin diffusion in standard NOE spectra of proteins. With care, TRNOE can thus provide powerful quantitative information on bound conformation.

Affinities and Timescales

The appearance and information content of an NMR spectrum of a protein/ligand mixture depend strongly on the rates of binding and tumbling of the components. This is why it is important to think about these rates, and understand their implications.

The binding of a ligand to a protein can be written

$$L + P \underset{k_{\text{off}}}{\overset{k_{\text{on}}}{\rightleftharpoons}} L \cdot P \tag{1}$$

The overall on-rate is k_{on}[L][P], and the off-rate is k_{off}[L.P]. At equilibrium, these are by definition equal. The dissociation constant K_d is [L][P]/[LP], which is therefore also equal to $k_{\text{off}}/k_{\text{on}}$. The association constant K_a is simply $1/K_d$.

For most ligand/protein interactions, binding happens as fast as ligand and protein can come together: in other words, the on-rate is diffusion controlled. The on-rate (k_{on}) is usually assumed to have a value of around 10^8 M^{-1}s^{-1}, and will only be significantly slower if the protein binding site is somehow buried or hidden (which is unusual, particularly for inhibitors as compared to substrates). We can therefore get a good estimate of the off-rate if we know the dissociation constant, since $k_{\text{off}} \approx 10^8 K_d$. A good drug often has a K_d in the low nM range, and therefore has a k_{off} of around 1 s^{-1} or less. By contrast, initial targets derived from screening programes will typically have K_d values in the high μM or low mM range, and will therefore have off-rates of around 10^5 s^{-1}. This leads to very different NMR behavior.

We also need to consider that the concentrations of samples in NMR are comparable to some of these numbers, and therefore the fraction of ligand bound is strongly dependent on K_d. It is easily shown that for the simple binding equilibrium shown above, the concentration of free ligand is given by

$$[\text{L}] = 0.5([\text{L}_0] - [\text{P}_0] - K_d + \{([\text{L}_0] - [\text{P}_0] - K_d)^2 + 4[\text{L}_0]K_d\}^{1/2}) \tag{2}$$

where [L$_0$] and [P$_0$] are the total concentrations of ligand and protein respectively. So for example, if the total protein concentration is 50 μM, K_d is 10 nM, and there is a 1:1 ratio of ligand to protein, then almost all the ligand is bound (only ca. 1.4% is free); if there is a 10-fold excess of ligand over protein, then to a good approximation one equivalent is bound and the other 9 are free. By contrast, with the same protein concentration, a 10-fold ligand excess and a much weaker K_d of 1 mM, the concentration of bound ligand is only 16 μM (i.e. only one-third of the protein is bound), and 97% of the ligand is free. Thus, the amount of bound complex depends strongly on K_d. This will be important when we come to think about what the NMR spectrum looks like.

The off-rate is important for another reason, namely because it defines whether exchange processes are in "fast" or "slow" exchange [1]. Confusingly, there are different definitions of what is meant by fast and slow, depending on what we are interested in. The most obvious is the chemical shift timescale: whether we see one signal or two. This depends on $\Delta\nu$, the difference in resonance frequency between the two signals, expressed in Hz. Fast exchange is when $k_{\text{off}} \gg \Delta\nu$. Thus if for example we are considering a ^{1}H spectrum at 500 MHz, in which free and bound signals are 0.3 ppm different, $\Delta\nu = 150$ Hz, so k_{off} must be 1000 s^{-1} or greater for fast exchange (corresponding to a K_d of 10 μM or weaker). Slow exchange requires k_{off} <30 s^{-1} and K_d 0.3 μM or

Graham A. Webb (ed.), Modern Magnetic Resonance, 1357–1362.
© 2008 *Springer.*

stronger. Thus, almost all initial leads and screening hits are in or close to fast exchange, while strong ligands are in slow exchange. Intermediate off-rate values give broadened signals. It is however worth noting that intermediate exchange looks different when the amounts of the two species are unequal, which would happen if for example there were an excess of free over bound ligand. In this situation, the appearance of the free signal is almost unaffected, while the bound signal is broadened so much that it is frequently unobservable [2]. It is therefore not easy to tell whether the ligand is in fast exchange on the chemical shift timescale simply by looking at the appearance of the signal.

A ligand undergoing exchange can of course be in slow exchange for some signals and fast exchange for others, depending on the chemical shift differences involved. Going to higher magnetic field pushes the system toward slower exchange, as does cooling the sample. A typical chemical shift change could be 0.3 ppm or 150 Hz in ^{1}H, as illustrated above, but 0.5 ppm or 25 Hz in ^{15}N and 0.3 ppm or 38 Hz in ^{13}C. Thus, a spectrum in slow exchange for ^{1}H could be in fast or intermediate exchange for ^{15}N or ^{13}C. Since the biggest difficulty for carrying out TRNOE experiments on many "interesting" (i.e. tight binding) ligands is that their off-rate is too slow, it is worth noting that better results can often be obtained by increasing the temperature and sometimes by going to lower field.

The other exchange rates that affect the spectra obtained are relaxation rates, and in particular the spin-lattice relaxation rate and the cross-relaxation rate. The spin-lattice relaxation rate R_1 is the inverse of the more familiar spin-lattice relaxation time T_1, and is the ultimate entropic sink: if the off-rate is much slower than R_1 (and in particular, R_1 of the bound state) then there is no way that any information on the bound state (such as an NOE) can ever be transferred over into the free state, because it is lost to relaxation before it can be seen. R_1 is typically around 10 s^{-1}, and therefore off-rates slower than 1 s^{-1} (i.e. K_d values stronger than 10 nM) usually mean that no information can be obtained about the bound state by observation of the free state. We will see an example of this below. The cross-relaxation rate is the rate responsible for the NOE (and a similar relaxation rate is responsible for cross-correlated relaxation), and it is typically slower than k_off, being around 1–10 s^{-1}. The important consequence of this is that NOEs can build up in one state, for example the bound state, and be transferred across to the free state by chemical exchange without significant loss of magnetization from spin-lattice relaxation: hence its name of transferred NOE or TRNOE. (Some authors have suggested that the abbreviation TRNOE can be confused with the transient NOE, and prefer other terms, such as exchange-transferred NOE (et-NOE) [3].) The TRNOE has recently been reviewed [3]. However, before we can consider the transferred NOE, we need to clarify a few things about the NOE.

The NOE

The NOE is a very useful technique for measuring distance in NMR, because the rate of buildup of the NOE (the cross-relaxation rate) is proportional to the inverse sixth power of the internuclear distance. In a homonuclear two-spin system, the cross-relaxation rate is given by [1]

$$\sigma = \left(\frac{\mu_0}{4\pi}\right)^2 \frac{\hbar^2\gamma^4}{10}\left(\frac{6\tau_c}{1+4\omega^2\tau_c^2} - \tau_c\right) \tag{3}$$

where $\mu_0/4\pi$ is a conversion factor, γ is the gyromagnetic ratio, τ_c is the correlation time of the internuclear vector, and ω is the spectrometer frequency (in rad s^{-1}, i.e. 2π times larger than the more conventional value in Hz). The correlation time is the time it takes for the relevant internuclear vector to rotate by approximately one radian. The crucial factor here is the term involving τ_c, which in practice means that the cross-relaxation rate scales with the correlation time, except for a hiatus around $\omega\tau_\mathrm{c} = 1$, where the cross-relaxation rate passes from positive to negative (Figure 1). The important point is that the cross-relaxation rate is much faster for large τ_c, i.e. for large proteins.

In principle, the relationship between NOE intensity and distance makes the NOE a very precise measure of distance. However, there are several factors that in practice make it much less precise than it should be, of which the most important are spin diffusion and internal mobility.

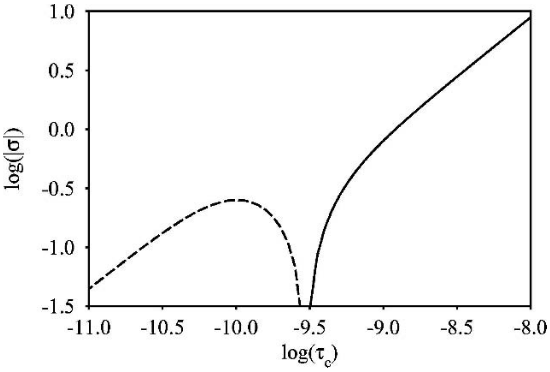

Fig. 1. Variation of the cross-relaxation rate with correlation time, calculated for two protons 2 Å apart for a 600 MHz spectrometer. For $\omega\tau_\mathrm{c} < 1.12$, σ is positive (dashed line), and for $\omega\tau_\mathrm{c} > 1.12$, it is negative (solid line).

Spin Diffusion

This is a process analogous to heat diffusion, whereby an NOE from one proton to another can subsequently diffuse to other protons throughout the protein. There are thus several pathways for NOE transfer, and therefore any spin diffusion immediately renders distance information less useful. This can be illustrated with a simple three-spin example (Figure 2), which shows that a third proton that bridges between the two protons being measured can reduce the apparent distance between them if it is significantly closer to both of them than they are to each other. Clearly, this is much more of a problem when trying to measure long internuclear distances. It is hard to detect the presence of spin diffusion (except using ROESY experiments, as described below), and therefore spin diffusion is normally handled by using rather wide ranges for NOE distance calibration and short mixing times. This clearly makes structure calculation less precise.

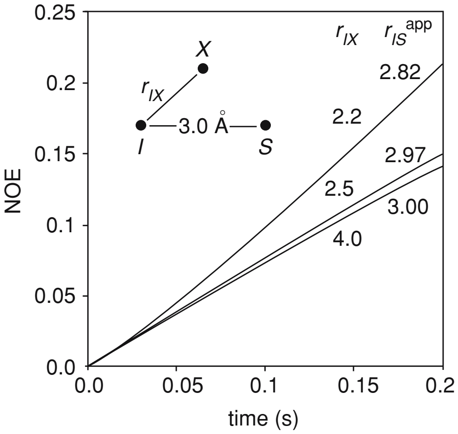

Fig. 2. Spin diffusion. Protons *S* and *I* are 3.0 Å apart, and there is a third spin *X* equidistant between *S* and *I*. The figure shows results for three positions of *X* with distances $r_{IX} = r_{XS}$ of 2.2 Å (dashed line), 2.5 Å (dotted) and 4.0 Å (solid line). The time course of *IS* NOESY crosspeak buildup is shown, calculated for a smallish protein with a correlation time of 5 ns on a 500 MHz spectrometer. It can be seen that whereas for $r_{IX} = 4$ Å the *IS* NOE builds up smoothly, for $r_{IX} = 2.2$ Å there is a "lag time" of about 30 ms, during which spin *X* has little effect on the NOE, but then the *IS* NOE buildup rate increases because of spin diffusion via *X*. The initial buildup over 200 ms was fitted by hand and converted to an apparent distance by taking the sixth root of the buildup rate. Spin diffusion reduces the apparent distance r_{IS} from 3.0 to 2.82 Å when proton *X* is close to both *I* and *S*. In most cases, such a reduction in apparent distance would have little effect on the calculated structure.

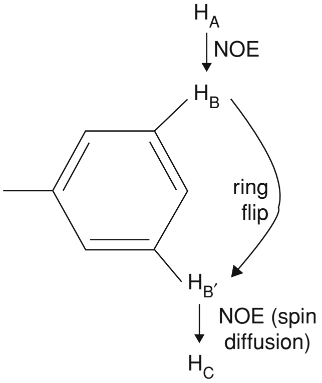

Fig. 3. The effect of ring flipping on NOEs. Proton *A* generates an NOE at *B*. If the phenylalanine ring flips 180°, then *B* ends up at *B′*, and can pass an NOE on to *C* by spin diffusion. This will be significant as long as the flip rate is greater than the NOE cross-relaxation rate, which is almost always the case. The buildup rate of NOE at proton *C* suggests it is close to *A*, when in fact it can be easily 8–10 Å away.

Internal Mobility

Internal mobility can affect the NOE in several ways. The main result, as for spin diffusion, is to make the relationship between NOE and distance less precise. Any mobility will cause the protons to have a range of distance separations. Because of the r^{-6} averaging, this almost always results in an apparent shortening of the distance. Very close protons cannot be brought any closer together, and so the distance averaging effect is more significant with more distant protons. In practice, this often makes the r^{-6} effect end up looking more like a r^{-5} or even r^{-4} effect. Potentially the most severe effect of motion is when there is an NOE to an aromatic proton. Flipping of the ring can lead to the NOE then being passed on by spin diffusion to protons on the other side of the ring (Figure 3). This will have a marked effect on apparent distances in the vicinity of the ring.

The Transferred NOE

The transferred NOE makes use of a particularly useful phenomenon, namely that the rate of buildup of the NOE is approximately proportional to the correlation time (Figure 1). The average cross-relaxation rate in a ligand exchanging between free and bound states is given by

$$<\sigma> = N_F\sigma_F + N_B\sigma_B \tag{4}$$

where N_F and N_B are the fractions of free and bound ligand. The cross-relaxation rate of bound ligand, σ_B, is much greater than the cross-relaxation rate of free ligand, σ_F. It is therefore easy to produce a situation where the observed NOE is dominated by cross-relaxation in the bound state. Depending on the exact values of σ_B and σ_F (which depend on the tumbling rate of bound and free ligand), ligand:protein ratios of 10–40 can be and are often used, and give useful quantitative results. A further helpful aspect of this high ligand:protein ratio is that one can use protein concentrations in the low μM range and still measure NOEs. An NOE measurement (almost always run as a NOESY experiment) then produces NOEs characteristic of the bound state. In the usual situation in which the off-rate is fast on the chemical shift timescale, the only signals observed are sharp and virtually identical to those of free ligand, and consequently are easily assigned. We therefore observe NOEs characteristic of the bound state, but seen on the signals of the free state. The experiment has a characteristic unusual for NMR spectra of proteins, that the experiment actually gets better as the protein gets bigger, because σ_B increases, and therefore the NOE is dominated more and more by the cross-relaxation rate in the bound state.

For many ligands, σ_F is so small as to be insignificant. It can (and should) always be checked by running a control NOE experiment in the absence of protein. For intermediate sized ligands, such as peptides, there is a particularly advantageous situation, in that the cross-relaxation rate goes through zero at $\omega\tau_c \approx 1$; as it happens, this is where many peptides come. This greatly reduces the need to worry about NOEs in the free peptide.

There have been a number of detailed simulations carried out on the TRNOE [4–7]. Figure 4 shows simulation results of a closely similar experiment, the STD experiment (discussed later), which show a complex dependence on K_d [8]. At K_d values weaker than 1 mM (right-hand side of Figure 4), the TRNOE falls off to zero because there is not enough ligand bound to give rise to an NOE. Conversely, at K_d values stronger than about 10 nM (left-hand side of Figure 4), the off-rate is so slow that bound ligand hardly ever dissociates from the complex, and the TRNOE again goes to zero. There is thus in this simulation a "window" of K_d of between 10 nM and 100 μM where the TRNOEs are not greatly affected by exchange rates and can be related simply to distance (see however the discussion in the figure legend). For really quantitative results (i.e. an NOE that is related *only* to the distance in the complex and is not affected by exchange), it is necessary to have k_{off} much greater than the cross-relaxation rate. An approximate guide to estimating cross-relaxation rates in proteins has been suggested: [3] $\sigma \approx -24 \times \text{MWt (kDa)}/r^6$ (Å). Protons cannot get much closer than 2 Å apart, which means that the largest possible cross-relaxation rate is approximately 0.375 × MWt, or 19 s^{-1} for a "typical" 50 kDa protein. This implies that k_{off} should be at least 100 s^{-1}, or alternatively K_d should be 1 μM or weaker. Of course, for protons at more realistic distances, this limit can be relaxed somewhat. As the molecular weight of the protein increases, the limitations on K_d become more stringent, such that for example for a 500 kDa protein, K_d should be 10 μM or weaker. This implies that for properly quantitative results, the window of K_d is very small, being only between 1 μM and 100 μM. Fortunately this is a range that includes a good proportion of ligands of interest, and one can go at least a factor of 10 to either side without losing much quantitative information. It should also be added that TRNOEs have been observed and used even with much more tightly bound ligands. Useful TRNOEs were for example observed for a ligand with a K_d of 30 nM [9].

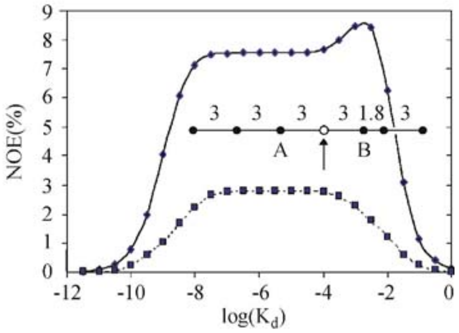

Fig. 4. The effect of irradiating a protein resonance (open circle) on ligand signal intensity, shown for two ligand signals, A (diamonds, solid line) and B (squares, dashed). The effect calculated is STD, which is closely similar to what would be measured in a TRNOE experiment. All distances are 3 Å except for the distance from ligand proton B to its nearest neighbor which is 1.8 Å. This near neighbor causes a rapid loss of NOE from B by spin diffusion: this loss (and the consequent reduction in the NOE measured at B) is not as severe in the case of TRNOE. A 10:1 excess of ligand over protein is used in the calculation, with $k_{on} = 10^9\ s^{-1}M^{-1}$, $\tau_c = 10^{-7}$ s, a 600 MHz spectrometer and a uniform leakage relaxation rate of 0.3 s^{-1} on all protons. The free ligand is assumed to have zero NOE. Using data from Jayalakshmi and Krishna [8].

Some of the early work on TRNOEs was overly precise and optimistic in the power of TRNOE to produce structural information. The pendulum therefore later swung in the opposite direction, with dire warnings about the dangers of over-interpreting TRNOE spectra [1]. More recent work has brought the pendulum back towards its proper position, and has shown that with proper controls, TRNOEs can give distance information that is very nearly as accurate as from conventional structure calculations. Apart from the problems discussed below, the main limitation is simply that ligands often bind in fairly extended geometries on protein surfaces, which means that most of the distances measurable by NOE are already close in terms of the covalent structure, and thus there are relatively few informative NOEs that can be measured. It is worth looking at the two most important pitfalls, as listed below:

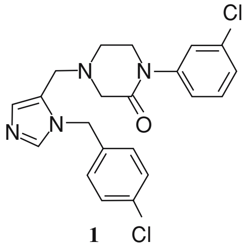
1. Spin Diffusion. This has already been described above, but in the TRNOE there is a further problem, that there could be spin diffusion from one ligand proton to another, going *via* a protein proton [10]. Such a transfer would be very hard to detect, and would seriously affect measured distances. Recent simulations have shown that in practice, this very seldom happens, basically because most ligands bind on the exposed surfaces of proteins and therefore are not close enough to the protein for this to happen (cf. Figure 2) [11,12]. In particular, if the ligand has a reasonably high density of protons (for example, a peptide) it would be uncommon for ligand-protein-ligand spin diffusion to affect a distance measurement. The spin diffusion problem is less severe if a short presaturation time is used [12]. However, the large excess of free ligand effectively dilutes the buildup of NOE on the bound ligand by exchanging with it, with the consequence that one can use longer mixing time for TRNOE experiments than for conventional NOE experiments on proteins: mixing times of 100–200 ms are common, even with very large proteins. (It should also be added that the large number of TRNOEs that can be measured also means that one inaccurate TRNOE is less likely to perturb the structure.) This does not remove the problem of spin diffusion within the ligand, which is as bad as it is in a conventional NOE measurement, and still implies a need for caution in interpreting NOEs as distances.

It has been noted that spin diffusion (of any kind) can be detected using a transferred ROESY experiment, in which spin diffusion gives rise to smaller NOEs of opposite sign to direct NOEs. Bax and co-workers have provided an elegant example of a TRNOE that disappeared on using a transferred ROESY experiment, and was thereby shown to be due to spin diffusion [13]. However, this experiment typically requires a low peptide:protein ratio (and more careful control experiments in the absence of protein), because the ratio of σ_B to σ_F is not as great as for NOESY. It is also more prone to artifacts, and has not proved as popular as one might expect. Where used, it tends to be used as a check that measured NOEs are genuine, rather than as a stand-alone method.

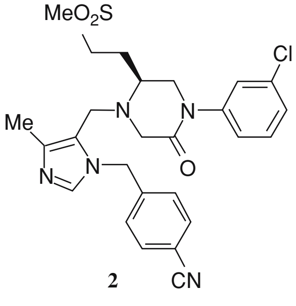
2. Nonspecific Binding. Usually, one uses something like a 30-fold excess of ligand over protein. Under these circumstances, a ligand that binds specifically, but in addition binds nonspecifically but 100-fold more weakly, will be fully bound at the tight binding site and almost fully bound at the weaker site, Equation (2). It will thus give equally strong TRNOEs from its strongly and weakly bound conformations (indeed, if it binds very strongly at the more specific site, these TRNOEs will be small for reasons shown in Figure 4, and thus almost all the TRNOE will in fact come from nonspecific binding!). This gives rise to averaged TRNOEs, which, if not spotted, will produce misleading distance information. This is best detected using a control experiment, in which a strong competitive ligand is added [7]. This will displace the ligand from the binding site, and any remaining TRNOEs must therefore arise from nonspecific binding. Nonspecific binding appears to be very common, and therefore a control experiment is extremely valuable: indeed, for quantitative results such an experiment is crucial.

Practical Implementation

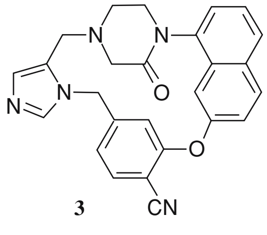
One of the beauties of TRNOE is that it is simple to do: one just needs to carry out a conventional NOESY experiment (in conjunction with a control using a tight inhibitor, to rule out nonspecific binding). It is common



1



2



3

to add a relaxation filter to the experiment, often in the form of a T_2 or $T_{1\rho}$ filter, to reduce broad signals from the protein and therefore make the baseline flatter and reduce integration problems. As an example, compound **1** is a lead compound as an inhibitor of farnesyltransferase (FTase), and therefore a potential antitumor agent. It binds to FTase with an IC_{50} of 2 nM, and its off-rate is therefore too slow to give TRNOEs. However, an analogue **2** has an IC_{50} of only 475 nM and is therefore suitable for TRNOE experiments. Measurements were carried out using 64 μM enzyme and 2 mM **2** (ca. 1:30), a typical concentration for such experiments. TRNOE experiments were carried out using several mixing times, going up to 300 ms. Secondary binding was identified by addition of an excess of a competitive ligand. Measurement of TRNOEs revealed an NOE between the cyanophenyl ring and the piperazinone ring, which prompted the authors to design a cyclised ligand **3** that resembled the bound conformation and has an IC_{50} of 0.1 nM.

Related Experiments

The TRNOE is closely related to two other experiments described in this volume, namely saturation transfer difference (STD) and transferred cross-correlated relaxation. The only difference between TRNOE and STD is that in STD one saturates the protein and transfers magnetization from protein to bound ligand, whereas in TRNOE one uses intramolecular NOEs in the bound ligand. (It is also true that STD is normally run as a steady-state NOE experiment, with irradiation of the protein resonance for several seconds, while TRNOE is normally run as a 2D transient experiment.) The dependence on off-rate and molecular size is the same, and it is therefore applicable in the same circumstances. This of course means that STD does not produce a signal for very tightly bound ligands. A neat method has been devised to get around this limitation, using competition experiments—for example, an STD seen to a relatively weakly binding ligand disappears on addition of a much tighter binding competitor, thus allowing the tight binding competitors to be identified in high-throughput screens. The same would hold with the TRNOE also, but it would of course be a less useful result. A combination of STD and TRNOE experiment is particularly valuable in screening strategies [14,15].

Drug–Quadruplex Interactions Studied by NMR

DNA quadruplex structures have been of considerable interest as supramolecular self-assembling systems [1] and because of their potential biological importance in the regulation of a variety of processes within the cell cycle including replication, transcription, and recombination [2]. The observation that the telomeric repeats at the ends of chromosomes (5′-TTAGGG in humans) are able to assemble in the presence of monovalent cations into folded structures containing stacked G-tetrads has bought them into focus as a drug target, notably to interfere with telomere maintenance in immortalized human tumor-derived cell lines by inhibiting the enzyme telomerase [1–6]. The novel fluorinated polycyclic quinoacridinium cation RHPS4 (Figure 1a) shows enhanced binding to higher-ordered DNA structures (triplex/quadruplex) and is a potent inhibitor of telomerase function [7,8]. To investigate the drug–quadruplex interaction, as part of a rational ligand design approach, we have studied by NMR the structure (Figure 1b) and dynamics of the RHPS4 complex with the intermolecular parallel-stranded quadruplex d(TTAGGGT)$_4$, formed from the human telomeric repeat [9,10].

Exchange Rates for Drug Binding to Quadruplex DNA

Fluorescence quenching studies have established that RHPS4 interacts with d(TTAGGGT)$_4$ with a binding affinity of 2.2×10^5 M [7]. NMR lineshape analysis during drug titration studies shows that the drug is in fast exchange between free and bound states with the quadruplex accommodating drug molecules at both the 5′-AG and 5′-GT steps at the ends of the core G-quadruplex structure [10]. Drug complexation was monitored using the downfield guanine imino proton resonances between 10 and 12 ppm. These initially shift upfield due to ring current effects from the drug, broadening significantly at a bound drug:DNA ratio of ~0.3, but subsequently sharpen as the fully bound state is reached.

For a ligand-binding interaction where free and bound states are in fast exchange [11,12], the observed chemical shift δ_{obs} is given by,

$$\delta_{\text{obs}} = \delta_{\text{f}} p_{\text{f}} + \delta_{\text{b}} p_{\text{b}} \tag{1}$$

The parameters δ_{f} and δ_{b} are the chemical shifts for the free DNA and the fully bound DNA:ligand complex, and p_{f} and p_{b} are the fractional populations of these species ($p_{\text{f}} + p_{\text{b}} = 1$), enabling the chemical shift change to be used to determine p_{b} as a function of drug concentration. The observed line width (LW$_{\text{obs}}$) is related to the populations of free and bound states with an additional exchange contribution given by the expression,

$$\text{LW}_{\text{obs}} = p_{\text{f}}\text{LW}_{\text{f}} + p_{\text{b}}\text{LW}_{\text{b}} + [p_{\text{b}}(1 - p_{\text{b}})^2 4\pi(\Delta\nu)^2]/k_{\text{off}} \tag{2}$$

where k_{off} is the off-rate (per second) and $\Delta\nu$ the chemical shift difference (Hz) between the *free* and fully *bound* states, and LW$_{\text{f}}$ and LW$_{\text{b}}$ the line widths in the free and bound states. The exchange contribution, and hence the off-rate, can be determined by monitoring LW$_{\text{obs}}$ as a function of the fraction bound (p_{b}) at each site. Selected 1D NMR spectra from the RHPS4 titration study at 303 K are shown in Figure 2a, with line width changes as a function of the p_{b} shown in Figure 2b. Data for the guanine imino proton resonances G5 and G6 were fitted to Equation (2) using values of $\Delta\nu$ of 205 and 415 Hz, giving estimated values for k_{off} of 1814 (±170)/s and 3812 (±250)/s. Given the uncertainty in line width measurements at values of p_{b} close to ~0.3 (Figure 2), the factor of ~2 difference in exchange rates measured using the two different probes probably represents a more realistic estimate of possible errors, at least in this context, and hence we report a mean value for k_{off} of 2800 (±1000)/s.

Thus, despite the fact that RHPS4 is a potent inhibitor of telomerase its interaction with quadruplex DNA is highly dynamic. Structural analysis reveals that the drug is not able to intercalate between the G-tetrads since the core structure is highly stabilized by K$^+$ ions which are

octahedrally co-ordinated to the O6 carbonyl of guanine bases in adjacent tetrads. Displacement of these ions is energetically costly. Consequently, quadruplex-binding ligands appear to associate with the terminal G-tetrads, binding at the 5′-AG and 5′-GT steps within the sequence 5′-TTAGGGT (Figure 1b), where the adjacent nucleotides are less well structured [9,10]. As we have shown, small energy barriers to binding and dissociation permit fast kinetics at these sites.

DNA Hairpin Folding and Slow Exchange Eqilibria

The mechanisms and pathways by which biomolecules fold to their native structures is well developed in the protein folding arena; however, the folding of DNA and large RNA assemblies is still poorly understood [13]. The process is likely to be just as complex, involving multiple pathways and kinetic traps originating from misfolded structures and non-native interactions [13]. DNA and RNA hairpins, consisting of a double stranded stem region and connecting loop, occur naturally in single stranded nucleotide sequences and serve a range of important biological functions. A number of DNA mini-hairpin sequences have been identified with extraordinary stability containing GNNA and GNA loop sequences (N = any nucleotide) where the purine bases fold back to form a G–A wobble base pair. In the most stable hairpin structures, the G–A pair preferentially stacks on an adjacent C–G base pair in the adjoining double stranded stem region [14,15]. We have exploited the 5′-C*GNA*G mini-hairpin motif (with a 5′-GAA loop) in the design of hairpins with mismatched or extrahelical bases for studies of drug recognition and binding [16]. We recently identified a 13-mer sequence (5′-GCTACGTAGTCGC) that folds in solution to form a hairpin with C–T mismatch (Figure 3a). In the presence of 100 mM NaCl (10 mM sodium phosphate, pH 7.0) the folded state is in slow exchange with the unstructured single strand with two sets of resonances assignable in 2D NMR spectra. The observation of two distinct species in slow exchange is unusual and indicative of a large activation energy barrier between folded and unfolded conformations. Significant chemical shift differences are observed between resonances in the two conformers (up to ~0.3 ppm), making this an ideal system for characterizing the folding kinetics via magnetization transfer experiments.

Slow Exchange Between Two Conformers

In the general case, two conformers A and B are in slow exchange when the first order rate constants k_A and k_B for interconversion are $\ll \Delta\nu_{AB}$, where $\Delta\nu_{AB}$ is the chemical shift difference in Hz between a nucleus X in the two structural environments A and B. Selective perturbation of one signal can result in magnetization transfer to the other due to the exchange between environments. Assuming that the longitudinal relaxation rates in the two conformers are not considerably faster than the exchange rate, the time-dependent change in intensity after the perturbation can enable the rate of exchange to be measured [11,17]. Selective inversion of nucleus X in conformation A results in the recovery of the magnetization of A via a double exponential process,

$$M_A(t) = C_1 e^{\lambda 1 t} + C_2 e^{\lambda 2 t} + M_A^{\infty} \qquad (3)$$

Similarly, inversion of A leads to transfer of magnetization to B with recovery of the magnetization of B also

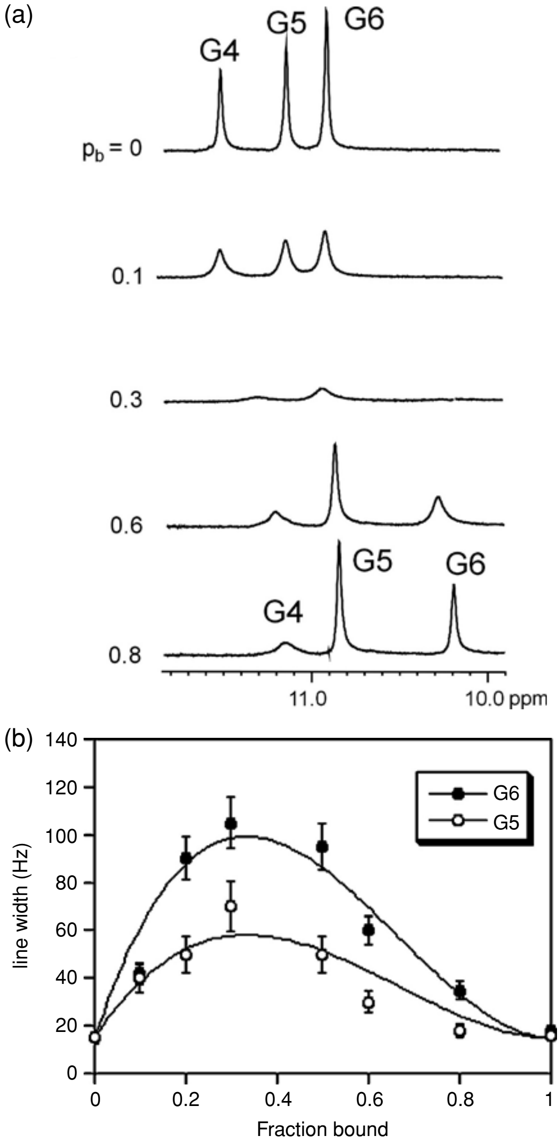

Fig. 2. (a) Selected 600 MHz 1D NMR spectra at 303 K showing the guanine imino proton resonances of the G-quadruplex structure d(TTAGGGT)$_4$ as a function of the fraction of drug bound (p_b); resonances are shifted upfield by ring current effects from the bound drug and initially broaden (maximum line width at $p_b \sim 0.3$) before again sharpening as the binding sites are filled. Fig. 3. (a) Proposed equilibrium between the hairpin conformation of the 13-mer d(GCTACGTAGTCGC) and the disordered single strand with interconversion rates k_A and k_B. (b) Magnetization transfer data showing the recovery of magnetization after selective inversion of the A4 H8 signal for the single stranded conformation at 8.23 ppm (open squares), and the change in intensity of A4 H8 (hairpin conformation) due to magnetization transfer (black dots); 600 MHz data collected at 308 K. Both data sets were analyzed using a double exponential fit [see Equations (3) and (4)]. The experimental parameters obtained are as follows (open squares): $C_1 = 0.458$, $\lambda_1 = 2.787$, $C_2 = 0.765$, $\lambda_2 = 9.892$, $M_A^\infty = 0.677$, and $M_A^0 = 0.521$; (black dots) $C_3 = 0.895$, $\lambda_1 = 2.572$, $C_4 = 0.455$, $\lambda_2 = 10.014$, $M_B^\infty = 1.022$, and $M_B^0 = 0.582$.

following a double exponential decay,

$$M_B(t) = C_3 e^{\lambda 1t} + C_4 e^{\lambda 2t} + M_B^\infty \tag{4}$$

where M_A^∞ and M_B^∞ are the equilibrium longitudinal magnetization of X in the two conformations A and B. The various parameters have the following relationships as solutions of McConnell's equations [18]:

$$\lambda_1 = \{-(k_{1A} + k_{1B}) + [(k_{1A} - k_{1B})^2 + 4k_A k_B]^{1/2}\}/2 \tag{5}$$

$$\lambda_2 = \{-(k_{1A} + k_{1B}) - [(k_{1A} - k_{1B})^2 + 4k_A k_B]^{1/2}\}/2 \tag{6}$$

$$C_1 = [(\lambda_2 + k_{1A})(M_A^\infty - M_A^0) - k_B(M_B^\infty - M_B^0)]/(\lambda_1 - \lambda_2) \tag{7}$$

$$C_2 = [-(\lambda_1 + k_{1A})(M_A^\infty - M_A^0) + k_B(M_B^\infty - M_B^0)]/(\lambda_1 - \lambda_2) \tag{8}$$

$$C_3 = [-k_A(M_A^\infty - M_A^0) - (\lambda_1 + k_{1A})(M_B^\infty - M_B^0)]/(\lambda_1 - \lambda_2) \tag{9}$$

$$C_4 = [k_A(M_A^\infty - M_A^0) + (\lambda_2 + k_{1A})(M_B^\infty - M_B^0)]/(\lambda_1 - \lambda_2) \tag{10}$$

where k_{1A} and k_A, and k_{1B} and k_B are related by

$$k_{1A} = k_A + R_{1A} \tag{11}$$

$$k_{1B} = k_B + R_{1B} \tag{12}$$

where k_A and k_B are the required rate constants (Figure 3), R_{1A} and R_{1B} the longitudinal relaxation rates, and M_A^0 and M_B^0 are proportional to the initial intensities immediately after the perturbation to the magnetization of A. Since conformers A and B are in equilibrium, the following relationship must also hold:

$$k_A M_A^\infty = k_B M_B^\infty \tag{13}$$

The double exponential nature of the time-dependence of the magnetization means that λ_1 and λ_2 can only be determined independently with any certainty if they differ by more than a factor of 3, otherwise only the combination $C_1\lambda_1 + C_2\lambda_2$ can be determined, as discussed in detail elsewhere [11,17]. This is remedied by repeating the experiment by selectively inverting signal B to provide another pair of independent combinations.

DNA Hairpin Folding Kinetics by Magnetization Transfer

Inversion transfer experiments were used to characterize the hairpin to single strand equilibrium at 308 K where the two conformers are significantly populated ($M_A^\infty/M_B^\infty = k_B/k_A = 0.662$). Selective inversion was achieved using a 180° Gaussian-shaped pulse with the excitation bandwidth optimized to give the desired selectivity. Perturbation of the A4 H8 signal at 8.23 ppm in the single strand conformation results in transfer of magnetization to the resonance of the folded hairpin at 8.28 ppm. The recovery curves for both resonances are illustrated in Figure 3b. A double exponential fit resolves two rate constants which differ by a factor >3. Making use of Equation (13) to substitute into Equations (11) and (12), and subsequent substitutions into Equations (5)–(10) using experimentally determined values for λ_1, λ_2, and C_1–C_4, enables all of the unknown rate constants in Equations (11) and (12) to be determined, from which we deduce that $k_A = 3.3/\mathrm{s}$ and $k_B = 2.1/\mathrm{s}$ at 308 K. Rate constants were similarly determined from the reverse experiment (inversion of the hairpin signal at 8.28 ppm), and from inversion of other resonance pairs, with all the data in very close agreement.

We have chosen experimental conditions under which the two conformations are of similar stability (at 308 K, $K_{eq} = 1.6$) with the slow rate of interconversion indicating that the two states are separated by a large activation barrier. Recent thermodynamic investigations involving mutation of residues in various mini-loop sequences, including 5′-C*GNA*G, suggest that stacking interactions are highly co-operative with base substitutions or functional group mutations leading to large changes in stability [19,20]. Thus, a significant kinetic barrier may originate from the requirement for a highly structured loop region in the transition state which may have many of the interactions of the fully folded state. Our investigations have shown that the introduction of the destabilizing C–T mismatch has enabled the equilibrium to be sufficiently perturbed to be able to detect both folded and disordered species simultaneously in slow exchange. Magnetization transfer methods are ideally suited to measuring the kinetics of such systems, and have similarly been employed in characterizing coiled-coil transitions in the folding of GCN4 leucine zipper peptides [21].

The Use of NMR in the Studies of Highly Flexible States of Proteins: Relation to Protein Function and Stability

Introduction

The power of NMR as a method for characterizing the solution state of proteins stems from the highly specific way that NMR reports on protein structure and dynamics. This is due to the fact that NMR parameters, such as chemical shifts, relaxation rates and exchange-rate parameters report specifically about the local environment around the investigated nuclei. This obviously requires that the relevant NMR resonances have been assigned to the individual nuclei of the protein structures, which with present day techniques for isotope labeling and multidimensional NMR methods is possible for proteins with molecular weights higher than 30 kDa. After the resonances have been assigned, the overall three-dimensional structure of a protein can be determined from distance and angular constraints derived from additional spectral information.

However, a detailed NMR determination of the three-dimensional solution structure of proteins may be hampered by the dynamics of the protein molecules. At the same time, a detailed characterization of the flexible regions in the protein is highly interesting due to the functional importance of these regions, as shown by several NMR studies in recent years [1–4]. To solve this immediate conflict, that is, to alleviate the impact of the dynamics on the NMR structure determination of proteins, while at the same time obtaining important information on their dynamics and flexibility, several approaches can be used. Here we illustrate some of the approaches that have been used in the studies of the structure and function of two flexible insulin mutants and a flexible state of human growth hormone (hGH).

One of the approaches concerns the determination of the relatively fast exchanging amide protons involved in weak intra- and intermolecular hydrogen bonds. This approach is useful in cases where the exchange rates of the amide protons are relatively fast while separate amide proton signals can still be observed, that is, the exchange takes place within an hour or less. This approach is illustrated using a monomeric insulin mutant that, although flexible, still forms a well-defined structure in water.

Another approach focuses on the use of the helix-promoting solvent 2,2,2-trifluoroethanol (TFE) to stabilize helices inherently encoded in the amino acid residue sequence of the protein. This approach is illustrated in the study of a highly flexible insulin mutant without a well-defined structure in water. TFE strengthens helical structures in peptides and proteins and induces helical structures in segments which have the propensity for forming helices [5,6]. It has also been found that TFE stabilizes β-turns and β-hairpins in proteins [7,8]. On the other hand, TFE disrupts the quaternary structure of proteins and reduces interactions between non-polar residues [9,10].

However, a complete assignment of the resonances may not always be possible. In particular, resonances in highly flexible regions in proteins may be broadened beyond detection and thereby preventing an assignment of these resonances. Still, NMR can provide valuable information about the structure and dynamics of such highly flexible proteins, despite an incomplete assignment. Here, this is exemplified by the study of hGH. A partial assignment can be used to track structural changes caused by variations in the solution conditions. Changes in pH, for instance, may result in alterations in the charge distribution on the protein surface, which may modulate both intra- and intermolecular coulombic interactions and hydrogen bond interactions. This, in turn, may give rise to changes in NMR parameters such as chemical shifts, relaxation rates and exchange rates of labile protons. Similarly, changes in the salt concentration and the buffer composition can modulate structure and stability of specific regions in proteins, as well as intermolecular interactions, while changes in temperature are likely to influence the stability of the structure of a protein and to affect exchange phenomena. Hence, by measuring the NMR parameters for a protein at different solution conditions, it is possible to obtain information about non-native and destabilized structural states, even if only a partial assignment is available.

Insulin Flexibility and Activity

Insulin is a 5.8-kDa peptide hormone with two chains, a 30-residue long A-chain and a 21-residue long B-chain, and with a three-dimensional structure as shown in Figure 1. Native insulin forms well-defined dimers and higher aggregates thereof in water solution, and in the presence of Zn^{2+} it forms a well-defined hexamer complexed with two zinc ions. However, the active form of insulin is the monomer. Therefore, the structure of several monomeric insulin mutants have been determined by NMR, and their *in vivo* activities have been compared, in order to elucidate the function of insulin and the mechanism of its interaction with the receptor, through the correlation between its structure and flexibility and its activity. However, active monomeric mutants are often highly flexible, making it necessary to use special NMR techniques to extract the dynamical and structural information. Here we describe the NMR investigations of two monomeric mutants, the des-[Phe(B25)] mutant, that is, an insulin mutant in which Phe in position B25 has been removed, and the T(B27)P, P(B28)T mutant (PT insulin), where Thr(B27) and Pro(B28) of the native insulin have been interchanged. In both cases, a hydrophobic patch that is surface exposed in native insulin is turned toward the inside of the molecule, resulting in intramolecular hydrophobic interactions that eliminate the aggregation propensity. Both mutants have a biological activity that is higher than that of native insulin. However, they also have flexible structures. In the case of des-[Phe(B25)]insulin this results in increased exchange rates of the H-bonded amide protons involved in the stabilization of the α-helices, while in the case of PT insulin the structure is too unstable in water solution to be determined by NMR.

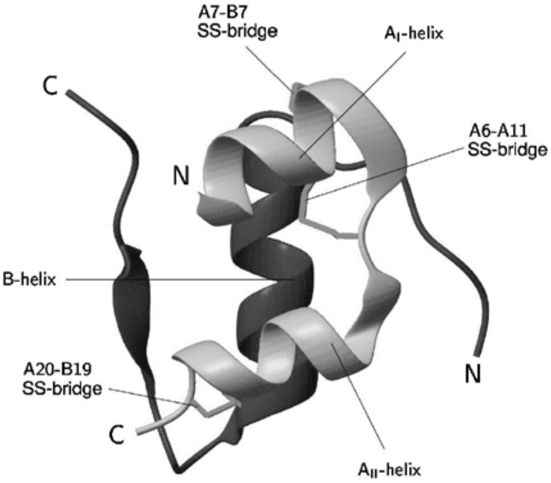

Fig. 1. The native insulin monomer consists of a 21-residue long A-chain (yellow) and a 30-residue long B-chain (red). Two disulfide bridges (SS bridge), CysA7-CysB7 and CysA20-CysB19, tie the two chains together, while a third disulfide bridge connects CysA6 and CysA11. The N- and C-terminal ends of the A-chain form α-helices ($A_{\rm I}$: A2–A8 and $A_{\rm II}$: A13–A20) connected by a loop. The central part of the B-chain forms a third helix (B10–B19). The C-terminal end of the B-chain forms an extended structure, while the N-terminal end is unstructured. (See also Plate 105 on page XXII in the Color Plate Section.)

Des-[Phe(B25)] Insulin: Quantitative Exchange Rates of Weakly H-bonded Amide Protons in Proteins from a Single 2D Experiment

To get more detailed information about the structure of the des-[Phe(B25)] mutant, the relatively fast exchange rates of the H-bonded amide protons were determined quantitatively using the two-dimensional (2D) NMR method for measuring exchange rates of the order of reciprocal hours (h^{-1}). This method is based on a single two-dimensional NOESY or TOCSY spectrum of the protein. It exploits the line broadening of the amide cross-peaks in the indirect dimension, caused by the hydrogen/deuterium exchange of the amide proton during the indirect evolution period when the protein is dissolved in D_2O. The method is described in detail in Ref. [11]. It allows the determination of amide proton exchange rates that are considerably faster than those, which can be measured by the conventional 2D approach based on series of NOESY spectra [12]. Furthermore, it is far less time consuming than the conventional 2D approach, since it is based on a single 2D experiment. At the same time, the accuracy of the rates determined by the method is high because data points from all the slices in the indirect dimension of the 2D experiment contribute to the determination of the rates. The accuracy can be further improved if the method is combined with a spectral analysis base on linear prediction. Moreover, the range of exchange rates covered by the method can be further expanded using the linear prediction model method described previously [13].

Using this method together with standard methodologies for NMR structure determination of proteins, it was found [14] that, although the des-[Phe(B25)] mutant has the normal insulin structure in water (Figure 1), the exchange rates of the H-bonded amide protons are relatively fast. Thus, the rates are about an order of magnitude faster than those of an insulin mutant where the hydrophobic patch is surface exposed, namely the B9(Asp) or S(B10)D mutant where Ser in position B9 has been substituted by Asp [15,16]. This clearly indicates that the structure of the des-[Phe(B25)] mutant is considerably less stable than that of the B9(Asp) mutant. Most importantly, the absence in the des-[Phe(B25)] insulin of

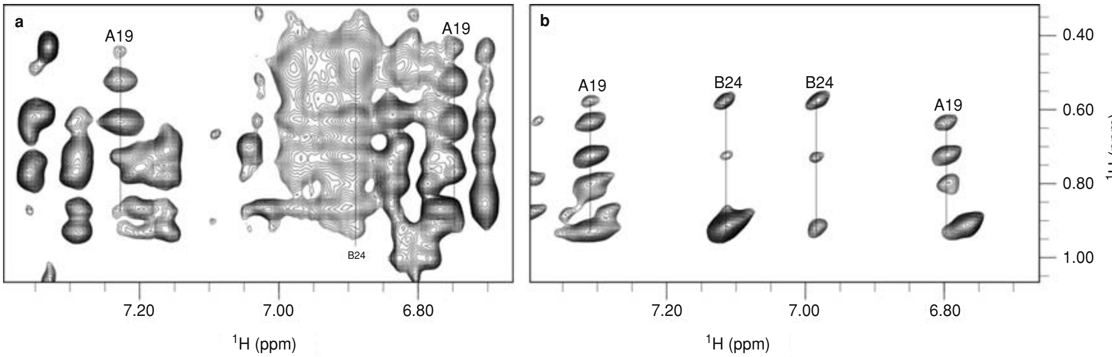

Fig. 2. The amide/aromatic region of an 800 MHz ^1H–^1H NOESY spectra of PT insulin showing the correlations between the aromatic side chain protons and aliphatic side chain protons (a) in pure water and (b) in 35% TFE-d_3. The broadening of the signals in the spectrum recorded in water reflects the high flexibility of the side chains. (Reproduced with permission from Ref. [17].)

slow exchanging amide protons, corresponding to the intermolecular hydrogen bonds associated with the dimer formation, show unambiguously that the mutant does not form a dimer in water solution. This is in contrast to the B9(Asp) mutant that forms a well-defined dimer in water, as reflected by the slow exchange of amide protons involved in intermolecular hydrogen bonds that stabilize the dimer.

PT Insulin: Stabilizing the Structure of an Unstructured Protein by 2,2,2-trifluoroethanol

In the case of proteins that are sufficiently flexible in water to escape any NMR structure determination, secondary or tertiary, the helix-promoting solvent TFE may stabilize the structure [10], allowing the determination of a sufficient number of NOE constraints for a regular NMR structure determination. This was demonstrated in a study of the structure and folding propensity of the highly flexible PT insulin mutant [17].

PT insulin is biologically active with an activity that is 50% higher than that of native insulin [18]. It can, therefore, adapt the conformation necessary for its binding to the insulin receptor (IR). However, it is also unusually flexible with a poorly defined structure in water. This is indicated by the broad NOESY cross-peaks between the side chain protons observed for the mutant dissolved in water (Figure 2a). Moreover, only a few slowly exchanging amide protons can be detected in the protein dissolved in water, and only at low temperature (15 °C). The slowly exchanging amide protons are all involved in weak hydrogen bonds associated with very loose secondary or tertiary structure elements. The strength of a hydrogen bond can be measured by the protection factor, P, of the amide proton involved in the H bond [19]. A more detailed description of the protection factor is given below together with the studies of hGH. Suffice it to mention here that a normal hydrogen bond corresponds to a protection factor of ≥ 25 [20], while the protection of the observed slow exchanging amide protons in PT insulin in water solution are in the range from 2.1 to 18.7.

When dissolved in a mixture of 35% TFE and water, PT insulin assumes a more stable structure, as shown by the relatively sharp and well-defined NOESY cross-peaks between the side chain protons observed for the mutant dissolved in this solvent (Figure 2b). Thus, a sufficient number of NOE-derived distance constraints and slowly exchanging amide protons could be identified to allow a regular NMR structure determination using the program X-PLOR [21]. Moreover, the structure that PT insulin assumes is identical to the structure of native insulin shown in Figure 1. That is, even though PT insulin does not have a well-defined structure in water, it has the propensity to form the native fold.

Model for the Insulin–Receptor Interaction

It is well established that the flexibility of the insulin molecule is important for its function. Thus, it was found [22] that an insulin mutant, where the N-terminal end of the A-chain was tied to the C-terminal end of the B-chain by a short peptide link, was biologically inactive even though it has a three-dimensional structure similar to that of native insulin (Figure 1). Also NMR studies of insulin mutants in which the C-terminal end of the B-chain is turned away from the rest of the molecule [23,24] indicate that such a structural change is required for insulin to interact with its receptor.

In the light of these findings, the concomitant high flexibility and biological activity of PT insulin is interesting.

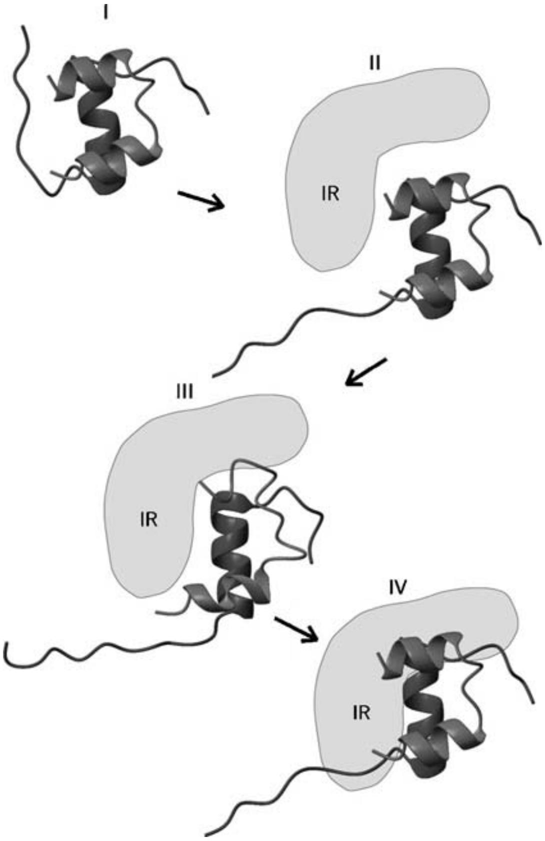

Fig. 3. Model of the interaction of native insulin with the insulin receptor (IR). I, free insulin in solution; II, detachment of the C-terminal part of the B-chain (vertical helix) from the rest of the molecule; III, unfolding of the A_I-helix; IV, refolding of the A_I-helix after navigating into the binding site of receptor (gray) and binding to the receptor. The enhanced biological activity of the PT insulin mutant could result from the fact that the A_I-helix of PT insulin is very loose or non-existing in water, yet it has the propensity to form the helix (see text). Therefore, PT insulin does not need to go through a genuine unfolding before navigating into the active site of the receptor. (Reproduced with permission from Ref. [17].) (See also Plate 106 on page XXII in the Color Plate Section.)

Together with the observation that the mutant has the propensity to form the native fold, these characteristics led to the suggestion of the mechanism for the binding of insulin to its receptor (IR) shown in Figure 3. This mechanism also includes a detachment of the C-terminal end of the B-chain from the rest of the molecule before the interaction with the receptor can take place, as suggested in previous studies [23,24].

The Acid State of Human Growth Hormone

In order to rationalize a rather puzzling study of hGH, the so-called acid state that occurs at pH 2.7, we shall compare this state with the native state of hGH at pH 7.0. hGH is a 191-residue four-helix bundle protein with a classical up-up-down-down cytokine topology [25]. The native state is characterized by a high thermal and chemical stability, similar to most native states of globular proteins. The acid state of hGH is more difficult to categorize, because it has characteristics of both the molten globule and the native state. Similar to the native state, the acid state has a high stability toward both chemical [26] and thermal denaturation and shows a cooperative unfolding behavior [27]. These features are contradictory to a classic definition of molten globules as defined by Ptitsyn [28]. They also differ from the behavior of other four-helix bundle proteins at similar solution conditions. Thus, the two cytokines, interleukin-2 and interleukin-4, were reported to adopt a classical molten globule state [29] and a “highly ordered molten globule” state [30], respectively, at low pH. In accordance with the stability data, far-UV CD measurements indicate that the structural properties of the acid state of hGH are very similar to those of its native state, suggesting that the helical content of the two states are similar. However, the near-UV CD spectrum of the acid state deviates from the spectrum of the native state and is more similar to the spectrum of denatured hGH [26]. This indicates that the aromatic side chains in the acid state are disordered, just like in the denatured state or a molten globule state. It is puzzling how it is possible to have a structural state with both a high stability toward denaturation and, at the same time, a disordered and flexible protein core.

Using standard three-dimensional triple-resonance techniques combined with uniform ^{13}C- and ^{15}N-labeling, only partial assignments of the hGH molecule were obtained [31]. In total, 60% and 75% of the backbone resonances were assigned for the native and acid states, respectively. Complete resonance assignment was not possible because of severe resonance overlap and line broadening effects [31].

However, even without access to the solution structure of hGH, NMR investigations of the protein allow a detailed comparison of the native and the acid states. The investigation includes analyses of the backbone chemical shifts, the amide and indole hydrogen/deuterium exchange rates, and backbone amide ^{15}N relaxation rates. Backbone C^{α} and H^{α} chemical shifts contain information about the secondary structure, and provide means for accessing the structural integrity of a protein under a particular set of experimental conditions. This information is derived by calculation of secondary chemical shifts and a subsequent comparison with reference values for helix,

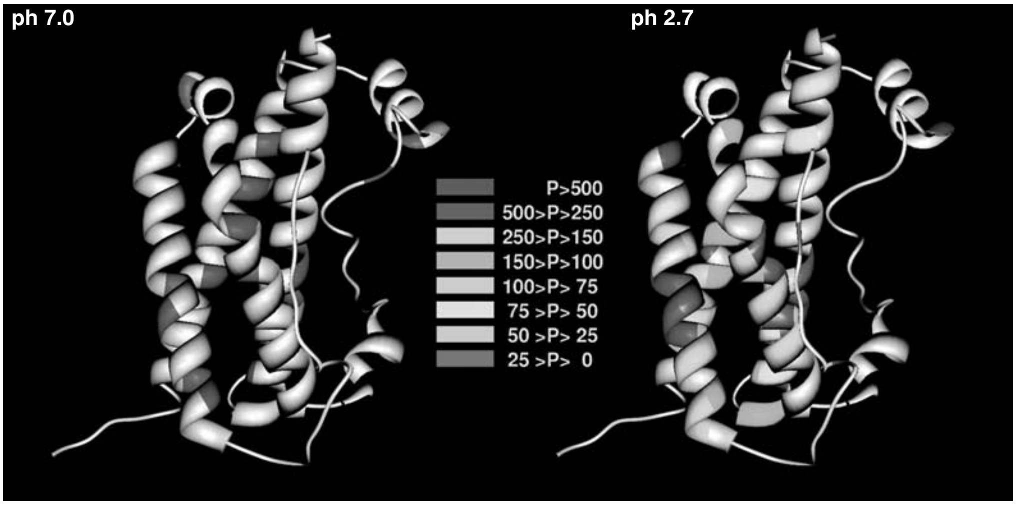

Fig. 4. Distribution of measured protection factors (P) for the native state (pH 7) and the acid state (pH 2.7) of human growth hormone. The protection factors are color mapped onto the three-dimensional structure as indicated in the figure. Structural parts colored in gray correspond to regions where the amide proton exchange rates could not be quantified. The figure was created with UCSF chimera [40]. (See also Plate 107 on page XXIII in the Color Plate Section.)

sheet, and extended structure [32]. Exchange-rate constants of labile protons report directly on solvent accessibility and in particular on the protection of labile protons by hydrogen bonds [33]. Sequence-related differences in intrinsic exchange-rate constants, k_{intr}, and their dependencies upon pH, are taken into account by calculation of protection factors $P = k_{\mathrm{ex}}/k_{\mathrm{intr}}$ [19], where k_{ex} is the experimentally derived exchange-rate constant. Measurement of ^{15}N longitudinal (R_1) and transverse (R_2) relaxation rates, and [^1H]–^{15}N heteronuclear NOE for each assigned amide ^1H–^{15}N pair, and analysis within the framework of the Lipari–Szabo model-free formalism [34,35]

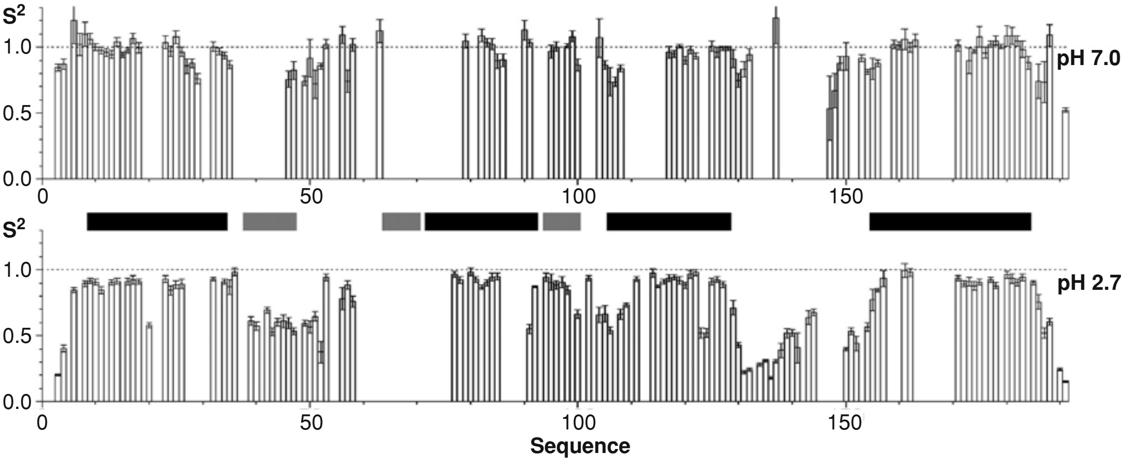

Fig. 5. Squared generalized order parameters (S^2) for the native state (pH 7.0) and the acid state (pH 2.7) of human growth hormone mapped as a function of the amino acid sequence. The black horizontal bars indicate the position of the four central helices A, B, C, and D forming the helix bundle (residues 9–34, 72–97, 106–128, and 155–184, respectively) and the gray horizontal bars indicate the position of the minor helices observed in the crystal structure of the hormone–receptor complex (PDB entry 3HHR).

provide a structural mapping of the so-called generalized order parameters, which reflect the restriction of the N–H bond vector on the pico- to nanosecond dynamics on a scale from zero to one. The ^{15}N relaxation measurements also provide information about exchange processes on the micro- to millisecond timescale as reflected in line broadening effects, and finally, information about the overall molecular tumbling rate and rotational diffusion anisotropy [36,37].

Backbone C^{α} and H^{α} assignments for the two states form the basis for a chemical-shift-based prediction of secondary structure [32]. This provides secondary structural data for the protein at the level of the individual residues without *a priori* knowledge of the overall structure. A comparison with the crystal structures of the free hormone (PDB entry 1HGU) and of the hormone bound to the extracellular domain of the receptor (PDB entry 3HHR) shows a high degree of similarity between the solution-state predictions at high and low pH and the two crystal structures [31]. The general conclusion that can be drawn from the NMR data is that the helix bundle scaffold is preserved at both high and low pH. However, subtle differences exist, including evidence for a helical propensity from residue 102 to 107 in the native solution state at neutral pH, which is not seen in the acid state. Also, the secondary chemical shifts indicate that the mini-helix from residue 94 to 100, observed in the crystal structure of the hGH–receptor complex but not in the crystal structure of free hGH, is present in the solution states.

The partial assignment of hGH gives access not only to structural information. NH exchange and backbone ^{15}N relaxation report on the flexibility of a molecule, and hence can help in the understanding of molecular stability.

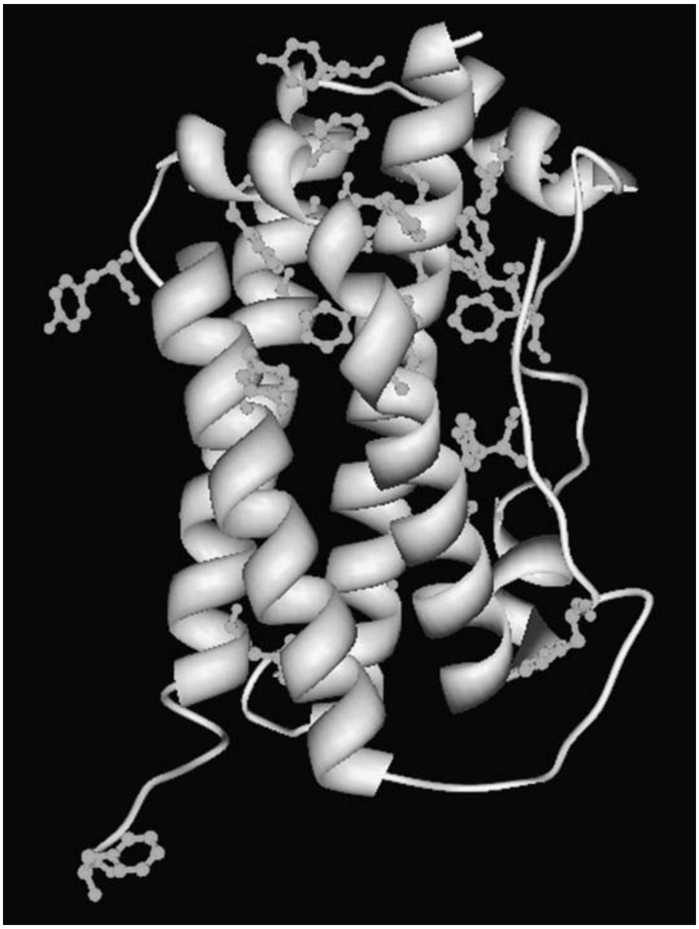

Fig. 6. Mapping of the aromatic residues in ball-and-stick representation on the ribbon diagram of human growth hormone shows a high density of aromatic groups in the north end of the molecule and a low density of aromatic groups in the south end of the molecule. The figure was created with UCSF chimera [40]. (See also Plate 108 on page XXIII in the Color Plate Section.)

For the native state of hGH, protection factors were determined for 22 backbone amide proton and despite the scarcity of the data, it is apparent that the protection factors are high throughout the helix bundle with values in the range 6×10^3 to 1×10^6. Furthermore, the indole NH of tryptophan 86 shows a high degree of protection ($P \sim 1 \times 10^6$) consistent with the hydrogen bond to $O^{\delta 1}$ of Asp169 first suggested by Bewley and Li [38] and later verified in the crystal structures. In the acid state, the backbone protection factors are orders of magnitude smaller than in the native state, and are in the range from 9×10^3 to 2×10^3, with the highest protection factors in the south end of the molecule. Figure 4 graphically illustrates the distribution of protection factors in the two solution states. Also, the Trp86 indole NH is exhibiting fast exchange with the solvent consistent with absence of the hydrogen bond to $O^{\delta 1}$ of Asp169 observed in the native state.

The backbone ^{15}N order parameters, S^2, for the native state are uniformly high throughout the sequence, corresponding to a highly rigid globular protein. This is in agreement with the high protection factors observed for this state. The acid state, on the other hand, displays increased flexibility throughout the sequence, but most pronounced in the long loop regions between the four main helices, as shown in Figure 5. In particular, the loop between helices C and D display order parameters as low as ~0.2, which is comparable to what is expected for an unfolded state [39]. Thus, the acid state of hGH is characterized by a preserved helix bundle structure with slightly increased overall flexibility as compared to the native state, but with highly mobile inter-helical loop regions.

The notion of the acid state as a well-defined, though more flexible, helix bundle with flexible loop regions is consistent with the high stability of the acid state toward denaturation. Also the native-like far-UV CD spectrum is indicative of a helix bundle structure with largely preserved inter-helical stabilizing interactions. On the other hand, the similarity of the near-UV CD spectrum with that of the denatured state of the protein suggests a certain degree of disorder of the aromatic groups, and seems to contradict the picture of a native-like helix bundle with preserved inter-helix stabilizing interactions. As shown in Figure 6, the majority of the aromatic side chains are located in the north end of the molecule. Thus, a unified picture is emerging, where the north end of the helix bundle is opening up resulting in a disorder of aromatic groups and an increased solvent access to amide groups—in agreement with near-UV CD and NH exchange data. At the same time, inter-helix interactions in the south end of the molecule are preserved, which can account for the high stability toward denaturation.

All taken together, the NMR investigation of hGH shows that important and detailed information about the structure and stability of proteins can be obtained from a multitude of available NMR data, despite an incomplete assignment of the NMR spectra.

NMR-based Metabonomics Techniques and Applications

John C. Lindon, Elaine Holmes, and Jeremy K. Nicholson
Biomedical Sciences Division, Imperial College London, Sir Alexander Fleming Building, South Kensington, London SW7 2AZ, UK

Introduction

Since the decoding of the human genome, there has been much interest in using changes in gene expression to discover the basis of disease and for the identification of new drug targets. However to date, the promise of the approach is yet to be comprehensively realized and there remains a difficulty in relating such changes to real conventional end points used in diagnosis and pharmaceutical development. The simultaneous measurement of many gene expression changes is termed transriptomics, and is usually carried out in an automatic fashion using so-called gene microarrays. The relevance of such gene changes is not always clear, which has led subsequently to efforts focused on the consequent protein level changes (a subject termed proteomics), but again it is not always possible to relate such changes directly to pathological events.

On the other hand, metabonomics, a whole systems approach for evaluating metabolite changes and pathway analysis through study of biofluids and tissues [1] offers a process whereby real end points can be obtained. In complex organisms, these three levels of biomolecular organization and control are highly interdependent, but they can have very different time scales of change. All of the technologies, which rely on analytical chemistry methods, result in complex multivariate data sets that require a variety of chemometric and bioinformatic tools for interpretation. The aim of such procedures is to extract biochemical information that is of diagnostic or prognostic value, and that reflects actual biological events. The areas where metabonomics impacts pharmaceutical R&D are:

- validation of animal models of disease, including genetically modified animals;
- preclinical evaluation of drug safety and ranking of compounds;
- assessment of safety in clinical trials and after product launch;
- quantitation, or ranking, of the beneficial effects of pharmaceuticals both in development and clinically;
- improved understanding of idiosyncratic toxicity;
- improved, differential diagnosis and prognosis of clinical diseases;
- better understanding of environmental population effects through epidemiological studies;
- patient stratification (pharmaco-metabonomics);
- nutrition, interactions between drugs, and between drug and diet;
- studies in environmental science.

Importantly, metabonomics also allows time-dependent patterns of change in response to stimuli to be measured. In multi-cellular organisms, there are a broad variety of time scales, varying widely according to gene, protein, pathway, and tissue. One important potential role for metabonomics therefore is to direct the timing of proteomic and genomic analyses in order to maximize the probability of observing “omic” biological changes that are relevant to functional outcomes.

Metabonomics, formally defined as the quantitative measurement of the dynamic multi-parametric metabolic response of living systems to pathophysiological stimuli or genetic modification, thus provides an approach which leads to real world end points. Metabolites can be identified and quantified, and changes can be related to health and disease, and are changeable by therapeutic intervention. The subject of metabonomics has been reviewed recently [2–4].

Metabonomics Analytical Technologies

The two principal methods that can produce metabolic profiles of biomaterials, comprise ^{1}H NMR spectroscopy [2] and mass spectrometry (MS) [5], the latter usually including a separation stage such as GC or LC. NMR has the advantages of being non-destructive, also applicable to intact tissues using magic angle spinning (MAS) methods [6], and provides detailed information on molecular structure, especially in complex mixture analysis. In addition, NMR can also be used to probe molecular dynamics as well as concentrations. MS is inherently considerably more sensitive than NMR, but it is necessary generally to employ different separation techniques for different classes of substances. Quantitation in MS can also be impaired by variable ionization effects, such that derivatization may be necessary. Most published mammalian studies have used NMR spectroscopy, but LC–MS is increasing in usage.

Typically metabonomics is carried out on biofluids that provide an integrated view of the whole systems biology. The biochemical profiles of the main diagnostic fluids, blood plasma, cerebrospinal fluid (CSF), and urine, reflect both normal variation and the impact of drug effects or disease on single or multiple organ systems [7]. Urine and plasma are obtained in a non- or minimally invasive fashion, and hence are appropriate for clinical trials monitoring and disease diagnosis. Different biofluids have characteristically different metabolic profiles (Figure 1). Although urine and plasma are the main diagnostic fluids, others have also been used in special cases. These include CSF, seminal fluids, digestive fluids, pathological fluids such as cyst fluid, and administered fluids such as dialysis fluids. A standard ^{1}H NMR spectrum of urine typically contains thousands of sharp lines from predominantly low molecular weight metabolites. Plasma contains low and high molecular weight components, which give a wide range of signal line widths. Protein and lipoprotein signals dominate ^{1}H NMR spectra of plasma, with small molecule fingerprints superimposed on them. Standard editing experiments based on T_1, $T_{1\rho}$, T_2, or diffusion coefficients can be used to select only the contributions from proteins, and other macromolecules and micelles, or alternatively to select only the signals from the small molecule metabolites. Each biofluid yields a characteristic ^{1}H NMR

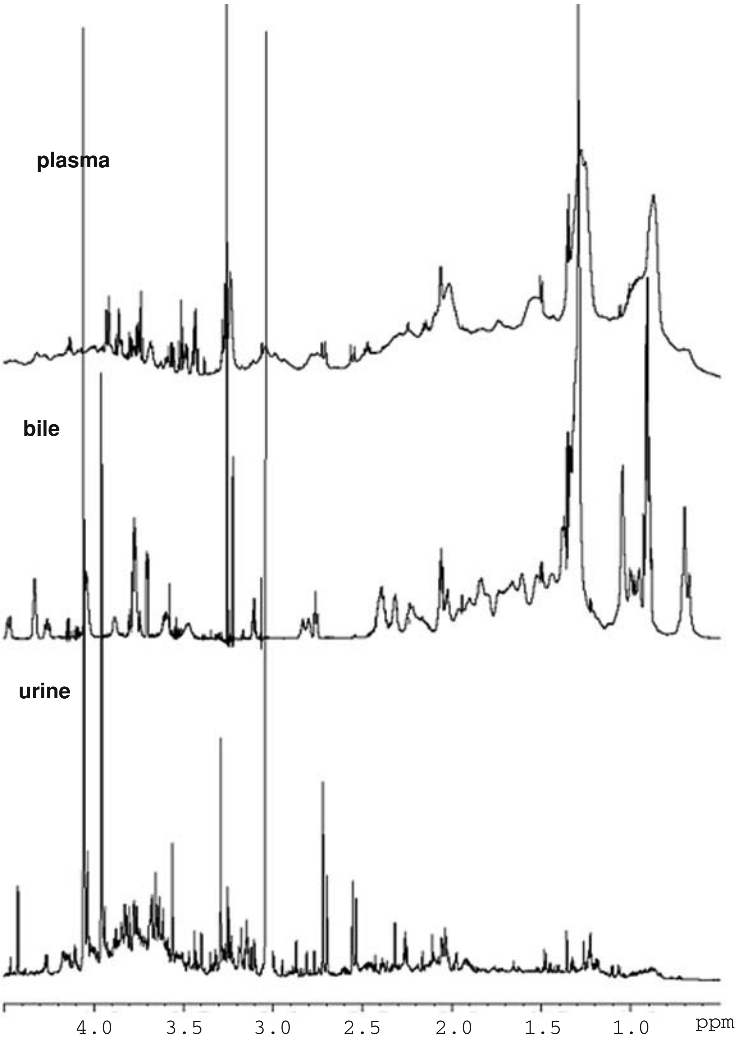

Fig. 1. 800 MHz ^{1}H NMR spectra with water peak suppression of control human biofluids, urine, gall bladder bile, and blood plasma showing characteristically different biochemical profiles.

spectroscopic fingerprint in which the spectral intensity distribution is determined by the relative concentrations of solutes, and in some cases by their intermolecular interactions. Standard spectra typically take only a few minutes to acquire using robotic flow injection methods. These entail robotic sample preparation involving buffering, addition of a chemical shift and quantitation standard such as TSP, and addition of D_2O as a magnetic field lock signal for the spectrometer. The large interfering NMR signal arising from water in all biofluids is easily eliminated by use of appropriate NMR solvent suppression methods such as NOESY presaturation or WET. Using NMR flow probes, the capacity for NMR analysis has increased enormously and now up to 200–300 samples per day can be measured.

Identification of the biomarkers (i.e. metabolites that change in level as a consequence of the pathology) detected in a biofluid NMR spectrum can involve the application of a number of other NMR techniques including two-dimensional (2D) experiments [2]. Although ^{1}H NMR spectra of urine and other biofluids are very complex, many resonances can be assigned directly based on their chemical shifts, signal multiplicities, and by adding authentic material and remeasuring the spectrum. 2D NMR spectroscopy can also be useful for spreading the signals out and for working out the connectivities between signals, thereby enhancing the information content and helping to identify biochemical substances. These include the ^{1}H–^{1}H J-resolved experiment, which reduces the contribution of macromolecules and yields information on the multiplicity and coupling patterns of resonances. Other 2D experiments such as COSY and TOCSY provide ^{1}H–^{1}H spin–spin coupling connectivities. Use of other nuclei can be important to help assign NMR peaks and here inverse-detected heteronuclear correlations, usually ^{1}H–^{13}C, can also be obtained by use of sequences such as HSQC or HMBC.

A major improvement in the scope of metabonomics has been made possible by the commercialization of miniaturized NMR probes. Now it is possible to study metabolic profiles by NMR using as little as 2–20 μl of sample, and examples have been published using CSF and blood plasma [8,9].

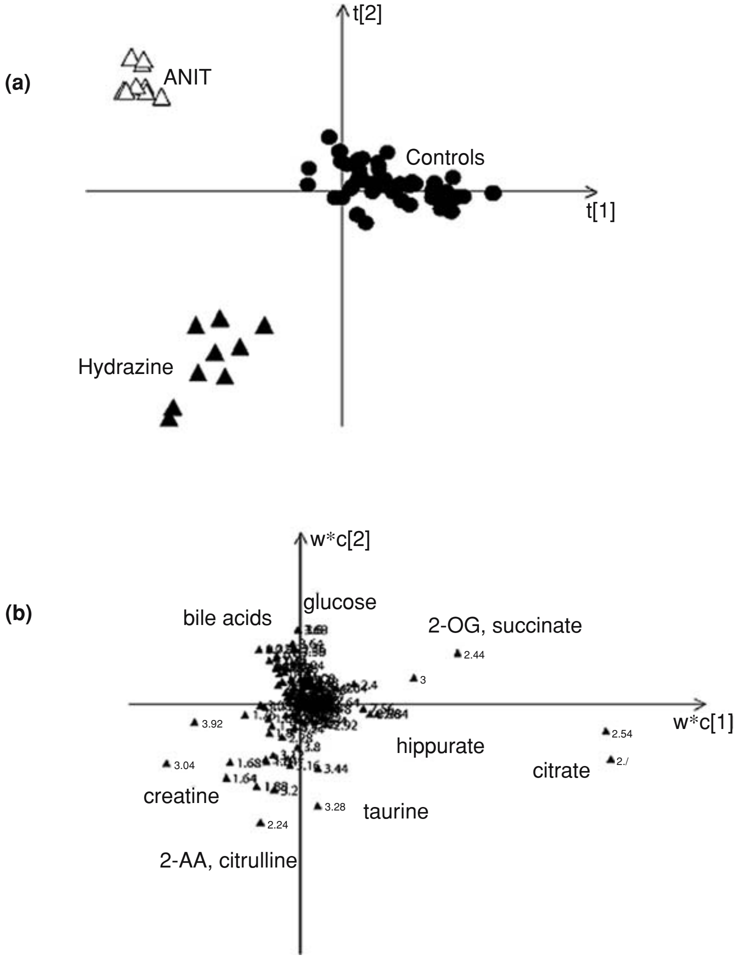
Cryogenic NMR probe technology, whereby the NMR detector coil and preamplifier are cooled to about 20 K, is now commercially available and provides an improvement in spectral signal–noise ratios of up to 500%. This improvement permits the routine use of natural abundance ^{13}C NMR spectroscopy of biofluids, such as urine or plasma, with acquisition times that enable a high throughput of samples. Information-rich ^{13}C NMR spectra of urine can be obtained using appropriately short acquisition times suitable for biochemical samples when using a cryogenic probe [10].

For metabolite identification, directly coupled chromatography–NMR spectroscopy methods can be used. The most powerful of these "hyphenated" approaches being HPLC–NMR–MS, [11] which can provide the full array of NMR and MS-based molecular identification tools. These include MS–MS for fragment ions and Fourier transform (FT)-MS or time-of-flight (TOF)-MS for accurate mass measurement and hence derivation of molecular empirical formulae.

Within the last few years, the development of high-resolution ^{1}H MAS NMR spectroscopy has had a substantial impact on the ability to analyze intact tissues [12]. Rapid spinning of the sample (∼4–6 kHz typically) at an angle of 54.7° relative to the applied magnetic field serves to reduce line broadening effects caused by sample heterogeneity, residual dipolar couplings, and residual chemical shift anisotropy. Thus, it is possible to obtain very high quality NMR spectra of whole tissue samples with no sample pretreatment. Such experiments indicate that diseased or toxin-affected tissues have substantially different metabolic profiles to those taken from healthy organs [13]. In addition, MAS NMR spectroscopy can be used to access information regarding the compartmentalization of metabolites within cellular environments. Such MAS NMR-based metabonomics can also be applied to *in vitro* systems such as tissue extracts [14], Caco-2 cells [15], or spheroids [16].

The NMR spectrum of a sample can be thought of as an object in a multi-dimensional set of metabolic coordinates, the values of which could be the spectral intensity at every data point. Similarity or differences between samples can then be evaluated using multivariate statistical methods or other pattern recognition approaches. One simple approach that has been widely used is to effect a dimension reduction from the typically 32K or 64K NMR intensity points describing each spectrum, down to a few dimensions to visualize similarities and differences between samples. This can be accomplished using principal components analysis (PCA). This constructs latent variables from linear combinations of the original descriptors to describe as much variation as possible in the data set, with first principal component (PC) explaining the maximum variation and successive components explaining decreasing amounts of variance with the constraint that all PCs are orthogonal to each other. The approach gives rise to two matrices based on the data, a scores and a loadings matrix. A plot of the PC scores shows the relationships between the samples (each point on the plot comprises one sample) and the PC loadings provide information on those variables, which contribute to the position of the samples in the scores plot. This is illustrated in Figure 2 for rat urine NMR spectra. The scores plot shows three clusters of samples, those of NMR spectra of control urine and those of NMR spectra of urine from animals dosed with two different liver toxins, hydrazine and a substance known as ANIT. These cause different biochemical changes and produce the separate clusters (Figure 2a). Examination of

Fig. 2. Classification of rat urine samples based on their ^{1}H NMR spectra using principal components (PC) analysis. Animals were dosed with hydrazine or ANIT, two model liver toxins operating by different biochemical mechanisms, or with dosing vehicle alone (controls). (a) PC scores plot where each spectrum is reduced to a single point and samples with similar metabolic profiles appear close to each other. (b) PC loadings plot where each point corresponds to the signal intensity a single NMR spectral region of width 0.04 ppm and the position of a spectral region point determines which regions are responsible for the corresponding clustering in the scores plot [17].



the loadings plot, Figure 2b, gives information on which NMR spectral regions are responsible for the clustering in the scores plot, i.e. a cluster with a low PC1 and a low PC2 score (such as hydrazine) will appear in the bottom left hand quadrant and the corresponding loadings or altered NMR spectral regions will be in the same quadrant.

In the real world, biochemical changes caused by disease, nutrition, lifestyle, drug therapy, or drug toxicity develop and recover in real time and there can be complex, time-related changes in NMR spectra of biofluids. Hence, in order to develop automatic classification methods, it has proved efficient to use advanced chemometrics and bioinformatics approaches, known as supervised methods, that also take time into account. In general, these methods allow the quantitative description of the multivariate boundaries that characterize and separate each class of sample in terms of their metabolic profiles, some providing a level of probability for the classification. By using a variety of chemometric methods, it is possible to use such models to provide classification probabilities or even quantitative response factors for a wide range of sample types. It is important to build and test such chemometric models using independent training data and validation data sets.

Subtle biochemical changes in ^{1}H NMR spectroscopic profiles of biofluids can be obscured in such analyses by interfering factors such as variations in pH, which can cause changes in NMR chemical shifts because of differences in ionization state of some molecules. In NMR spectroscopy of urine, one means of limiting the effects of pH on the chemical shift of sensitive moieties is to add a standard amount of buffer to the sample prior to NMR spectroscopic analysis. Alternatively, mathematical algorithms can be used to realign the chemical shifts of resonances from protons near ionizable groups displaced by pH effects [18]. Some spectral regions, such as those containing water or urea, are very variable due to water NMR peak suppression effects. In addition, many drug compounds or their metabolites are excreted in biofluids and these can obscure significant changes in the concentration of endogenous components. Therefore, it is usual to remove these redundant spectral regions prior to chemometric analysis.

One example of a robust automatic data reduction method that has been widely used is the division of the NMR spectrum into regions of equal chemical shift ranges followed by signal integration within those ranges [19]. Automatic data reduction of 2D NMR spectra can be performed using a similar procedure, in which the spectrum is divided by a grid containing squares or rectangles of equal size, and the spectral integral in each volume element is calculated.

Selected Applications of Metabonomics

Preclinical Drug Candidate Safety Assessment

There is evidence through the recurring need to withdraw drugs from the market place that drug safety assessment approaches used in the pharmaceutical industry can still fail. There is a need for methodologies that can pick up potential problems earlier, faster, more cheaply, and more reliably. A recent survey of market withdrawals during the period 1960–1999 has identified hepatotoxicity as the most common reason for withdrawal [20]. Minimizing attrition caused by drug adverse effects is therefore one of the most important aims of pharmaceutical R&D, and metabonomics has been used extensively in evaluating the adverse effects of candidate drugs.

In this application, NMR-based metabonomics can be used for (i) definition of the metabolic hyperspace occupied by normal samples, (ii) rapid and simple classification of the sample as normal or abnormal (this enables spectrometer automation for data acquisition), (iii) classification of target organ toxicity, (iv) site and mechanism of action within the organ, (v) identification of biomarkers of toxic effect, and (vi) evaluation of the time course of effect, e.g. the onset, evolution, and regression of toxicity. The role that metabonomics has in the evaluation of xenobiotic toxicity has been comprehensively defined by the Consortium for Metabonomic Toxicology (COMET) formed between five pharmaceutical companies and Imperial College, London, UK [21]. The aim of this project is to define methodologies and to apply metabonomic data generated using ^{1}H NMR spectroscopy of urine and blood serum for preclinical toxicological screening of candidate drugs. This has been achieved by generating databases of spectral and conventional results for a wide range of model toxins (147 in total) that serve as the raw material for computer-based expert systems for toxicity prediction. The project goals of the generation of comprehensive metabonomic databases (now around 35,000 NMR spectra) and multivariate statistical models for prediction of toxicity (initially for liver and kidney toxicity in the rat and mouse) have completely been achieved.

A study operated to the same detailed protocol and using the same model toxin was carried out over seven sites in the companies and contract research organizations. This was used to probe both the analytical and biological variation that could both arise through the use of metabonomics. The inter-site NMR analytical reproducibility revealed a high degree of robustness where split samples were analyzed both at Imperial College and at various company sites, giving a coefficient of variation of about 1.6%. The biological variability was evaluated by a detailed comparison of the ability of the companies to provide consistent urine and serum samples with all samples measured at Imperial College. There was a high degree of consistency between samples from the various companies, and the differences between samples were small compared to the biochemical effects of the toxin, where dose-related effects could be distinguished [22]. Following this successful start, metabonomic models have been constructed for urine from control rats and mice, enabling identification of outlier samples and the metabolic reasons for the deviation. Building on this, and with the completion of all planned studies, and the development of new chemometrics methodology to meet the challenges thrown up by this project, workable expert systems for prediction of liver and kidney toxicity have been generated.

To achieve this goal, a new approach to the classification of a large data set of COMET samples has been developed, termed—Classification Of Unknowns by Density Superposition (CLOUDS)—a novel non-neural implementation of a classification technique developed from probabilistic neural networks [23]. Modeling the urinary NMR data according to organ of effect (control, liver, kidney, or other organ), using a model training set of 50% of the samples and predicting the other 50%, over 90% of the test samples were classified as belonging to the correct group with only a 2% misclassification rate between the classes. This work showed that it is possible to construct predictive and informative models of metabonomic data, delineating the whole time course of toxicity—the ultimate goal of the COMET project.

Genetic Differences and other Physiological Effects by Metabonomics

In order to determine therapeutic effects, it is necessary to understand any underlying physiological variation and to this end, metabonomics can be used to separate classes of experimental animals such as mice and rats according to a number of inherent and external factors based on the endogenous metabolite patterns in their biofluids [24]. Such differences may help explain differential toxicity of drugs between strains and inter-animal variation within a study.

Metabonomics is also being used for the phenotyping of mutant or transgenic animals and the investigation of the consequences of transgenesis such as the transfection process itself [25]. This suggests that the method may be appropriate for following treatment regimes such as gene therapy. It is important to differentiate often-seen unintended consequences of the genetic engineering process from the intended result, because pharmaceutical companies are developing genetically engineered animal models of disease using transfection procedures. Metabonomic approaches can give insight into the metabolic similarities or differences between mutant or transgenic animals and the human disease processes that they are intended to simulate and their appropriateness for monitoring the efficacy of novel therapeutic agents.

The importance of gut microfloral populations on urine composition has been highlighted by a study in which axenic (germ-free) rats were allowed to acclimatize in normal laboratory conditions and their urine biochemical composition was monitored for 21 days [26].

Many other effects can be distinguished using metabonomics, including male/female differences, age-related changes, estrus cycle effects in females, diet, diurnal effects, and interspecies differences and similarities [24].

Integrated Metabonomic Studies

The value of obtaining multiple NMR data sets from various biofluid samples and tissues of the same animals collected at different time points has been demonstrated. This procedure has been termed "integrated metabonomics," [13,14] and can be used to describe the changes in metabolic chemistry in different body compartments affected by exposure to toxic drugs. Such timed profiles in multiple compartments are themselves characteristic of particular types and mechanisms of pathology and can be used to give a more complete description of the biochemical consequences than can be obtained from one fluid or tissue alone. An example is given in Figure 3 that shows ^{1}H NMR spectra from intact liver tissue, tissue extracts, and blood plasma from a mouse after administration of a toxic dose of paracetamol. Building on this, it has also been possible to integrate data from transcriptomics and metabonomics to find common metabolic pathways implicated by both gene expression changes and changes in metabolism [27].

Disease Diagnosis

Many examples exist in the literature on the use of NMR-based metabolic profiling to aid human disease diagnosis, including the use of plasma to study diabetes, CSF for investigating Alzheimer's disease, synovial fluid for osteoarthritis, seminal fluid for male infertility and urine in the investigation of drug overdose, renal transplantation, and various renal diseases. Most of the earlier studies have been reviewed [7].

Some studies have been undertaken in the area of cancer diagnosis using perchloric acid extracts of various types of human brain tumor tissue.[28] The spectra were classified using neural network software giving ∼85% correct classification. Tissues themselves can be studied by metabonomics using the MAS technique and published examples include prostate cancer [29] and renal cell carcinoma [30]. Other recent studies include an NMR-based urinary metabonomic study of multiple sclerosis in humans and non-human primates [31].

Currently, the only reliable diagnostic method for coronary heart disease (CHD) is the injection of X-ray opaque dye into the blood stream and visualization of the coronary arteries using X-ray angiography. This is both expensive and invasive with an associated 0.1% mortality and 1–3% of patients experiencing adverse effects. Recently metabonomics has been applied to provide a method for diagnosis of CHD non-invasively through analysis of a blood serum sample using NMR spectroscopy [32]. Patients were classified into two groups, those with normal coronary arteries and those with triple coronary vessel disease, as based on an angiographic examination. Around 80% of the NMR spectra were used as a training set to provide a two-class model after appropriate data filtering techniques had been applied and the samples from the two classes were easily distinguished. The remaining 20% of the samples were used as test set and their class was then predicted based on the derived model with a sensitivity of 92% and a specificity of 93% based on a 99% confidence limit for class membership.

It was also possible to diagnose the severity of the CHD that was present by employing serum samples from patients with stenosis of one, two, or three of the coronary arteries. Although this is a simplistic indicator of disease severity, separation of the three sample classes was evident even though none of the wide range of conventional clinical risk factors that had been measured was significantly different between the classes.

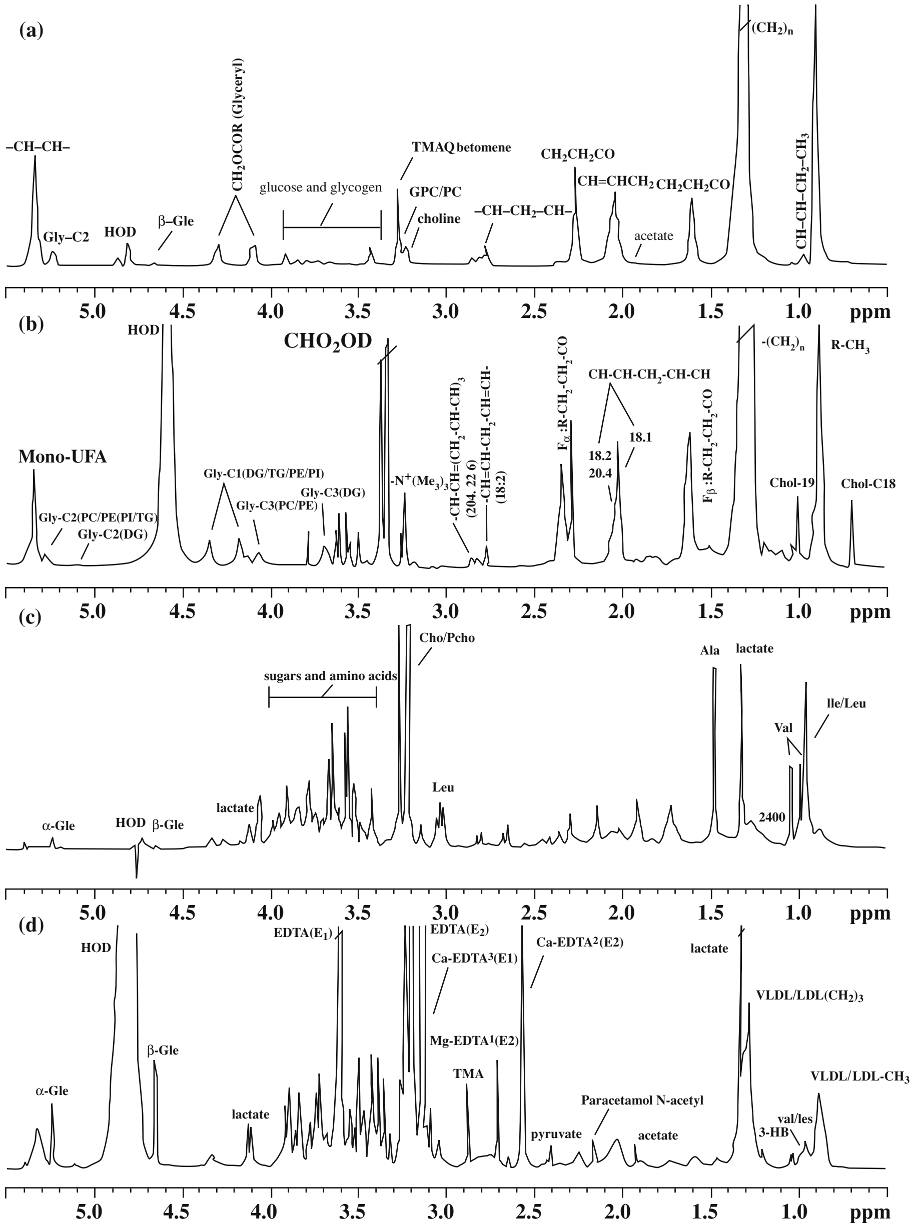


Fig. 3. (a) 600 MHz ^1H MAS NMR CPMG spin-echo spectrum of intact liver tissue; (b) 600 MHz standard ^1H NMR spectrum of a lipid-soluble liver tissue extract; (c) 600 MHz solvent suppressed ^1H NMR spectrum of an aqueous-soluble liver tissue extract; (d) 500 MHz ^1H NMR CPMG spectrum of blood plasma. All spectra are from animals treated with a toxic dose of paracetamol (500 mg/kg) and sacrificed at 240 min after dosing. Key: 3HB, 3-D-hydroxybutyrate; Cho, choline; Chol, cholesterol; Glu, glucose; GPC, glycerophosphorylcholine; Gly, glycerol; LDL, low-density lipoprotein; P Cho, phosphocholine; TMAO, trimethylamine-*N*-oxide; VLDL, very low-density lipoprotein.

Conclusions

Although there continues to be a need for advances in metabonomic analytical technologies both in NMR and MS, NMR is likely to remain the method of choice for a broad impartial survey of metabolic profiles, especially given recent gains in sensitivity through the use of cryoprobe detectors. MS coupled to a separation stage is always likely to yield better detection limits for specific classes of metabolite, but is inherently less general.

NMR-based metabonomics is now recognized as an independent and widely used technique for evaluating the toxicity of drug candidate compounds, and it has been adopted by a number of pharmaceutical companies into their drug development protocols. For drug safety studies, it is possible to identify the target organ of toxicity, derive the biochemical mechanism of the toxicity, and determine the combination of biochemical biomarkers for the onset, progression and regression of the lesion. Additionally, the technique has been shown to be able to provide a metabolic fingerprint of an organism (metabotyping) as an adjunct to functional genomics, and hence has applications in the design of drug clinical trials and for evaluation of genetically modified animals as disease models. The potential and real impact of metabonomics on all stages of pharmaceutical R&D is encapsulated in Figure 4.

Using metabonomics, it has proved possible to derive new biochemically based assays for disease diagnosis and to identify combination biomarkers for disease, which can then be used to monitor the efficacy of drugs in clinical trials. Thus, based on differences observed in metabonomic databases from control animals and from animal models of disease, diagnostic methods and biomarker combinations might be derivable in a preclinical setting. Similarly, the use of databases to derive predictive expert systems for human disease diagnosis and the effects of therapy, require compilations from both normal human populations and patients before, during, and after therapy. In human studies, metabonomics also has the potential for disease diagnosis and possibly even prognosis.

Protein Misfolding Disease: Overview of Liquid and Solid-State High Resolution NMR Studies

Harald Schwalbe and Julia Wirmer

Institute for Organic Chemistry and Chemical Biology, Center for Biomolecular Magnetic Resonance, Johann Wolfgang Goethe-Universität, Marie-Curie-Strasse 11, D-60439 Frankfurt/M, Germany

Protein Misfolding Diseases

The failure of proteins to fold into their functional forms can occasionally lead to "protein misfolding" or "protein conformational" diseases. Many among the most common and debilitating of these diseases are associated with the formation of protein amyloid, an insoluble material that is deposited as fibrils or plaques in different tissues and organs of the body. Amyloid formation is known to be accelerated by a variety of cellular factors, including metal ions, such as copper and zinc, and interactions with other species, such as lipids and RNA. It is implicated in many medical conditions including Alzheimer's disease and the transmissible prion disorders. It is becoming increasingly recognized that the switch from a normal to a diseased state of the cell in protein misfolding diseases is induced by a shift in the equilibrium between different conformational and aggregation states of a polypeptide chain that are present under normal conditions. The native state [N] of a protein can be investigated in great detail using X-ray crystallography and NMR-spectroscopy. Our understanding of states other then the native one, however, is only now emerging. Liquid and solid-state high-resolution NMR spectroscopy are the major structural techniques to determine structure and dynamics of the polypeptide chain under a variety of different conditions. They describe proteins in their native state [N], in unfolded states [U], in transient intermediates [I], and in their fibrillar and prefibrillar states (Figure 1).

Natively Unfolded Proteins Involved in Protein Misfolding Diseases

Non-native and unfolded states of proteins have also come into interest recently from the observation that an axiomatic linking of the function of a protein to a persistent fold might not be general, because a number of proteins have been identified that lack intrinsic globular structure in their normal functional form [1–3]. The expressions "intrinsically unstructured" and "natively unfolded" are being used synonymously, the latter being coined by Schweers *et al.* in 1994 in the context of structural studies of the protein tau [4]. Intrinsically unstructured proteins are extremely flexible, non-compact, and reveal little if any secondary structure under physiological conditions. In 2000, the list of natively unfolded protein comprised 100 entries [5]. Natively unfolded proteins are implied in the development of a number of neurodegenerative diseases including Alzheimer's disease (deposition of amyloid-β, τ-protein, α-synuclein), Down's syndrome and Parkinson disease to name a few [5]. They are predicted to be ubiquituous in the proteome [6,7] and algorithms available as a web-program (http://dis.embl.de/) have been developed to predict protein disorder [8]. According to the predictions, 35–51% of eucaryotic proteins have at least one long (>50 residues) disordered region and 11% of proteins in Swiss-Prot and between 6 and 17% of proteins encoded by various genomes are probably fully disordered [6]. Proteins predicted to be intrinsically unstructured show low compositional complexity. These regions sometimes correspond to repetitive structural units in fibrillar proteins. Therefore, it does not seem unlikely that lack of structure of the polypeptide chains in some states of a protein plays an important role in the development of fibrillar states and this further supports the importance for detailed structural and dynamic investigations of non-native states of proteins. It has also been noted by Gerstein that the average genomially encoded protein is significantly different in terms of size and amino acid composition from folded proteins in the PDB [9]. This difference would indicate that the structures deposited in the PDB are not random and in turn that they cannot be taken as representative for the entire structural diversity of polypeptide chains.

Brief Background in NMR Parameters

NMR is able to provide both dynamic and structural information about proteins in a variety of different states at atomic resolution. NMR has the potential for probing residual structure, the size of aggregating molecules, and variation in the internal dynamical properties on the basis of diffusion-weighted NMR spectroscopy, heteronuclear relaxation measurements, paramagnetic enhancement of

Graham A. Webb (ed.), Modern Magnetic Resonance, 1387–1391.

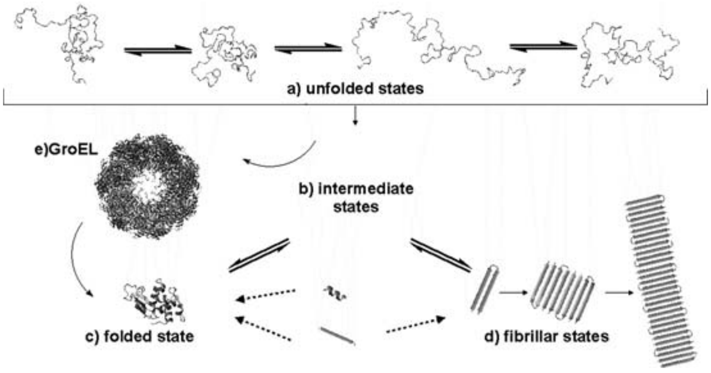

Fig. 1. The characteristics of states accessible to a protein differ widely in their structural and kinetic properties. The different conformations adopted by a polypeptide chain can range from the native, often monomeric state (c), in which a single conformation exists and which is built up from secondary structure elements and their specific arrangements, to the ensemble of conformers representing the random coil state of a protein (a). The individual members of this ensemble have widely different compaction, dynamics, local, and non-local conformations. Protein folding preceeds via formation of folding intermediates (b) whose structure and dynamics may be modulated by protein–protein interactions with molecular chaperones such as GroEL (scaled down by a factor of 2) (e) shown in the figure. At the other extreme of conformational states, proteins can aggregate and form oligomeric states called fibrils (d). Liquid and solid-state NMR spectroscopy can provide detailed information on structure and dynamics in all of these states.

relaxation induced by paramagnetic spin labels, and residual dipolar couplings (summarized in Table 1). More recently, NMR techniques have been developed to characterize the structural transitions from unfolded states of protein, via low molecular oligomers to fibrils. Such studies include both static and time-resolved experiments.

Proteins Involved in Misfolding Diseases Studied by NMR

Two proteins intimately linked to neurodegenerative illnesses seem to have a possible function in copper homeostasis: the amyloid precursor protein (APP) of Alzheimer's disease, and the prion protein (PrP), which causes transmissible spongiform encephalopathies (TSE). APP gives rise to the amyloid Aβ peptide and the prion protein PrP^c can convert to the variant isoform PrP^{Sc} of Creutzfeldt-Jakob's disease (CJD). The protein Cu,Zn dismutase (SOD) is a metalloprotein for which familial mutants are linked to familial amyotrophic lateral sclerosis (FALS). The three proteins are known to interact: The prion protein specifically binds copper and native PrP charged with copper has superoxide dismutase (SOD1) activity. In turn, overexpression of APP alters brain copper content and attenuates SOD1. On the other hand,

Table 1: Overview of NMR parameters and their conformational dependence

NMR parameter	Conformational dependence
Chemical shift δ (ppm)	Multiple torsion angles: ϕ, ψ, ω, χ_1
Scalar couplings ^nJ (Hz)	Single torsion angles via Karplus equations
Homonuclear NOEs (a.u.)	Distances, dependence on correlation time, and motional properties
Heteronuclear relaxation (Hz)	Motional properties, dependence on τ_c, S^2, τ_e[a]
Residual dipolar couplings RDC (Hz)	Overall shape, dynamics, S[b]
H/D exchange	Exchangeable H^N
Diffusion	Radius of hydration (R_h)
Photo CIDNP	Accessible Trp, Tyr, His

[a] τ_c correlation time for overall rotational tumbling, S^2 order parameter of local dynamics, τ_e correlation time for local dynamics
[b] S order parameter for local dynamics

for the other systems discussed here, α-synuclein and transthyretin, no metal induced misfolding is currently being discussed in the literature.

Amyloid Precursor Protein

Cleavage of APP by β- and γ-secretases results in amyloid forming peptides containing 39–43 residues referred to as the Amyloid β-peptide (Aβ). The Aβ is the major constituent of the plaques in the brains of Alzheimer patients. The presence of copper inhibits Aβ production and stimulates the non-amyloidogenic pathway of APP in cells and in transgenic animals overexpressing APP. The soluble and the fibrillar form of various peptides of Aβ have been studied using liquid and solid-state NMR spectroscopy: conformations in the soluble form range from α-helical conformations via random coil to β-sheet conformations, depending on solvent condititions, pH values and peptide concentration. In membrane mimicking environments such as SDS, the N-terminus is unstructured (residues 1–14) while α-helical conformation is found from residue 15–36 with a kink from residues 25–27 [10–13]. A high propensity for aggregation is found in solution and the conformation in solution is often found to be in an equilibrium between random coil conformation [14] and β-sheet conformers [15] with increased β-sheet propensity at high concentration, high temperature and high salt conditions. However, at very low concentrations and at 0 °C, a conformational equilibrium between a left handed 3(10) helix and random coil conformations is found [16]. Solid-state NMR studies revealed the structure of the amyloid fibrils formed by Aβ (1−40): approximately the first 10 residues of the peptide are disordered in the fibril, residues 12–24 and 30–40 adopt β-strand conformations and form parallel β-sheets through intermolecular hydrogen bonding. The two β-sheets within a single peptide unit form an antiparallel sheet [17]. The structural model found for the Aβ(1–40) is very similar to structural models of smaller (11–25, 16–22) and larger (1–42) peptides [18,19].

Prion Protein

Prion protein (PrP^c) is a glycosyl-phosphatidyl-inositol (GPI) anchored membrane protein of 35 kD. Its conformational altered scrapie form (PrP^{Sc}) is associated with neurodegenerative diseases. Cellular PrP^c is synthesized in three topologic forms, secreted ^{sec}PrP and the single-spanning membrane proteins of opposite orientations ^{Ntm}PrP, and ^{Ctm}PrP. Increases in ^{Ctm}PrP are associated with the development of neurodegenerative disease. The conformational properties of a protein are generally thought to be determined by specific elements in the sequence; for the prion protein these are the N-terminal sequence, a hydrophobic stretch around residue 100, a putative transmembrane domain, and the C-terminus for GPI anchor addition. The signal sequence plays a decisive role in determining the membrane orientation of the PrP. ^{Ctm}PrP contains an uncleaved N-terminal signal peptide.

NMR solution structures have been reported for PrP^c from several species [20–31]. Interestingly, it was shown that only few of the disease related mutations lead to reduced stability of N [26]. Residues 23–121 comprise a flexibly disordered tail in contrast to the well-ordered 125–228 core part. Cu^{2+} binding to histidines located in the flexible part of the protein (high affinity octarepeat regions are found between residues 51–90 and low affinity binding sites are formed by His96 and His111) induces a shift towards β-sheet conformation as shown by liquid-state NMR [32–36]. In particular, the conformational shift induced by binding of His96 and His111 is remarkable, as these residues are part of the infectious region (residues 90–231) [24]. β-sheet conformation has also been observed by liquid and solid-state NMR studies on fibrillar states: a hydrogen exchange study of the fibrillar form of the 106–121 peptide revealed 50% β-sheet structure, which is located in the center portion of the peptide [37]. Complete β-sheet structure was found by solid-state NMR investigation on the fibrillar state of a peptide corresponding to the infectious P101L mutant of residues 89–143 [38].

α-Synuclein

α-synuclein is associated with Parkinson's disease, a neurodegenerative disorder affecting some five million people worldwide. This disease is characterized by the formation of proteinaceous inclusions called Lewy bodies that are known to be composed primarily of aggregated α-synuclein. There is mounting evidence that the oligomeric species that are formed during the process of aggregation of the monomeric α-synuclein are at the origin of the pathology. In solution, α-synuclein can be either found in a monomeric, substantially unfolded conformation, or it can form several morphologically different types of aggregates, including oligomers, amorphous aggregates, and amyloid-like fibrils. Its normal function is poorly understood, but it is believed that it includes transient or reversible lipid interactions [39]. NMR studies of the lipid bound form of α-synuclein revealed that the C-terminus of the protein remains free in solution, while the N-terminus of the protein binds to the lipids in a helical conformation [40–43]. This helical conformation in the lipid bound state remains nearly unchanged in the early onset mutations (A30P, A53T) [43]. More interesting results were found by NMR studies on the natively unfolded monomeric form free in solution: the protein is more compact than expected for a highly denatured protein [44] and residual helical structure is present in the N-terminal part of α-synuclein (residues 18–31) [40,45,46]. This residual helical structure is diminished in one of the early onset mutants A30P, while enhanced β-sheet propensity around the mutation site in the other early onset mutant A53T is observed [45]. Changes in these parts of the sequence (residues 22–93) were also observed upon binding of aggregation promoting polyamines at the C-terminal part (residues 109–140) [47]. Taking all NMR investigations on the monomeric form in solution together, clearly the N-terminal part of the protein is the aggregation nucleus.

Cu-Zn-Superoxide Dismutase

Mutations in the gene for cytosolic SOD are linked with familial FALS. The active site of each monomer of SOD (153 residues) contains one copper and one zinc ion. The enzyme catalyzes the dismutation of superoxide to dioxygen and hydrogen peroxide. FALS-related mutations are concentrated either in the metal-binding loop or in loops III (38–40) and V (90–93). In this protein, metal ions have a fundamental role for protein stabilization, correct folding, and in increasing protein rigidity. Binding of the metal ions is of fundamental importance to stabilize its secondary structure and to define the tertiary interactions relevant for the relative orientation of the two sheets forming as can be shown by a comparison of the NMR strucutures in the presence and the absence of metal ions [48,49]. A comparison of WT SOD and the FALS-related mutant G93A based on NMR dynamics revealed that indeed a in the β-barrel loops III and V are a lot more dynamic and thus less stable in the mutant than in the wild type proteins [50].

Transthyretin

Transthyretin (TTR) is a homotetrameric protein that is involved in the transport of thyroid hormones and retinol in human serum. A large number of mutations (more than 80 different ones) have been found that lead to misfolded forms of the protein. These misfolded forms are implicated in amyloid diseases such as familial amyloidotic polyneuropathy and senile systemic amyloidosis. A combination of hydrogen exchange experiments coupled with NMR detection have compared WT TTR under native conditions and under conditions that are known to promote amyloid formation: These studies revealed that amyloidogenic behavior is linked to destabilization of one half of the β-sandwich structure of TTR [51]. These findings were further confirmed by additional NMR studies of some of the amyloidogenic mutants [52,53]. Liquid-state NMR studies of amyloidogenic peptides (TTR10–20 and TTR105–115) showed that the peptides are unstructured in solution [54,55]. In contrast, the TTR105–115 peptide in its fibrillar state is in an extended β-sheet conformation, with its backbone and side chain torsion angles close to their optimal values for this secondary structure element. In addition, long-range order could be detected that is generally associated with crystalline materials by solid-state NMR [56,57].

^{19}F NMR Spectroscopy for Functional and Binding High-Throughput Screening

Marina Veronesi and Claudio Dalvit
Chemistry Department, Nerviano Medical Sciences, 20014 Nerviano, Milan, Italy

NMR screening has emerged as a powerful and reliable approach for identification of potential drug candidates [1]. The technique is now recognized for its impact on the drug discovery process and has become an important tool for lead identification, lead validation, and lead optimization in many pharmaceutical companies and universities [2–17]. A plethora of different NMR experiments has been proposed in the literature for performing these tasks. Two of these approaches, recently introduced, use fluorine NMR spectroscopy. FAXS (fluorine chemical shift anisotropy and exchange for screening) [18,19] and 3-FABS (three fluorine atoms for biochemical screening) [20] allow one to perform binding and functional high-throughput screening (HTS), respectively, and determine the dissociation binding constant (K_D) and the 50% mean inhibition concentration (IC_{50}) of the identified binders and inhibitors, respectively. This chapter provides an insight into the theory and practical aspects of these two experiments and presents applications to the screening of different biomolecular targets.

FAXS

Competition ligand-based NMR screening experiments were introduced for overcoming all the limitations associated with ligand-based NMR screening experiments [21–23]. The screening of chemical mixtures or single compounds against the biomolecular target of interest is performed in the presence of a weak- to medium-affinity ligand of known binding constant referred to in its role as the spy or reporter. Changes in the transverse or selective longitudinal relaxation rates of the spy resonances are monitored. Signals from the molecules screened are not utilized. Often the screening is performed in the presence of an additional molecule that does not interact with the receptor and referred to in its role as the control molecule. This compound represents an internal reference. Competition NMR-based screening, originally proposed with proton detection experiments, was subsequently extended to fluorine detection experiments [18,19]. For these experiments it is sufficient to have a spy molecule containing either a CF or a CF_3 moiety. This approach offers some unique advantages. (i) Absence of overlap permits the screening of large chemical mixtures and automated analysis of the spectra. (ii) Protonated solvents, buffers, or detergent do not interfere with the measurements thus allowing, for example, the screening against membrane proteins. (iii) The ^{19}F transverse relaxation rate R_2, given by Equation (1), is a sensitive parameter of binding events since it contains spectral densities calculated at zero frequency for both the heteronuclear ^{19}F–^{1}H dipolar interactions and the ^{19}F chemical shift anisotropy (CSA) interaction [24]:

$$
\begin{aligned}
R_2^{F} = {} & \frac{\gamma_F^2\gamma_H^2\hbar^2\tau_c}{20}\sum_{H_i}\frac{1}{r_{FH_i}^6}\left\{4+\frac{1}{1+(\omega_F-\omega_H)^2\tau_c^2}\right. \\
& +\frac{3}{1+\omega_F^2\tau_c^2}+\frac{6}{1+\omega_H^2\tau_c^2} \\
& \left.+\frac{6}{1+(\omega_F+\omega_H)^2\tau_c^2}\right\} \\
& +\frac{2}{15}\Delta\sigma^2\left(1+\frac{\eta_{CSA}^2}{3}\right)B_0^2\gamma_F^2\tau_c \\
& \times\left\{\frac{2}{3}+\frac{1}{2(1+\omega_F^2\tau_c^2)}\right\} \qquad (1)
\end{aligned}
$$

The H_i correspond to all the protons of the spy compound and of the protein close in space to the fluorine atom and r_{FH_i} is the internuclear distance between proton H_i and the fluorine atom of the spy molecule. $\Delta\sigma$ is the CSA of the ^{19}F atom and is given by $\Delta\sigma = \sigma_{zz} - (\sigma_{xx} + \sigma_{yy})/2$ where the different σs are the components of the chemical shift tensor. The asymmetry parameter η_{CSA} is given by $\eta_{CSA} = (3/2)(\sigma_{xx} - \sigma_{yy})/\Delta\sigma$, B_0 is the strength of the magnetic field, γ_H and γ_F are the proton and fluorine gyromagnetic ratios, respectively, ω_H and ω_F are the proton and fluorine Larmor frequencies, respectively, and τ_c is the correlation time.

Owing to the large CSA of ^{19}F (as much as few hundreds ppm) it will contribute significantly, according to Equation (1), to the transverse relaxation of the fraction of bound spy molecule [18,25–28]. CSA contribution to

Graham A. Webb (ed.), Modern Magnetic Resonance, 1393–1399.

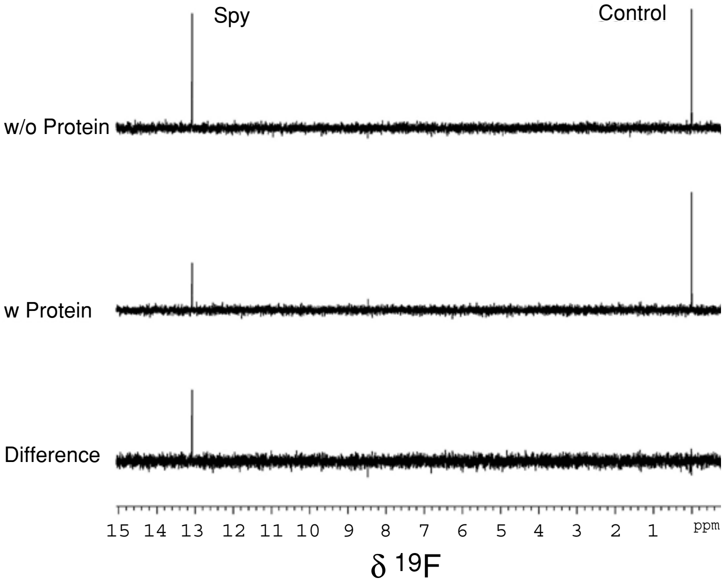

Fig. 1. One-dimensional ^{19}F NMR spin-echo ($n2\tau = 100$ ms) spectra recorded for the identification of a spy and control molecule required for FAXS. The two molecules are the weak-affinity ligand PHA-739917 and the non-interacting trifluoroacetic acid (TFA) molecule and the protein is the p21 activated kinase. The chemical shifts are referenced to TFA. The concentration of PHA-739917 and TFA was 50 and 15 μM, respectively. The spectra were recorded in the absence (top) and the presence of 1.5 μM of the protein (middle). In the difference spectrum (bottom) only the signal of the spy molecule is visible. Reprinted with permission from Dalvit *et al*. [18]. © 2002 Bentham Science Publishers.

transverse relaxation is directly proportional to the square of the magnetic field thus resulting in a more pronounced effect at stronger magnetic fields.

For a weak-affinity spy molecule the observed transverse relaxation $R_{2,\text{obs}}$ is given by [29,30]:

$$R_{2,\text{obs}} = \frac{[\text{EL}]}{[\text{L}_{\text{TOT}}]} R_{2,\text{bound}} + \left(1 - \frac{[\text{EL}]}{[\text{L}_{\text{TOT}}]}\right) R_{2,\text{free}} + \frac{[\text{EL}]}{[\text{L}_{\text{TOT}}]}\left(1 - \frac{[\text{EL}]}{[\text{L}_{\text{TOT}}]}\right)^2 \times \frac{4\pi^2(\delta_{\text{free}} - \delta_{\text{bound}})^2}{K_{-1}} \quad (2)$$

where $[\text{EL}]/[\text{L}_{\text{TOT}}]$ and $(1 - [\text{EL}]/[\text{L}_{\text{TOT}}])$ are the fraction of bound and free ligand, respectively, $R_{2,\text{bound}}$ and $R_{2,\text{free}}$ are the transverse relaxation rate constants for the ligand in the bound and free states, respectively. The last term in Equation (2) is the exchange term where δ_{bound} and δ_{free} are the isotropic chemical shifts of the fluorine resonance of the spy molecule in the bound and free states, respectively, and $1/K_{-1}$ is the residence time τ_{res} of the spy molecule bound to the protein.

Typically, a Carr–Purcell–Meibom–Gill (CPMG) spin-echo scheme [31,32] with a long 2τ interval between the train of 180° pulses (where $2\tau > 5\tau_{\text{res}}$) [33,34] is used in these experiments before the acquisition time. This is possible because the evolution with the heteronuclear ^{1}H–^{19}F scalar couplings is refocused at the end of the scheme. However, the 2τ period should not be very long in order to minimize signal attenuation originating from the spatial diffusion of the spy molecule.

The steps required for the screening with FAXS are described below:

1. A library of ^{19}F (CF or CF_3) containing molecules well characterized, chemically stable, and with high aqueous solubility is tested in mixtures against the receptor of interest for the identification of the potential spy and control molecules. STD [35], WaterLOGSY [36], or spin-echo ^{19}F experiments [18,19,37], as the example of Figure 1, are used for the identification of the two molecules.
2. The K_D of the identified spy molecules are determined with either ITC or fluorescence spectroscopy. The spy molecule is then selected on the basis of its K_D and the presence of only one binding site.
3. After the selection of the spy and control molecules, titration experiments as a function of the protein concentration are recorded and the intensity ratio of the two fluorine signals is plotted as a function of the fraction of protein-bound spy molecule [21], as shown in the example of Figure 2. The fraction of bound compound is calculated by using its K_D value and the equation:

$$\frac{[\text{EL}]}{[\text{L}_{\text{TOT}}]} = \frac{[\text{E}_{\text{TOT}}] + [\text{L}_{\text{TOT}}] + K_D}{2[\text{L}_{\text{TOT}}]} - \frac{\sqrt{([\text{E}_{\text{TOT}}] + [\text{L}_{\text{TOT}}] + K_D)^2 - 4[\text{E}_{\text{TOT}}][\text{L}_{\text{TOT}}]}}{2[\text{L}_{\text{TOT}}]} \quad (3)$$

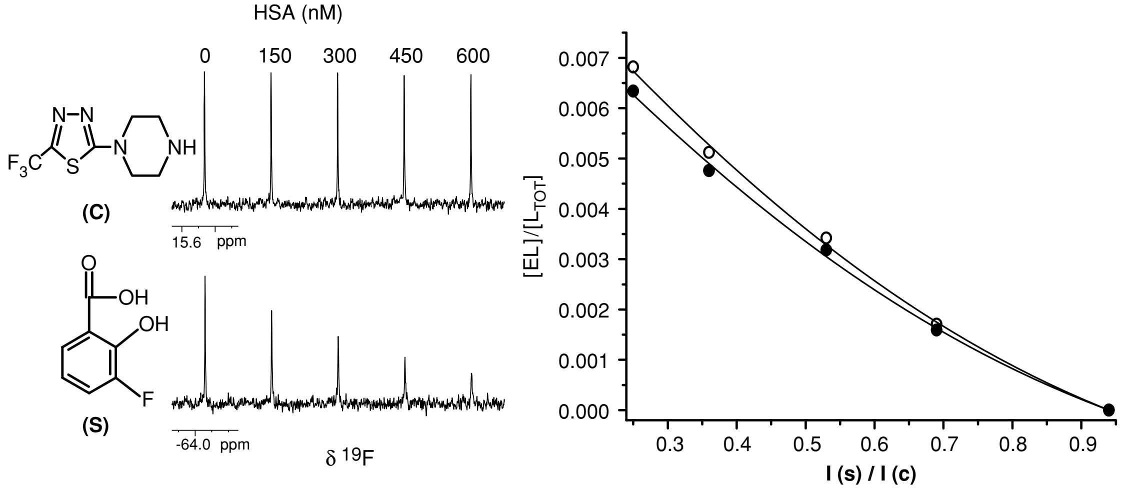

Fig. 2. (Left) One-dimensional ^{19}F NMR spin-echo spectra ($n2\tau = 80$ ms) recorded for the spy molecule 2-hydroxy 3-fluorobenzoic acid (**s**) and the control molecule 1-[5-(trifluoromethyl)1,3,4-thiadiazol-2-yl]piperazine(**c**) as a function of HSA concentration. The concentration of (**s**) and (**c**) was 50 and 25 μM, respectively. (Right) Plot of the signal intensity ratio (x-axis) of the two ^{19}F signals of (**s**) and (**c**) as a function of the fraction of bound spy molecule ([EL]/[L_{TOT}]) (y-axis). The last point on the right corresponds to the value in the absence of the protein. Two ratios ([EL]/[L_{TOT}]) were calculated using the limits of the ITC-derived K_D value of 41 ± 3.3 μM for (**s**) and using Equation (3). Values indicated by open circles were calculated with a K_D of 44.3 μM, values indicated by filled circles were calculated with a K_D of 37.7 μM. The curves represent the best fits of the experimental points. Reprinted with permission from Dalvit *et al.* [19]. © 2003 American Chemical Society.

where [E_{TOT}] and [L_{TOT}] are the total concentration of enzyme and ligand, respectively, and [EL] is the concentration of bound ligand.

4. The experimental conditions for the FAXS are then selected according to the graph of Figure 2. Compounds are tested in mixtures or as a single compound in the presence of the two molecules. Displacement of the spy molecule results in a shift of the R_2 parameter toward the intrinsic of the free state. When mixtures are used, deconvolution is then performed for the identification of the active compound. The screening with FAXS against human serum albumin (HSA) is shown in Figure 3. For screening, a total spin-echo period ($2n\tau$) is selected for which the signal of the spy molecule is approaching zero. The presence in the mixture of 5-CH_3 D, L Trp, and sucrose, known as non-binders, do not alter the spectrum of the spy molecule. In contrast, the presence in the mixture of the warfarin derivative 4-hydroxy-3-[1-(*p*-iodophenyl)-3-oxobutyl] coumarin (PNU-24009) results in the reappearance of the signal of the spy molecule thus identifying the NMR-hit.
5. The extent of displacement of the spy molecule is then used to calculate the binding constant K_I of the NMR-hit. Since [L_{TOT}] in the NMR screening experiments is known and fixed, the concentration of [EL] in the presence of the competing molecule can be calculated from the titration curve of Figure 2. The knowledge of [L_{TOT}], [EL], and [E_{TOT}] permits determination of the apparent dissociation binding constant K_D^{app} of the spy molecule in the presence of the competing molecule according to the equation:

$$K_D^{app} = \frac{[E_{TOT}][L_{TOT}] - [E_{TOT}][EL] + [EL]^2 - [L_{TOT}][EL]}{[EL]} \tag{4}$$

In the assumption of a simple competitive mechanism, the K_D^{app} is then used to extract the binding constant K_I of the NMR-hit according to the equation:

$$K_I = \frac{[I]K_D}{K_D^{app} - K_D} \tag{5}$$

where [I] is the concentration of the NMR-hit. The NMR-derived K_I values obtained with a single experimental point compare favorably with the values derived from full titration fluorescence or ITC measurements [18,21,38]. A major advantage of NMR applied to these measurements is the direct determination of the concentration of the NMR-hits thus providing reliable K_I values.

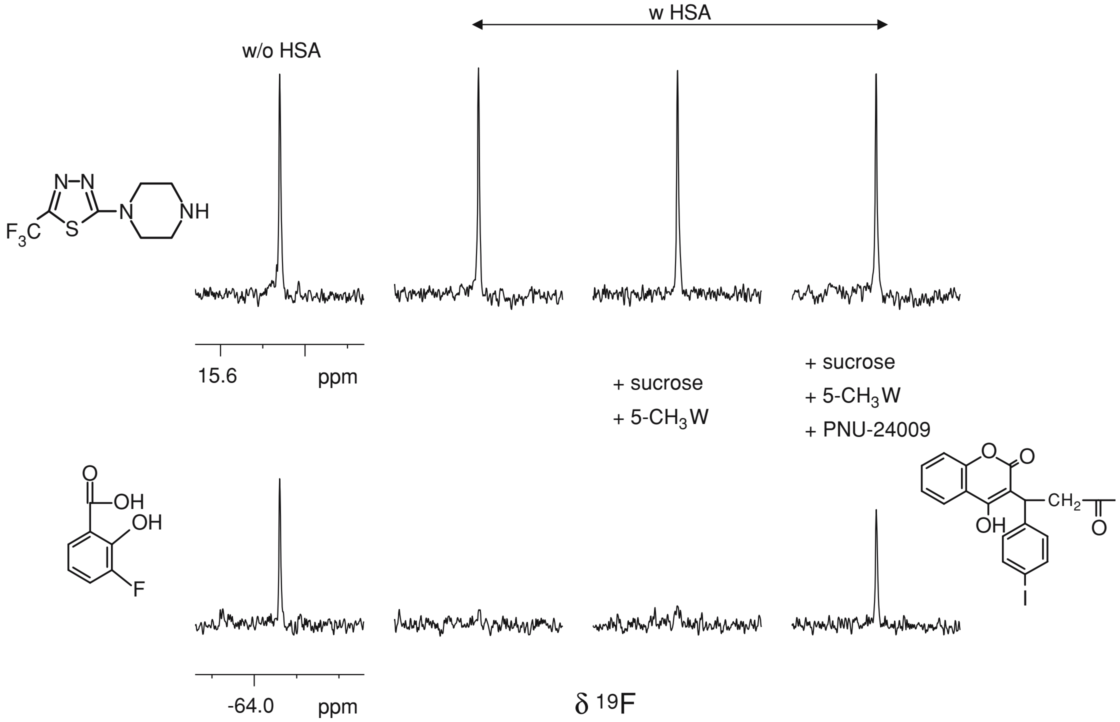

Fig. 3. FAXS performed with **(c)** (top) and **(s)** (bottom). The spectra were recorded with a total spin-echo period of 160 ms with an interval between the 180° pulses (2τ) of 40 ms. The concentration of **(s)** and **(c)** was 50 and 25 μM, respectively. The spectra on the left were recorded in the absence of protein while all the other spectra were recorded in the presence of 600 nM HSA. 3-FABS

NMR has been extensively used for characterizing the product or products of an enzymatic reaction and for gaining insight into the kinetics of the reaction (see, for example, Refs. [39,40]). A high substrate concentration was necessary for these studies due to the low sensitivity of the NMR technique. The required high concentration represents a major hurdle for the utilization of this approach to functional screening purposes, since only the very strong inhibitors would be detected. The goal in a primary screening is the identification also of weak- and medium-affinity inhibitors derived from a diversity of chemical classes.

A way to overcome the sensitivity limitation is to tag the substrate with a CF_3 moiety and use ^{19}F NMR (with proton decoupling) as the method of detection. The principle of this approach named 3-FABS [20] is described in Figure 4. The high receptivity of ^{19}F NMR spectroscopy, the 100% natural abundance of the isotope ^{19}F and the presence of three fluorine atoms result in ^{19}F NMR signals of high intensity. Modification of the substrate through the enzymatic reaction results in changes of the fluorine chemical shift tensor components even when the CF_3 moiety is distant from the reaction site. Therefore, distinct ^{19}F signals for the substrate and product (or products) are observed. The process involved with 3-FABS requires the following steps [20]:

1. Determination of the linear range (first-order region) of the enzymatic reaction. This is achieved by monitoring the course of the reaction within the NMR tube. ^{19}F spectra at different intervals are recorded and the ^{19}F signal integral of the substrate or product (products) is plotted as a function of the time elapsed from the beginning of the reaction. Screening and K_M measurements are then performed in an end point format. The reaction is quenched with either a strong inhibitor, a denaturating or a chelating molecule after a delay for which the reaction is still linear and sufficient product is formed.

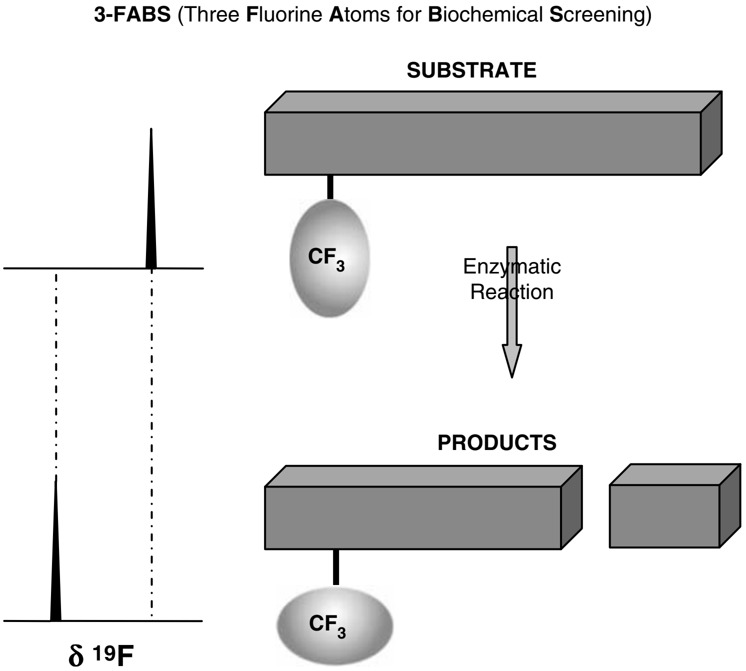

Fig. 4. Schematic diagram of the 3-FABS method. The enzyme in the example is a protease that cleaves the peptide bond with the formation of two products.

2. Determination of the K_M of the substrate and cosubstrate. This is achieved by performing the reaction at different substrate or cosubstrate concentrations. The K_M is measured using the following equation [41]:

$$V = \frac{[S]}{K_M + [S]} V_{max} \tag{6}$$

   where V is the initial speed of the reaction and V_{max} is the maximum speed that would be observed if all the enzyme $[E_{TOT}]$ is complexed with the substrate ($V_{max} = K_{cat}{*}[E_{TOT}]$, where K_{cat} is the catalytic rate constant) and [S] is the substrate concentration. V is obtained experimentally by measuring the integral of the ^{19}F NMR signal of the product divided by the incubation time of the reaction. A plot of these values as a function of [S] permits the determination of K_M and V_{max}.
3. Screening, as shown in Figure 5, is performed in an end point format using either chemical mixtures or single compound at a substrate concentration in the range 2–5 K_M. In every screening run a sample without test molecules is recorded. This sample represents the reference with 0% inhibition. Deconvolution of the active mixtures is then performed for the identification of the inhibitors.
4. The IC_{50} value of the detected inhibitor is obtained by simply recording experiments at different inhibitor concentration and by monitoring the integral of the product or substrate ^{19}F NMR signal as shown in Figure 5. A plot of these values as a function of the inhibitor concentration allows the determination of IC_{50} according to the equations:

   a) monitoring the substrate signal

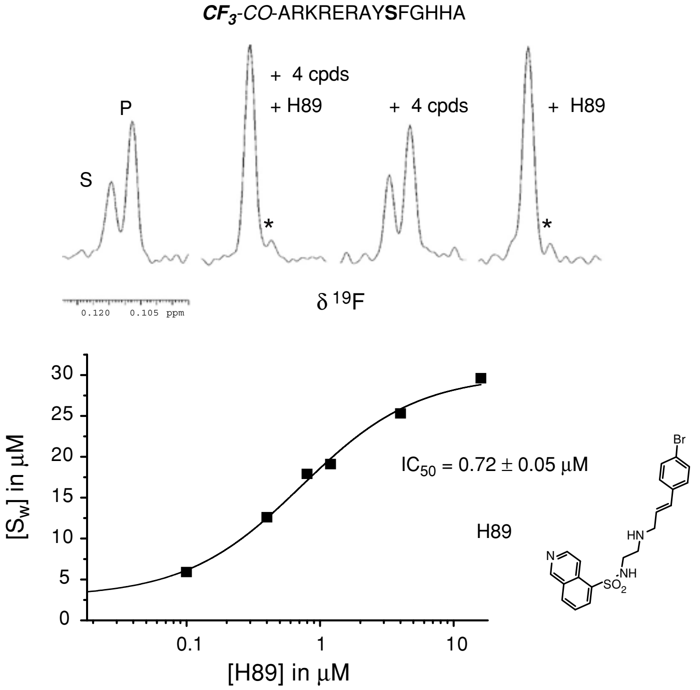
$$[S_w] = \frac{[S_{w/o}] - [S_{TOT}]}{1 + ([I]/IC_{50})^n} + [S_{TOT}] \tag{7}$$

   b) monitoring the product signal

$$[P_w] = \frac{[P_{w/o}]}{1 + ([I]/IC_{50})^n} \tag{8}$$

   where $[S_w]$ and $[S_{w/o}]$ are given by the integrals of the substrate signal in the presence and absence of the inhibitor, respectively, $[P_w]$ and $[P_{w/o}]$ are given by the integrals of the product (or products) signal in the presence and absence of the inhibitor, respectively, and $[S_{TOT}] = [P_{w/o}] + [S_{w/o}] = [P_w] + [S_w]$. $[S_{TOT}]$ is the substrate concentration used for the experiments and it represents an internal reference, [I] is the concentration of the inhibitor, IC_{50} the concentration of the inhibitor

Fig. 5. Screening and deconvolution (top) and IC_{50} measurement (bottom) for compound H89 [43] performed with 3-FABS. The substrate is the N-terminal trifluoracetylated AKTide [44], the enzyme is the Ser/Thr kinase AKT1. The five compounds are (2-amino-6 methylquinazolin-4 ol, ethyl 2-quinoxalinecarboxylate, 5-methylbenzimidazole, methyl isoquinoline-3-carboxylate, and N-(2-{[(2E)-3-(4-bromophenyl)prop-2-enyl]amino}ethyl, known as H89). The activated enzyme AKT1, peptide, ATP, and compound concentrations were 25 nM, 30 μM, 131 μM (~2 K_M), and 10 μM, respectively. S and P represent the CF_3 signal of the peptide and the phosphorylated peptide, respectively. IC_{50} was measured with Equation (7), but the same value was obtained with Equation (8). The asterisks indicate the tiny amount of phosphorylated peptide in the presence of H89. Reprinted with permission from Dalvit *et al.* [20]. © 2003 American Chemical Society.



at which 50% inhibition is observed and n is the cooperativity factor (known also as Hill slope). In the absence of allosteric effects (i.e. $n = 1$) a meaningful value for IC_{50} can be derived with a single experimental point. This is possible because the values for both plateaus are known. These are $[S_{w/o}]$ and $[S_{TOT}]$ if Equation (7) is used and $[P_{w/o}]$ and the 0 value if Equation (8) is used.

Typically, enzyme concentration in the low nanomolar is used, but if the reaction is fast (substrates with large K_{cat}/K_M) and the enzyme is stable at room temperature for few hours the concentration can be further reduced [42]. This can be appreciated in the example of Figure 6 where the screening against the protease trypsin is performed with only 50 pM enzyme concentration. With cryoprobe technology optimized to fluorine NMR detection it will be possible, in some fortunate cases, to perform 3-FABS at enzyme concentration in the femtomolar range.

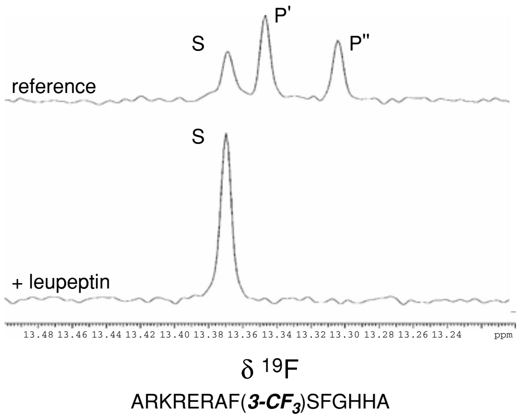


Fig. 6. 3-FABS performed with the protease trypsin (Roche Molecular Biochemical Cat. No. 1418475) at an enzyme concentration of only 50 pM. The substrate concentration was 30 μM. The reaction was performed in 50 mM Tris pH 7.5 and 0.03% Triton X-100 (Sigma X-100) at 20 °C and quenched after 6:40 hours with 0.5 mM phenylmethylsulfonyl fluoride (PMSF). S is the original peptide and P′, P″ are two different products of the enzymic hydrolysis. In the presence of 20 μM leupeptin no product formation is observed. Reprinted with permission from Dalvit *et al.* [42]. © 2004 Elsevier Science Ltd.

Conclusion

The fluorine NMR approaches FAXS and 3-FABS represent powerful tools for performing HTS and determining the K_D and IC_{50} values of the identified hits. The low protein consumption required by these methodologies compares favorably with the concentration used with the other techniques used in HTS. In addition, the two NMR techniques have some important advantages. Their simplicity together with the possibility of directly monitoring the real concentration, purity, stability, and solubility of the screened compounds results in reliable lead molecule detection and precise quantification of their strength. It is envisioned that the speed and easy set-up of FAXS and 3-FABS together with their broad range of applications will play a major role in the drug discovery process for discovering potent, bioavailable, and safe clinical candidates.

Applications of Receptor-Based NMR Screening in Drug Discovery

Philip J. Hajduk
Global Pharmaceutical Research and Development, Abbott Laboratories, Abbott Park, IL 60064, USA

Introduction

High-throughput screening (HTS) of large corporate compound libraries has become the primary strategy for lead generation in the pharmaceutical industry. However, despite the advances in screening and chemistry technologies over the last decade, there has been little increase in the rate of discovery of quality drug leads [1,2]. One of the primary reasons for this problem is the nature of the hits that come from traditional HTS campaigns. Most hits tend to look "drug-like," with molecular weights <500 and $C\log P$ values <5, but the optimization process tends to increase both size and hydrophobicity—leading to compounds with significantly poorer drug-like properties [3]. An additional problem is the large numbers of false positives that potentially come from HTS campaigns, confounding lead triage and the identification of quality leads that act via the intended mechanism of action [4].

Recently, NMR-based screening has become a powerful complement to traditional HTS technologies to identify lead compounds that have high potential for further optimization. Unlike conventional HTS, most NMR-based screening applications focus on the identification of low molecular weight, low-affinity compounds from which high-affinity drug candidates can be constructed. In addition, NMR screening has been particularly successful when closely integrated with other drug discovery technologies, including HTS, X-ray crystallography, and high-throughput organic synthesis. There have been many excellent reviews on the applications as well as the theoretical and experimental aspects of NMR-based screening [5–14]. In this review, the rationale, advantages, and applications of fragment-based screening will be presented, with particular emphasis on receptor-based methods for NMR screening.

Fragment-Based Screening: Identifying "Hot Spots" on Protein Surfaces

Over the last decade, it has become widely recognized that the interaction energy of a protein with its natural ligand or receptor is not necessarily evenly distributed over the binding surface, but instead can be highly localized to specific regions of the protein surface called "hot spots." This was first recognized in mutational analyses of protein–protein interactions [15], but has also been extended to the study of protein–ligand interactions [16]. These studies imply that there are relatively small regions of the protein surface that impart the majority of the free energy of binding with the ligand, while additional interaction surface primarily serves to modulate specificity. This has significant implications for drug design, in that the rapid identification and optimal utilization of the energetic focal point of the binding site can accelerate the discovery of potent molecules with good lead-like or drug-like properties [2]. Unfortunately, the large compounds that come from typical HTS campaigns tend to interact sub-optimally with the hot spot, while gaining potency by interacting with peripheral sites in the binding pocket that have little potential for further optimization (Figure 1a). This can confound subsequent optimization, as the region of the compound that interacts with the hot spot (which has the greatest potential for increasing binding affinity) is initially unknown and must be discovered through several rounds of blind chemical modification. Unfortunately, even after this "core" piece is discovered, it is often difficult to modify in the context of the lead molecule without incurring unacceptable losses in potency.

As an alternative to pursuing relatively high molecular weight, sub-optimal leads, fragment-based screening is becoming a powerful tool in the drug discovery arena. In fragment-based screens, low molecular weight (typically 100–300 Da) compounds that interact optimally with the hot spot of the active site are initially pursued. By targeting only a small region of the binding site, the chances of identifying a compound that interacts optimally in the pocket are increased dramatically [17]. In addition, because of the reduced complexity of the protein–ligand interface, the number of compounds that need to be screened is drastically reduced. Typical fragment libraries reported in the literature tend to be on the order of 10^3–10^4 compounds, compared to the 10^6 compounds typically evaluated in HTS assays. There are a variety of ways to utilize fragment leads in drug design efforts, as will be described

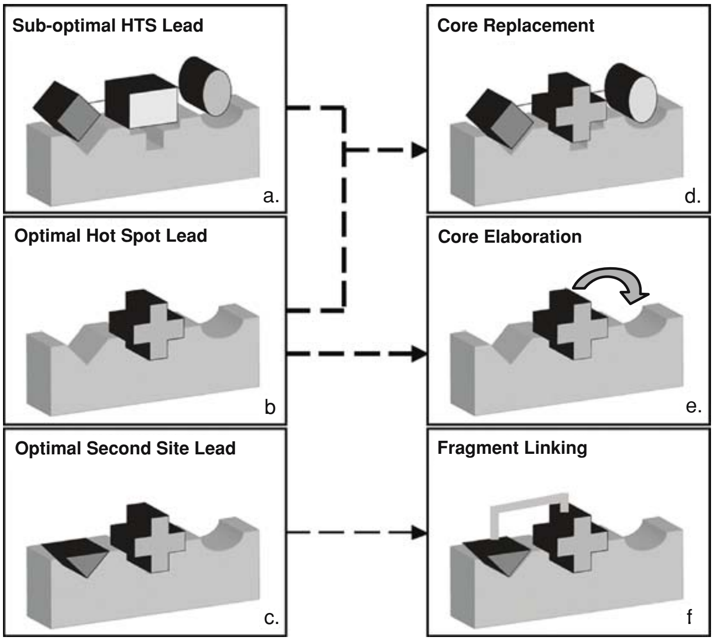

Fig. 1. Fragment-based strategies for the design of novel drug leads. (a) Representation of a high-throughput screening lead (connected shapes) binding sub-optimally to the protein target (gray surface). Sub-optimal binding is depicted by poor packing and shape complementarity. (b) Identification of a fragment lead (cross) that interacts optimally with the protein, indicated by close packing and good shape complementarity. (c) Identification of two ligands (cross and triangles) that bind to proximal subsites on a protein surface. (d) Core replacement strategy for lead design, in which the fragment identified in (b) is incorporated into the lead compound depicted in (a). (e) Core elaboration strategy, in which the fragment identified in (b) is directionally modified via high-throughput synthetic means to produce large libraries of compounds that can access neighboring subsites. (f) Fragment-linking strategy, in which the two fragments identified in (c) are linked to produce a high-affinity ligand.

below. However, these leads first need to be reliably identified. While attractive starting points for design, these fragment leads tend to bind with low affinity to the target (e.g. K_D values of 10–1000 μM)—which can complicate biochemical means of detection. As a result, a host of new technologies have been developed or elaborated for the express purpose of enabling fragment-based drug design. Such methodologies include NMR-based screening (both target-based and ligand-based) [10,11], high-throughput X-ray crystallography (e.g. CrystaLEAD) [2,18], mass spectroscopy [19], surface plasmon resonance [20], fragment tethering [21], and dynamic combinatorial chemistry [22]. This review will focus on receptor-based methods for fragment-based screening. The reader is referred to other sections in this handbook for more thorough discussions of other aspects on NMR-based screening in drug discovery and design.

Receptor-Based NMR Screening

Receptor-Based NMR screening monitors the perturbations in the protein signals upon addition of a test compound. The target is isotopically labeled and two-dimensional $^{15}N/^{1}H$- or $^{13}C/^{1}H$-correlation spectra are collected. Screening is typically performed against mixtures of 10–30 compounds, and the mixtures that produce the largest chemical shift perturbations are deconvoluted to identify the leads. NMR screening based on chemical shift perturbations of the resonances of the protein target is a profoundly reliable method for detecting protein–ligand interactions, and has significant advantages over other screening methods. The observation of discrete, stable chemical shift perturbations is strong evidence for a specific, well defined binding event. As a result, target-based NMR screening is essentially immune to false positives that can arise from non-specific binding or compound aggregation [23]. In addition, the spectral editing essentially eliminates the ligand signals, enabling the experiments to be performed even at very high ligand concentrations. Finally, the unique chemical shift perturbation "fingerprint" induced by ligand binding can be used not only to detect binding, but also to identify the ligand-binding site. This is shown in Figure 2 for $^{13}CH_3$-labeled protein kinase A (PKA) (mutant form). Addition of adenosine gives rise to characteristic chemical shift perturbations, and all screening hits that shift these same peaks can be classified as ATP-site ligands (Figure 2A). However, ligands can be identified that bind to alternative pockets on the protein (Figure 2B). These pockets can potentially be independently exploited for the development of therapeutics or ligands for these sites can be reliably classified and safely ignored if it is determined that the site is therapeutically irrelevant. In either case, this unique feature of receptor-based NMR screening makes it a powerful tool in the discovery and characterization of ligands for protein targets.

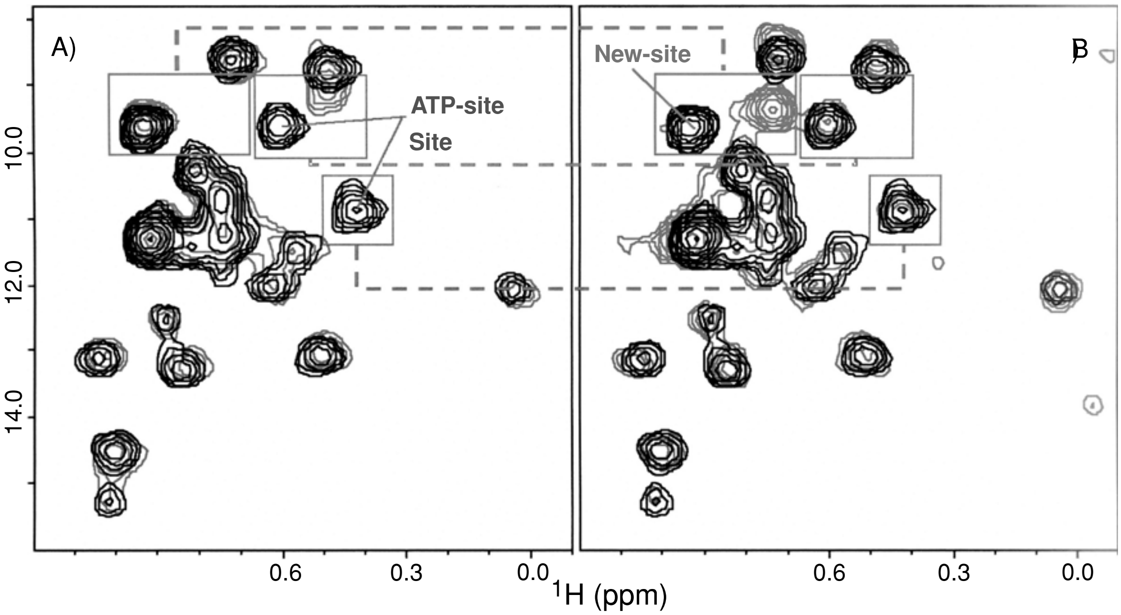

Fig. 2. Expanded section of $^1H/^{13}C$-HSQC spectra (showing isoleucine-δ signals) acquired on a mutant form of protein kinase A (PKA) in the absence (black contours) and presence (red contours) of (A) ATP-γS and (B) a test compound that binds to a site on PKA other than the ATP-binding site. The unique chemical shift fingerprint for each binding site can be used to classify new compounds as ATP- or non-ATP-site ligands. (See also Plate 109 on page XXIV in the Color Plate Section.)

With the advance of cryogenic probes [24] and cost-effective ^{13}C-methyl labeling [25], target-based NMR screening utilizing ^{15}N- or ^{13}C-labeling can now routinely be applied to targets with MW in excess of 40 kDa. For larger targets, extensive deuteration and the use of TROSY pulse sequences can significantly increase this MW limit [25,26], although the high cost associated with extensive deuteration usually limits these applications to lead validation and characterization. Another limitation of receptor-based screening is that cost-effective and efficient labeling can currently only be achieved in bacterial systems. While isotopic labeling in insect cell systems has recently been reported [27], such methods are still in their infancy. Thus, for high MW targets or those that can only be produced in baculovirus or mammalian cells, the ligand-based NMR methods described elsewhere in this volume should be explored.

Utilization of Fragment Leads in Drug Design

Receptor-based NMR screening has been quite successful at its desired objective: the identification of low MW leads that bind to hot spots on protein surfaces and that would be difficult or impossible to detect using any other method. Figure 3 shows the molecular weight and pK_D values for more than 750 NMR leads that we have derived from receptor-based screens against more than 20 protein targets. By intentional library design, the leads are small (average MW of 234 ± 56 Da), and this results in leads that are quite weak (average pK_D of 2.7, which translates to a K_D value of 500 μM). The key question is how to utilize these hits in drug design. Three strategies for utilizing NMR-derived fragments in drug design will be briefly described: (1) core replacement, (2) high-throughput core elaboration, and (3) fragment linking.

Core Replacement

As mentioned above, most leads from HTS interact sub-optimally with the hot spot of the binding site. In contrast, as shown in Figure 1b, fragment-based screening attempts to identify a low molecular weight fragment that takes full advantage of the available binding interactions. One approach to exploiting these fragments is to incorporate the optimized core back into the lead molecule. This strategy is called core replacement and is shown schematically in Figure 1, where the optimized core (Figure 1b) is synthetically incorporated into the lead molecule (Figure 1a) to produce a compound with improved interactions with the target (Figure 1d). This approach can be especially

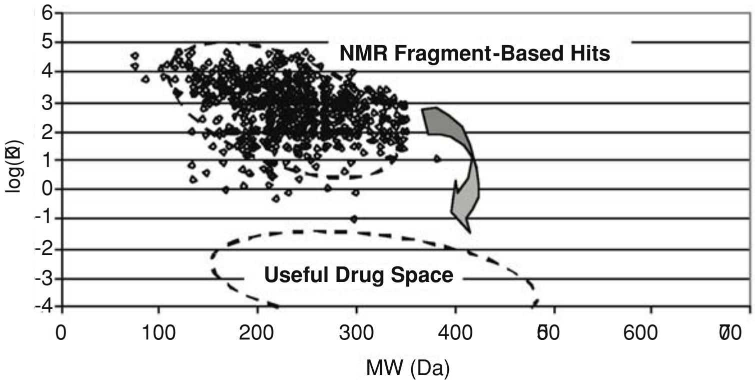

Fig. 3. Plot of molecular weight (in Da) vs. affinity [expressed in terms of log(K_D), where K_D is in μM units] for more than 750 leads derived from receptor-based NMR screens against more than 20 protein targets.

useful in breaking out of existing structural classes to address unanticipated safety, pharmacological, or intellectual property issues.

Core replacement strategies have been effectively used to address non-drug-like properties of several leads (Table 1). For example, reported inhibitors of both the SH2 domain of Lck and protein tyrosine phosphatase 1B (PTP-1B) contain highly charged phosphotyrosine (pTyr) mimetics that can severely limit cellular permeability and oral bioavailability. Receptor-based screening was able to identify singly charged moieties that could serve as superior pTyr replacements for these targets [28,29]. Significantly, in the case of PTP-1B, a class of isoxazole leads were incorporated back into the lead series, resulting in potent compounds that exhibited increased Caco-2 permeability and dose-dependent cellular activity [29]. A core replacement strategy was also implemented in the design of inhibitors of urokinase, in which the highly basic phenylguanidine group was successfully replaced with a more neutral aminobenzimidazole moiety [30].

High-Throughput Core Elaboration

While the leads from NMR-based screening are only of low molecular weight and affinity, they can be viewed as small molecule scaffolds that can be rapidly elaborated through combinatorial chemistry or high-throughput parallel synthesis. While many scaffolds have been utilized in the design of combinatorial libraries [31,32], it is typically unknown whether any scaffold possesses inherent binding affinity for any given target. In this sense, it is significant to note that an NMR-derived lead with a K_D value of only 1 mM represents more than 4 kcal/mol of binding energy. Thus, such leads are ideal for use in target-directed library design. The design of such libraries is

Table 1: Published examples of receptor-based fragment approaches in the design of novel drug leads

Target	Fragment approach	Result	References
Lck-SH2	Core replacement	Novel pTyr mimetics	[28]
UK	Core replacement	Novel, sub-μM inhibitors	[30]
PTP-1B	Core replacement	Novel, cell permeable inhibitors	[29]
Erm-AM	Core elaboration	Novel, μM inhibitors	[34]
PTP-1B	Core elaboration	Novel, selective, nM inhibitors	[35]
Oxidoreductases	Core elaboration	Novel, selective, nM inhibitors	[36]
FKBP	Linked fragment	Novel, nM ligands	[39]
Stromelysin	Linked fragment	Novel, nM ligands	[40]
Stromelysin	Linked fragment	Improved bioavailability	[41]
AK	Linked fragment	Structural diversity	[42]
LFA	Linked fragment	Improved solubility	[43]
PTP-1B	Linked fragment	Novel, nM inhibitors	[44]
DHPR	Linked fragment	Novel, nM inhibitors	[36]
HCV protease	Linked fragment	Non-peptidic, μM inhibitors	[50]

significantly enhanced when structural information on the protein–ligand complex can be obtained either from NMR or X-ray crystallography. The process of core elaboration is shown schematically in Figure 1, where the optimized fragment lead (Figure 1B) is synthetically modified to produce libraries of compounds in the expectation of accessing a neighboring pocket to increase both binding affinity and target specificity. A wide range of chemistries is available for the elaboration of suitable scaffolds. In particular, polymer assisted solution phase (PASP) synthesis is rapidly emerging as a method of choice for library preparation via parallel synthesis [33].

High-throughput core elaboration has been effectively utilized in the design of targeted libraries for ErmAM [34], PTP-1B [35], and various oxidoreductases (Table 1) [36]. In the case of ErmAM, a millimolar lead derived from receptor-based screening was rapidly elaborated at multiple positions, resulting in a more than 200-fold gain in potency [34]. For PTP-1B, a library of 76 compounds was prepared around an NMR-based lead resulting in compounds with K_I values <100 nM—representing a 30-fold gain over the parent compound [35]. Most significantly, members of this library exhibited moderate selectivity over highly homologous phosphatases, suggesting that such selectivity could be achieved with a small molecule inhibitor. NMR-SOLVE [37] was implemented to target the oxidoreductase family by first identifying a low molecular weight ligand that inhibited multiple members of the family, and then rapidly elaborating this core to increase affinity and specificity. From a library of 300 compounds, nM inhibitors of three oxidoreductases (LDH, DHPR, and DOXPR) were identified. Significantly, while the initial core was essentially non-selective with respect to these oxidoreductases, the resulting inhibitors exhibited 10- to 100-fold selectivity.

Fragment Linking

By far the most powerful utilization of fragment-based screening in drug design is the linked fragment approach. As depicted in Figure 1, a linked fragment strategy involves identifying not simply one (Figure 1B) but two fragments that bind simultaneously to the protein at neighboring sites (Figure 1C). The two fragments are then linked together (maintaining their spatial geometry) to produce high-affinity, highly optimized leads (Figure 1F). One of the most significant advantages of the linked fragment approach is that the amount of chemical space that is sampled increases exponentially with the size of the fragment library [38]. For instance, an NMR screen in which 10,000 compounds are tested for independent binding to two subsites on a protein covers as much chemical space as screening ~100 million single compounds. The linked fragment strategy has been utilized in two related approaches: (1) the *de novo* construction of high-affinity ligands and (2) the optimization of existing leads by identification of new substituents. The construction of high-affinity ligands from pieces that have been identified via NMR has been described for FKBP [39], stromelysin [40,41], adenosine kinase [42], LFA [43], PTP-1B [44], and DHPR [36]. In all of these cases, screens were performed to identify ligands for peripheral sites that bound simultaneously with a first-site ligand, and nM ligands were produced after linking. The strategies for *de novo* construction vs. lead optimization differ only in the sense of the desired end: generation of a novel structural series vs. improved physicochemical properties of an existing series.

Receptor-Based Methods for Lead Validation and Characterization

In addition to their use as screening tools, receptor-based NMR Methods are being increasingly utilized as lead validation tools. Often, HTS yields tens or even hundreds of compounds that modulate the biochemical response with apparent IC_{50} values on the order of 10 μM or less. As many assays utilized by HTS can be complex, multi-component systems, some number of the hits will actually disrupt or inhibit an assay component other than the target of interest. In addition, false positives can result from the method of detection (e.g. interference from fluorescent or colored compounds), or mechanisms such as non-specific binding, compound aggregation [23], or compound reactivity [45]. Thus, it is extremely valuable to identify false positives as early as possible in the hit evaluation process in order to focus resources on those hits that have the highest potential to become bonafide leads.

Typically, complex, target-specific secondary assays are used to eliminate false positives from the original primary screening hits. However, NMR is a universal tool that has been successfully applied in the evaluation of leads from a variety of screening formats, including activity assays, ligand competition assays, whole-cell screens, affinity-based screens, and virtual ligand screening (VLS) [4,46,47]. It has also been demonstrated that, using specific labeling strategies, multiple protein targets can be simultaneously evaluated for binding to test compounds—opening the door for monitoring compound selectivity in a single experiment [48]. Table 2 shows results on published targets for which NMR follow-up of HTS or VLS hits was employed. In all of the cases listed, ligands were confirmed that could be prioritized for further follow-up. However, the majority of compounds derived even from HTS or affinity-based screens did not form a stable complex with the target of interest. In fact, it is our experience that, on average, <20%

Table 2: Examples of receptor-based NMR methods for the validation of leads derived from HTS, affinity screening, and virtual ligand screening campaigns

Target	Discovery technology	No. of hits tested	No. of hits confirmed	Ultimate result	References
LFA	HTS	2	2	Clinical candidate	[43]
Bcl-xL	HTS/affinity	55	23	Novel structural series	[53]
MurF	Affinity	11	2	Novel, nM lead series	[51]
RGS4	Affinity	50	1	Validated lead series	[46]
FBP	VLS	100	1	Novel structural series	[54]
IGFPB-1	VLS	3	1	Novel structural series	[52]
DNA gyrase	VLS	14	7	Novel structural series	[20]

of all leads from HTS campaigns are suitable for further evaluation [4]. Thus, a combination of the inherent strengths of both HTS and NMR represents a powerful strategy for the identification of lead compounds that bind with high affinity to and specificity for the protein target. Such compounds have high potential for further optimization through medicinal chemistry and/or structure-based design approaches.

Summary

In summary, receptor-based NMR methods for fragment lead identification have been used in a number of design strategies. Significantly, these design strategies can be used throughout the entire course of pre-clinical drug discovery—including initial lead identification, potency optimization, and even modulation of physicochemical properties to aid in candidate selection. Even more significant, however, is the fact that compounds from several programs employing receptor-based NMR screening and fragment design have already gone beyond the pre-clinical setting into the clinic (e.g. matrix metalloproteinase inhibitors [49] and inhibitors of the LFA–ICAM interaction [43]). This is ample validation that the methods described in this review can be used to produce ligands not only with high affinity, but also with the appropriate drug-like properties for use in therapeutic intervention in man.

NMR SHAPES Screening

Christopher A. Lepre and Jonathan M. Moore
Vertex Pharmaceuticals, Inc., Cambridge, MA 02139-4242, UK

Introduction

The SHAPES strategy is a process that employs nuclear magnetic resonance (NMR) spectroscopy to screen small, drug-like molecules in a directed search for novel (or improved) medicinal chemistry leads. This strategy typically integrates NMR screening experiments with other enabling methods in drug discovery such as enzymatic assays, high-throughput screening (HTS), X-ray crystallography, molecular modeling, and combinatorial chemistry. There are three components of any NMR-based lead discovery strategy: (1) a carefully selected library of screening compounds, (2) a NMR screening method that is well-suited to the target of interest, and (3) effective use of the information obtained through screening to generate or optimize drug leads for that target. Each of these aspects will be discussed in this chapter to provide an overview of how NMR SHAPES screening may be used in drug discovery. For additional reading, we have recently published more detailed treatments of each of these components, i.e. NMR screening library design [1,2], experimental approaches [3–5], and examples of SHAPES applications [6,7].

Principles of SHAPES Screening

The SHAPES screening strategy was developed based on two assumptions. The first assumption is that information about molecules that bind to a target with relatively low affinities may be used to direct the design of more potent inhibitors of that target. Any biophysical method that is capable of detecting weak interactions between ligands and macromolecules can be used, however, NMR methods are particularly well suited for this purpose. In many cases, NMR methods are capable of identifying inhibitors of a target that are beyond the limits of detection by traditional enzyme assays. The second assumption inherent in the SHAPES strategy is that compounds containing molecular fragments found in successful drugs are more likely to possess desirable, drug-like properties (such as good oral bioavailability, low toxicity, metabolic stability, and good synthetic accessibility) than random molecules. Thus, the SHAPES method uses simple NMR techniques to detect binding of a relatively small but diverse library of low molecular weight, soluble compounds to a drug target. The resulting SHAPES screening hits are then used to guide molecular modeling efforts, synthesize combinatorial libraries, and bias the choice of compounds selected to undergo high throughput enzymatic screening (Figure 1). Integration of the SHAPES strategy with iterative ligand structure determination has proven to be very useful for deriving pharmacophore models and rapidly achieving dramatic improvements in inhibitor potency with minimal synthetic effort.

Design of the SHAPES Compound Library

The design of an NMR screening library based on molecules derived from known drugs evolved from a modeling study carried out at Vertex Pharmaceuticals [8]. In this study, 5120 drugs covering a spectrum of therapeutic indications were selected from the Comprehensive Medicinal Chemistry database and computationally reduced to graph frameworks (i.e. unadorned rings and linkers). The authors found that only 32 simple frameworks described approximately half of the drugs in the database. When atom type and bond order were included in the analysis, only 41 "complex" frameworks, or scaffolds, described about a quarter of the known drugs. These findings implied that a relatively small number of molecular "shapes" could be used in a screening library for a wide variety of therapeutic targets.

Although many of the factors responsible for the failure of clinical candidates are not well understood, it was believed that commonly recurring drug scaffolds are predisposed to having favorable clinical properties. Therefore, the original SHAPES library was built with compounds containing the most common scaffolds found in known drugs, combined with commonly occurring drug side chains (identified in a later study [9] (Figure 2). Subsequently, the library has been expanded to incorporate drug-like and "lead-like" [10] compounds that contain linkages amenable to combinatorial chemistry, are targeted against targets from a particular gene family, or exhibit diverse pharmacophores [1,2].

The SHAPES library has been designed to satisfy stringent criteria for compound solubility, drug-likeness (or lead-likeness), and synthetic accessibility. Details of the compound selection process and overall library design have been described previously [1,2]. More generally, starting from a database of over 1 million commercially

available compounds, computational filters were applied to remove compounds predicted to have poor solubilities or other physicochemical properties (using "Rule of 5" [11] and other criteria [1]), as well as to eliminate compounds possessing undesirable functional groups [12]. Candidates surviving the filtering process were then clustered using the Jarvis–Patrick method [13], and individual compounds were picked manually from the centroids of the clusters. Mixtures of compounds were then chosen with NMR considerations in mind, i.e. to minimize NMR resonance overlap and avoid interactions between the components. Prior to screening, the mixtures were checked for aggregation by recording 2D NOESY experiments.

NMR Methods for Screening Compound Libraries

Because the molecules in the SHAPES screening library are typically small (<350 MW) and unelaborated, they are expected to have lower average affinities than most compounds screened by HTS. To enable the broadest possible range of affinities for detection, we use well-known NMR-based methods capable of identifying molecules that bind with dissociation constants ranging from low micromolar (and lower for some methods [14,15]) to millimolar in a single experiment.

We have recently reviewed and compared these methods in detail [4,5]. Although protein-based detection methods [16,17] are very useful for mapping the binding sites of hits on protein targets, ligand-detected methods for primary screening consume less reagents, do not require isotopic labeling, and may be used for many types of targets with no limit to molecular mass.

Many approaches have been proposed that monitor differences in ligand NMR parameters in the free vs. bound states. These approaches have used transverse relaxation rates, selective longitudinal relaxation rates, exchange-transferred NOE, and translation diffusion coefficients as probes of interactions between small molecules and a macromolecular target. In these experiments, a small molecule binder will transiently assume the much slower rotational and translational mobility of the much larger receptor, exhibiting changes in the aforementioned relaxation and diffusion parameters.

A second class of experiments does not rely on differences between ligand free and bound state parameters, but rather takes advantage of ^{1}H magnetization transfer from the target to the ligand. These experiments have distinct advantages, because binders to the target experience the magnetization transfer, while non-binders do not. This phenomenon results in significant simplification of spectra and identification and deconvolution of hits. The two most commonly used of this latter class of experiments are the Saturation Transfer Difference (STD) [18] and WaterLOGSY [19,20] methods. In the STD experiment, the target is saturated via a train of radiofrequency pulses. Upon saturation, spin diffusion occurs throughout the protein matrix to the binding site, and is transferred to ligands during the ligand residence time. WaterLOGSY relies similarly on initial saturation of the receptor, however the mechanism for saturation differs, in that either saturation or inversion of solvent water molecules is the initial step, followed by transfer of that magnetization to sites on the target via multiple pathways, and subsequently to the binding ligand. A more rigorous physical treatment of magnetization transfer processes in both the STD and WaterLOGSY classes of experiments may be found elsewhere [5].

Our preferred method for detection of ligand binding to protein targets is saturation transfer difference spectroscopy [18], which offers high sensitivity, low

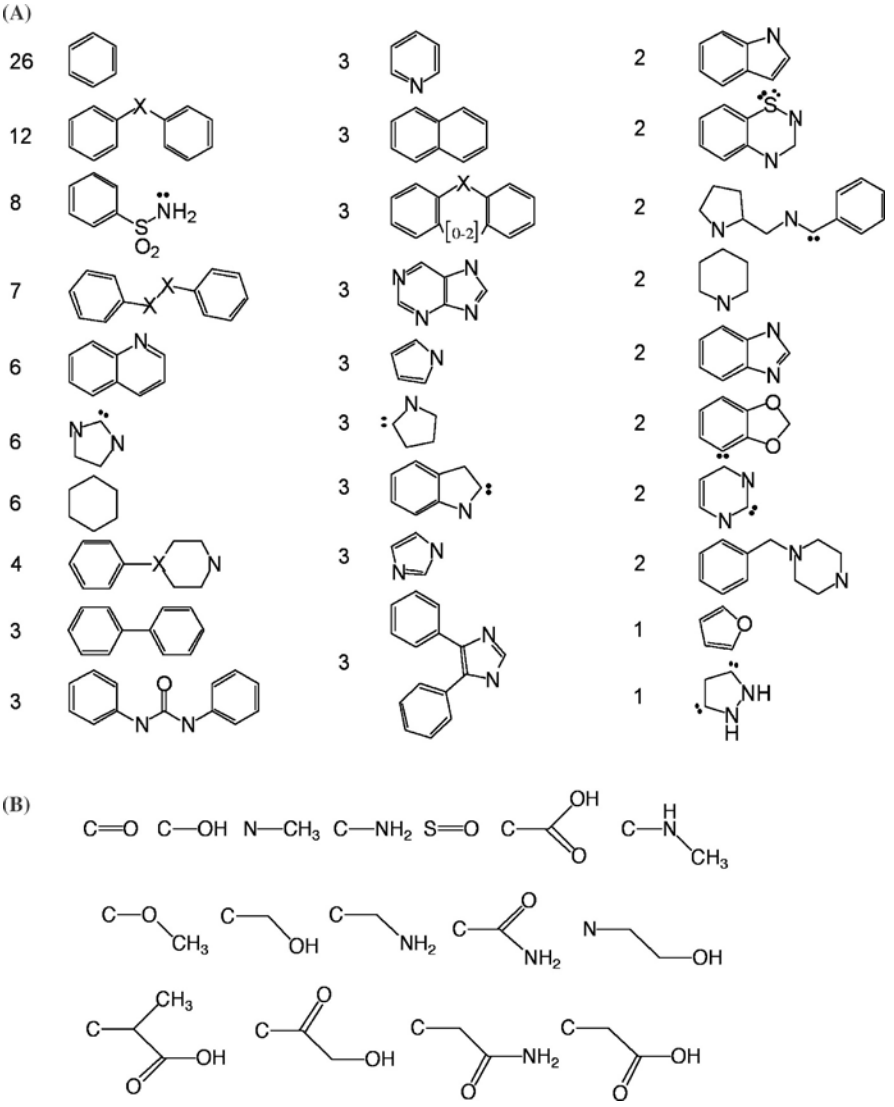

Fig. 2. (A) Molecular frameworks used in the SHAPES library. The numbers denote the frequency of occurrence of each framework. Side chain positions are indicated by lone pairs. "X" denotes a C, N, O, or S atom. Frameworks representing less common classes of drug scaffolds are not shown. (B) Common drug side chains used in the SHAPES library. The left-most atom indicates the point of attachment to the framework. *Source:* Reproduced with permission from ref. [3].

protein consumption, and the ability to tune the detection range of the experiment [3,5]. SHAPES screening hits are validated by detection of inhibition (e.g. by enzymatic assay), competition with a known inhibitor (e.g. by NMR displacement experiment), or localization to the active site (e.g. by NMR chemical shift mapping experiments or crystallographic soaking studies). An example of STD spectra for a mixture of ligands is shown in Figure 3. For nucleic acid targets, WaterLOGSY is the method of choice, as the multiple sites for interaction of water molecules with the nucleic acid molecules compensate for the reduced proton

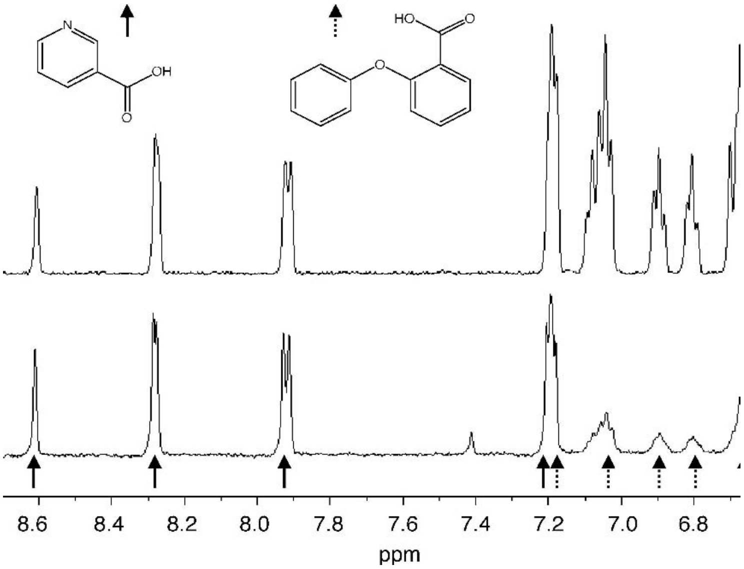

Fig. 3. Comparison of (top) the 1D ^{1}H NMR spectrum of two potential small molecule ligands in the absence of target and (bottom) the STD [18] spectrum of the same mixture in the presence of p38 MAP kinase. Resonances from nicotinic acid and 2-phenoxy benzoic acid are marked with asterisks and diamonds, respectively. Only peaks from the ligand that binds to p38, 2-phenoxybenzoic acid, appear in the STD spectrum. The sample contained 35 μM p38 MAP kinase, 1 mM ligands, 100 mM deutero-Tris, 10% deutero-glycerol, 20 mM deutero-DTT at pD* = 8.4. Experiments were carried out at 278 K. The 1D spectrum was collected using a standard NOESY pulse sequence with 16K data points, 128 transients and a relaxation delay of 3 s. 2K data points were collected with 256 transients each for the on and off resonance spectra. Internal subtraction was achieved via phase cycling. On resonance irradiation was at $\delta = 0.74$ and off-resonance at $\delta = -20$ ppm. A pulse train of 60 Gaussian selective pulses of 50 ms duration separated by a 1 ms delay was used to saturate the protein. *Source:* Reproduced with permission from ref. [3].

density in this class of macromolecule vs. protein targets [6,21].

Implementation of SHAPES Screening

SHAPES screening has been implemented at Vertex at several stages of drug discovery projects: very early in the life cycle, before a conventional enzymatic screen is run to find leads (pre-HTS); in the mid-life of a discovery project, in the event that HTS has not produced viable leads (post-HTS); and late in a project, when mature leads are undergoing final optimization to become preclinical candidates (lead optimization). Effective use of information from SHAPES screens is essential for successful implementation of the method. SHAPES hits are followed up using one or more of three strategies [2,5]: (1) primary hits are combined or linked together into larger, more potent molecules; (2) the scaffolds from primary hits are systematically elaborated by adding functional groups to make more complex molecules; and (3) portions of primary hits or a lead molecule are systematically varied. We present here examples that illustrate these three follow-up strategies applied to each of the three principal implementations of the SHAPES method.

Pre-HTS Screening

SHAPES screening is most commonly applied at the pre-HTS stage of a project, when a new protein first becomes available and the HTS screen is still under development. Because NMR screening requires no assay development and only a few milligrams of protein, it is possible to find SHAPES hits, then purchase analogs or synthesize a combinatorial library around these hits quickly enough to be included in an initial HTS run, thereby enriching the HTS library with scaffolds known to bind to the protein.

Validated hits from pre-HTS SHAPES screens are most often followed up by purchasing more elaborate analogs, as has been described elsewhere [1,7]. Retrospective analysis of HTS screening results has shown that compounds containing SHAPES scaffolds (those shown to bind by NMR) typically have hit rates about tenfold higher than general screening compounds that do not contain those scaffolds [6]. Higher enhancements are possible by designing combinatorial libraries around SHAPES scaffolds. For example, SHAPES screening of regulatory erythroid kinase (REDK) identified a novel class of ATP-competitive inhibitors with IC50s of 100–200 μM. A 64 compound combinatorial library was synthesized around this scaffold, 14 of which (22%) had IC50s better than 5 μM (including several that were sub-micromolar) when subsequently included in the HTS screen. This small, focused combinatorial follow-up library thus improved upon the potency of the primary SHAPES hits by two orders of magnitude and enhanced the HTS hit rate by around 170-fold. The observation of such enhancements validates the assumption that binding information from compounds with weak affinities can lead to discovery of significantly (e.g. several orders of magnitude) more potent inhibitors.

SHAPES screening has also been applied to targets for which high throughput enzymatic assays are unavailable, and can identify reagents for use in developing such assays. These targets include RNA [6,21] and non-enzymatic proteins, such as molecular transport proteins and receptors. For example, SHAPES screening was used as a primary screen to find leads for human adipocyte lipid binding protein (ALBP), a putative therapeutic target for treating type II diabetes [22–26] for which a HTS assay was unavailable. Using a prototype 100-compound SHAPES library, thirteen ligands were found with affinities ranging from 0.3 μM to 800 μM. A fluorimetric assay and chemical shift (^{1}H and ^{15}N) perturbation studies confirmed that these ligands bind in the lipid-binding pocket. Several fluorescent analogs of the SHAPES hits bound avidly in the ALBP lipid-binding pocket, including 1-anilinonapthlalene-8-sulfonic acid (1,8-ANS), which exhibits an apparent dissociation constant of 0.4 μM. These analogs were later used to develop a high-throughput fluorescence-based competition assay.

In order to identify more potent binders, two primary SHAPES hits were soaked into crystals of apo-ALBP and the structures of the complexes solved by crystallography. This structural information, along with molecular models of other hits, was used to identify likely protein interaction sites. Twelve commercially available analogs were screened in order to explore variations at positions predicted to make favorable protein contacts. All of the analogs inhibited lipid binding to ALBP and the bound structures of several were subsequently determined by crystallography. This information was used to design a second-generation follow-up library of 134 commercially available compounds that was calorimetrically screened, yielding nine leads with sub-micromolar affinities, including a compound class with Kd values of 80–100 nM.

Fatty acid binding proteins, unlike most enzymes, have considerable space in the lipid binding pocket that can accomodate a variety of fatty acid substrates as well as bound water molecules. Understanding the binding modes of different ligands by solving multiple crystal structures allows one to derive a pharmocophore model describing key interactions in the binding pocket that may be accessed to achieve higher affinity and selectivity. A pharmacophore model for ALBP based on eight different crystal structures is shown in Figure 4.

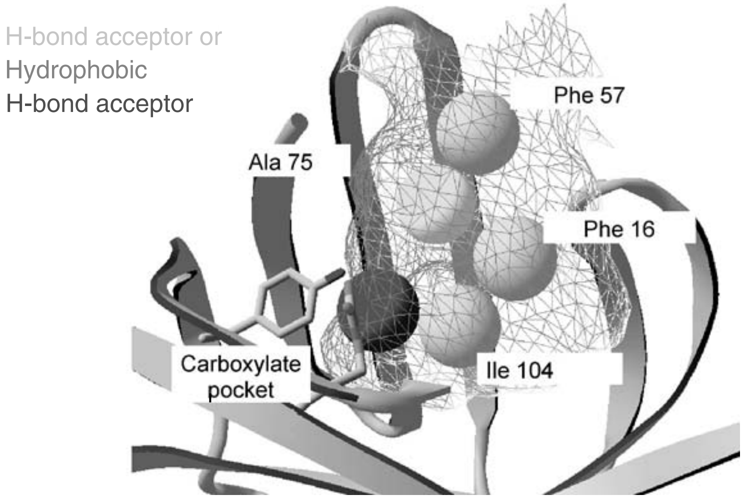

Fig. 4. Pharmacophore model for ALBP derived from ligand binding and crystallographic studies. (See also Plate 110 on page XXIV in the Color Plate Section.)

This example demonstrates that by combining NMR-based screening, computational methods, and X-ray crystallography, it is possible to rapidly converge upon multiple sub-micromolar lead classes (in this case, by testing only ~250 compounds), using modest resources and without requiring chemical synthesis or a HTS assay. The information derived from this work serves as an excellent starting point for a structure-based drug design program for this unique class of drug target.

Post-HTS Screening

We have also applied SHAPES screening to targets for which conventional HTS and medicinal chemistry have failed to produce viable leads. For example, the c-Jun N-terminal kinase Jnk3, a potential target for the treatment of stroke and Parkinson's disease [27,28], was one of the first targets screened by the SHAPES method, after extensive medicinal chemistry efforts to adequately improve the potency of the HTS hits. NMR screening of a 100 compound prototype SHAPES library yielded 17 hits with very weak (approximately millimolar) affinities, 13 of which were confirmed to target the ATP site [7].

Attempts to soak the SHAPES hits into crystals of apo-Jnk3 for crystallographic studies were unsuccessful (presumably due to their low affinity). In the absence of structural information about the bound hits, two approaches were taken to design follow-up libraries. First, approximately 200 analogs containing combinations of binding fragments were chosen by using substructure-matching and similarity based searches of a database of commercially available compounds.

Second, compounds were selected using a virtual screening procedure. The SHAPES screening hits were computationally docked into the ATP site of the crystal structure, and four produced distinct, energetically reasonable bound orientations. A substructure search for commercially available analogs was then carried out using the four preferred molecules, followed by filtering for drug-like character [12], to give a starting set of 1647 compounds. These candidates were then docked into the ATP site and the best 171 conformers from the consensus of four scoring functions [29] were then manually reduced to 94 top picks.

These procedures selected approximately 300 compounds that were then screened in an enzymatic assay, yielding 8 inhibitors with potency better than 20 μM, a hit rate tenfold higher than was observed in the original HTS screen of Jnk3 using a random compound library. Interestingly, none of the SHAPES-derived inhibitor classes were found in the original HTS screen of Jnk3, even though compounds containing those scaffolds were present in the random HTS library. The compounds representing those scaffolds in the HTS library are more highly elaborated, which presumably reduces the likelihood of binding. The unelaborated SHAPES scaffolds are more likely to bind, albeit with affinities too weak to detect reliably by enzymatic methods. These results support the idea that NMR screens of weakly binding scaffolds can be used to direct HTS to novel classes of compounds that might otherwise be missed.

The SHAPES leads were followed up by medicinal chemistry after efforts to develop the leads from the original HTS screen were unsuccessful. Several hundred compounds were prepared (mostly in combinatorial libraries) based on four SHAPES-derived leads, producing three sub-micromolar classes of compounds, shown in Figure 5. X-ray structures of examples from each class of compounds complexed to Jnk3 suggested routes for improving the potency of these inhibitors. By incorporating substituents to access all available binding pockets in the active site, a number of compounds were synthesized which were able to inhibit Jnk3 activity with potencies better than 10 nM.

Lead Optimization

NMR screening of molecular fragments has been used by other laboratories to selectively optimize portions of existing lead molecules for the purpose of improving potency, novelty, or ADME properties [30,31]. A recent example from our own laboratory combines virtual screening and NMR screening to selectively optimize a portion of an ATP site inhibitor of a protein kinase involved in inflammation. The original lead molecule consisted of three fragments (depicted schematically in Figure 6): a central scaffold, a group that hydrogen-bonds to the protein backbone of the inter-domain hinge and a group that forms an unusual salt bridge with nearby charged side chains. The latter group was of particular interest because optimizing this novel interaction offered a potential means to improve the selectivity for this kinase vs. other kinases.

An NMR screening library of fragments targeting the salt bridging site was selected using virtual screening. The ATP-site conformation derived from the crystal structure of the lead compound bound to an analogous kinase was used as a template for computationally docking 20,000 small, commercially available compounds, which were pre-selected for their putative salt bridging ability. Twenty-four compounds were then manually chosen from the best-scoring 0.8% of docked compounds; these were purchased and screened by NMR. Fourteen of these compounds (58%) bound to the kinase with potencies in the millimolar range. The hit rate with this virtual screening-derived library was approximately fivefold higher than that measured for a comparable NMR screen that used the diverse SHAPES library. The binding site of the NMR hits was determined by using a double

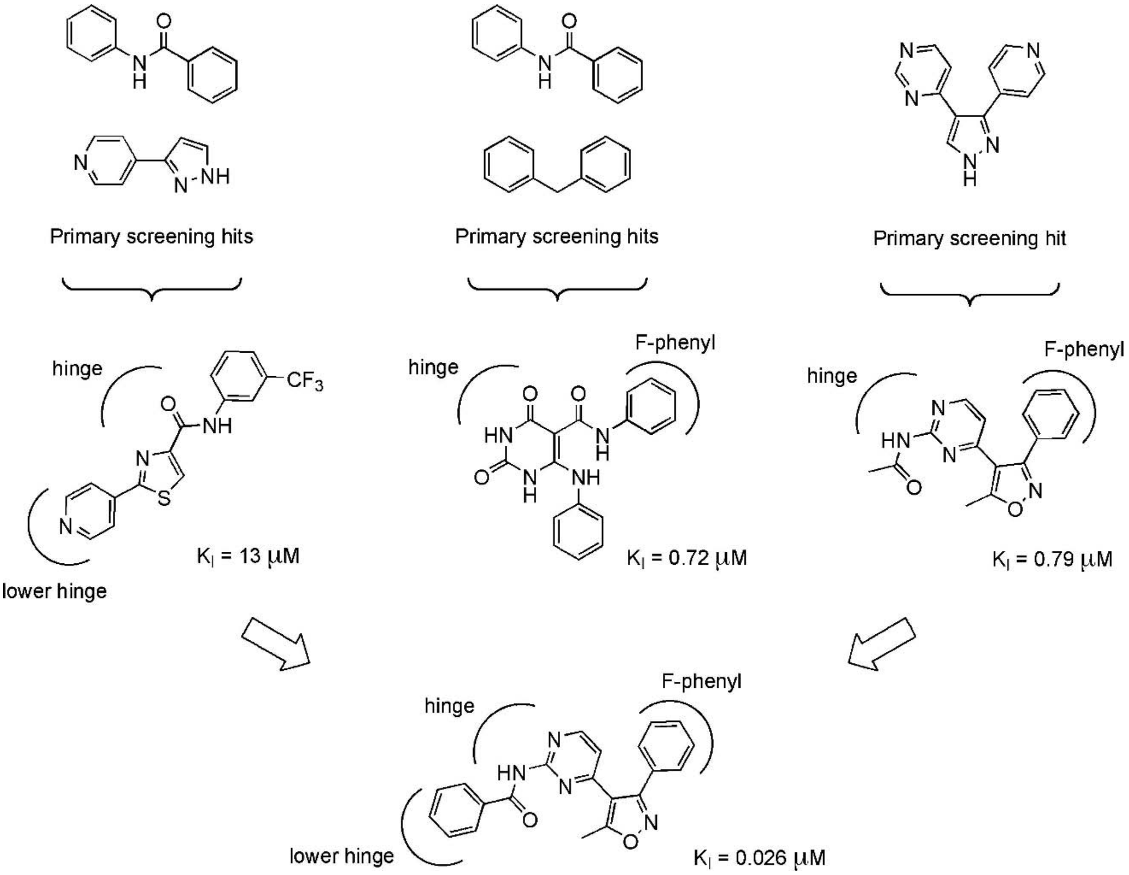

Fig. 5. Evolution of Jnk-3 SHAPES screening hits into potent leads. The SHAPES hits (top row) were followed up by screening commercially available compounds containing random combinations (left and center columns) and variations (right column) of scaffolds found in the primary hits. Crystal structures of the three lead classes (center row) revealed three ATP site subsites (hinge, fluorophenyl pocket, and lower hinge pocket) that were occupied by functional groups on the lead molecules. Each lead molecule contacts two of the three subsites, leading to synthesis of a third generation molecule (bottom row) that contacts all three. *Source*: Reprinted with permission form ref. [5].

knockoff filter (Figure 6), a two-step competition binding experiment that first uses a moderate-affinity inhibitor that binds only to the core and hinge sites, followed by a high-affinity inhibitor that binds to all three sites. Ten of the 14 hits (71%) behaved as expected in the double knockoff filter, indicating that they bound at the salt bridge site.

This example demonstrates that the combination of virtual and NMR screening can be used not only to enrich a library with active compounds, but also to preferentially discover compounds that bind to a desired site. Intermolecular NOEs or chemical shift perturbation data can then be used to determine the relative proximity and orientation of the bound fragments, enabling the design of more potent linked compounds. In this manner, thousands of putative replacement fragments can be efficiently screened prior to carrying out chemical synthesis.

Conclusion

NMR SHAPES screening can be an extremely useful tool for the identification of drug leads. Even in the absence of HTS hits, the SHAPES screening process is capable of identifying chemically accessible, drug-like fragments that can be rapidly translated into potent lead compounds. As illustrated in the examples, the unique ligand-binding data derived from NMR SHAPES screening and subsequent integration with other enabling technologies (such

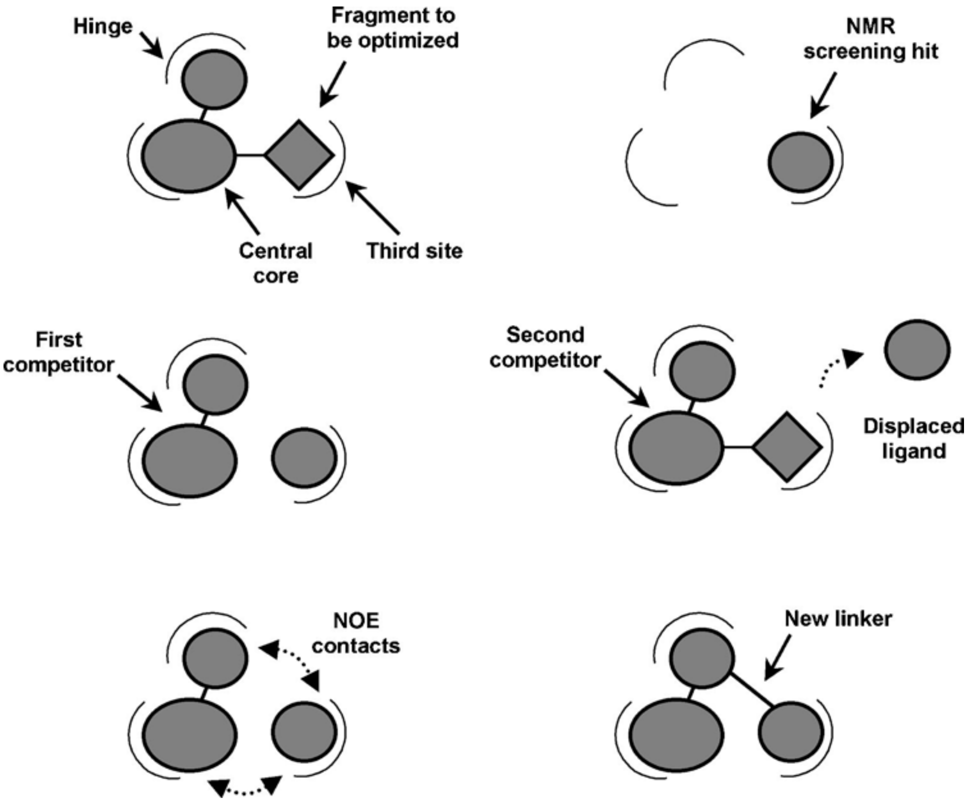

Fig. 6. Fragment optimization process. The original lead molecule (top left) consists of a hinge-binding motif, central scaffold, and a functional group (diamond) to be optimized in the third subsite. A library of fragments is selected by virtual screening and the binding fragments are identified by NMR screening (top right). The binding site of a NMR screening hit with low (e.g. millimolar) affinity is determined using a double knockoff competition experiment. The binding (or displacement) of the NMR hit at each step is measured using the same NMR method as was used for the screen. First, the sample is spiked with a moderate (e.g. micromolar) affinity competitor compound that occupies only the hinge and central sites (center left); if the NMR hit is in the third site it will not be displaced. The sample is then spiked (center right) with a second competitor compound (i.e. the original lead molecule) that occupies all three sites and has an affinity, high enough (nanomolar) to displace the first competitor; if the NMR hit is in the third s site it will be displaced as well. A new, higher concentration sample containing the first competitor and the NMR is then used to determine the relative orientations of the two bound molecules by means of intermolecular NOEs (lower left). Using this information, a linked compound is designed, possibly even incorporating a novel linkage site (lower right).

as X-ray crystallography, computational chemistry, and other biochemical and biophysical techniques) can greatly accelerate the discovery of lead molecules, as well as aid in optimization of existing leads.

NMR-Based Screening Applied to Drug Discovery Targets

Jennifer J. Gesell, Mark A. McCoy, Mary M. Senior, Yu-Sen Wang, and Daniel F. Wyss
Schering-Plough Research Institute, Department of Structural Chemistry, Kenilworth, NJ 07033, USA

Abstract

While conventional bioassay-based high-throughput screening (HTS) remains a mainstream approach for lead discovery, its limitations have driven the development of alternative and complementary tools. In this regard, novel NMR-based approaches that have emerged over the last few years show great promise. We have used NMR-based screening approaches for a variety of drug targets to identify low molecular weight (MW) small molecule hits from customized libraries, which subsequently could be optimized into leads through focused, structure-guided chemistry. Focus was placed on targets for which HTS failed to identify suitable leads. This report discusses different NMR-based screening techniques and follow-up strategies for lead discovery and illustrates their application to the NS3 protease and NS3 helicase domains of the hepatitis C virus (HCV).

NMR for Lead Discovery

NMR methods are solidly established for studying molecular interactions [1]. In the last few years various NMR approaches have been developed to aid in lead discovery [2–13]. They involve different NMR screening methods [14–34] to identify initial compounds which often bind only weakly, in the μM–mM range, to the drug target. Intelligent and focused follow-up strategies enable their development into potent, sub-μM inhibitors for use as leads in drug discovery projects [35–46]. An interesting NMR-based biochemical screening method was also recently introduced [47]. NMR-based screening has several advantages over more traditional screening methods which are important for lead discovery: (1) it can reliably detect site-specific ligand binding even for compounds with very weak affinities which are typically missed in HTS (dissociation constants (K_D) up to $\sim 10^{-2}$–10^{-1} M); (2) it is a universal screening technique that unlike bioassays, requires no prior knowledge of a protein's function and therefore, does not require the development of specific assays for each target; (3) it allows the concomitant determination of K_D (or K_I) values over a large affinity range and thus, provides structure-activity relationship (SAR); information (4) it can provide crucial structural information for both the target and the ligand with atomic resolution for the subsequent optimization of weak initial hits into strongly binding lead candidates; (5) it can report on the quality of either the target or the ligand during the NMR screen which reduces the rate of false positives; (6) it is less prone to false positives due to trace contaminants; (7) the final lead does not need to be present in the initial screening library and because affinity is built up progressively, it is derived from a large virtual library. Despite these advantages, once higher affinity ligands are produced, it is always prudent to verify that they show the desired activity in a functional bioassay. Although NMR screening is, in principle, slower than conventional HTS, it can provide good, reliable starting points for focused chemistry to produce leads.

NMR-Based Screening Techniques

Many NMR observables can be used to monitor small molecule-protein interactions as a consequence of either global effects or local effects which occur upon complex formation [6,7,20]. Because the small molecule ligand adopts motional properties in the bound state that are similar to those of the drug target (slow motion), but very different from those in its unbound state (fast motion), observation of ligand binding based on global effects is restricted to the small molecule ligand where the effects are most pronounced. On the other hand, local NMR effects of complex formation such as intermolecular magnetization transfer or chemical shift perturbations (CSP) may be observed on the protein target and/or the small molecule ligand. In addition, structural information may be available as effects are mostly localized at the intermolecular binding sites.

NMR methods for detecting ligand-binding fall into two main categories that are based on whether signals from the protein target or the ligand are monitored (see also the reports by P.J. Hajduk and J.M. Moore in this volume). Methods within each category have inherent limitations, such as sample availability, solubility, stability, and molecular size, which dictate the choice of the NMR

screening approach taken to discover hits for a particular drug target.

Target-Detected 2D Heteronuclear NMR-Based Screening

We have used 2D heteronuclear NMR-based screening, in which the protein target is isotopically labeled with ^{15}N or ^{13}C, to assist lead discovery in several programs. HSQC-based screening detects ligand-binding based on chemical shift changes of protein signals which occur near the ligand-binding site. HSQC-based screening is simple (a single tube experiment with only the target and compound), robust (isotopic editing ensures that only the protein target is observed), and information-rich. The NMR correlation spectra not only give detailed information about whether the compound binds, with virtually no limit on the K_D value, but also yield a distinct pattern of CSP that serves as a fingerprint for binding to a specific region of the protein target. Thus, compounds that bind at the active site can be readily distinguished from those that bind outside the active site, or that, for one reason or another, do not bind to the target of interest at all. If CSP of the protein target are analyzed in a more quantitative manner, often the exact ligand-binding site can be determined rapidly [7,48]. In addition, the detailed binding orientation of the ligand with respect to the protein surface may be available, especially if good quality CSP data of closely related ligands are available [7,49] (Figure 1 and see below).

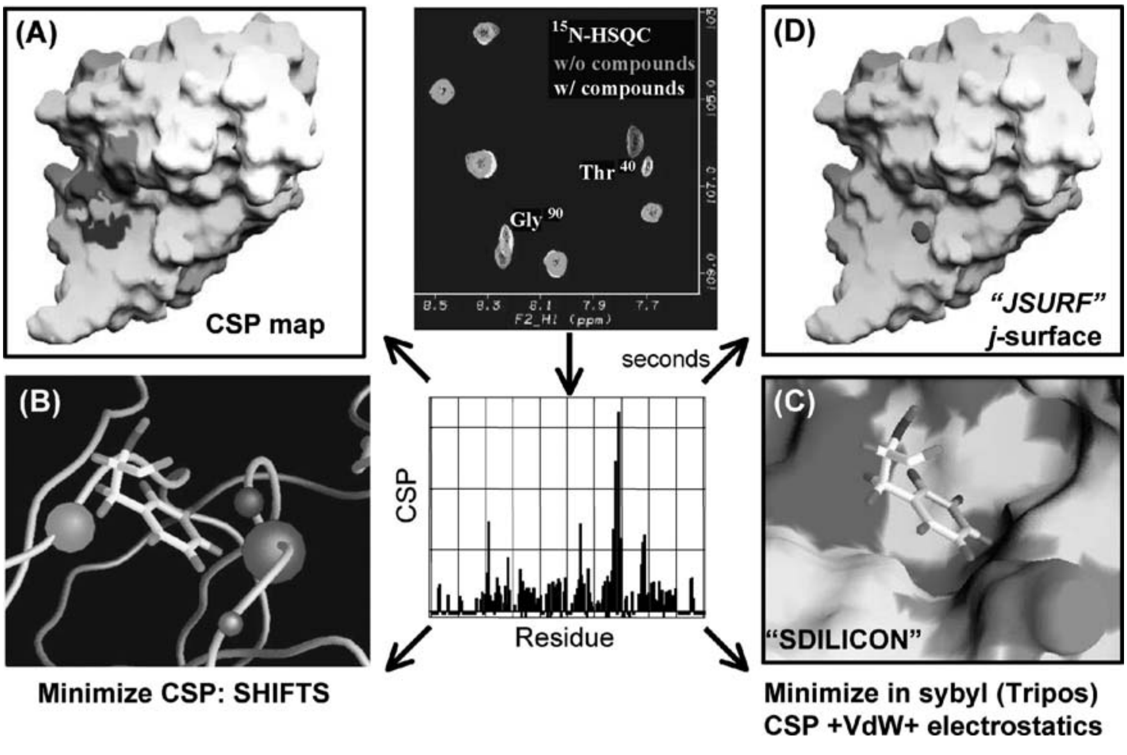

Fig. 1. New tools to determine structures of protein-small molecule ligand complexes using NMR chemical shift perturbation. (A) A CSP map is used to approximate the interaction site of an aromatic ligand binding to the HCV NS3 protease domain [7]. This map was created by coloring protein residues for which significant CSP (center) were observed in ^{15}N-^{1}H HSQC spectra; each color represents a different residue. The resulting map is diffuse; it suggests that the ligand binds the unprimed side of the substrate channel but no particular site is suggested by this data. (B) Ring location and orientation is determined on an atomic level by minimizing the difference between experimental and simulated CSP [49]. (C) Ring location and orientation when energy minimized against van der Waals and CSP [7]. (D) A ligand j-surface (magenta), created from the same data used in Figure 1A localizes the ligand-binding site to the S$_1$-pocket [48]. Recently, these procedures have been implemented into two programs, "SDILICON" and "JSURF" (http://tonga.usip.edu/gmoyna/sdilicon/index.html). (See also Plate 111 on page XXIV in the Color Plate Section.)

HSQC spectra can also reveal if the protein target was folded during the screen or if addition of the compound mixture caused the drug target to aggregate, unfold or precipitate. The verification of the chemical structure of NMR-detected hits by NMR and mass spectrometry and the determination of their aqueous solubility under the screening conditions using NMR, make this type of screen very reliable. Moreover, HSQC-based NMR titrations can be used to determine accurate K_Ds for weakly interacting ligands which are in fast exchange on the NMR time scale between their bound and free states (typically $K_D >\sim 10\mu$M).

However, efficient application of HSQC-based screening requires large amounts of isotope-labeled protein and is typically limited to smaller proteins (MW >~40–60 kDa). This restricts its application to a subset of proteins which do not aggregate at concentrations around 100 μM in an aqueous buffer, and to those that can be overproduced in high isotope-labeled yields (mg/l cell culture). Therefore, several ligand-detected 1D NMR screening methods have emerged over the last few years [7,8,15,17,18,20,30–33] which require no isotope labeling of the target, use significantly less target (micrograms vs. milligrams), and are for proteins of almost any MW.

Ligand-Setected 1D NMR-Based Screening

The saturation transfer difference (STD) [15] and water-ligand observed via gradient spectroscopy (WaterLOGSY) [17,18] experiments are the most sensitive methods in this category. The STD method relies on transfer of saturation to detect ligand binding; only STD signals from compounds in a mixture which directly interact with the drug target are observed. STD NMR is based on the intermolecular transfer of saturation from the protein to the bound small molecule ligands which in turn, by fast chemical exchange between their bound and unbound states, is moved into solution where it is detected. For high-affinity ligands, the saturation cannot effectively be transferred further to the free state of the small molecule ligands due to slow chemical exchange resulting in no observable STD effect, that is, ligand peaks are not observed in the difference spectrum. WaterLOGSY is a related experiment that is based on the transfer of magnetization from bulk water to the protein binding site and onto a bound ligand. The concentrations of both the protein and the compound mixture can be adjusted to adjust the sensitivity of such screens.

Because the ligand-detected methods usually require no isotope labeling of the protein, use less protein (~10–1000× less) than the target-detected approaches, can be applied to protein targets of almost any MW (even perform best for large proteins), and are useful when no 3D structure of the drug target is available, they are widely used in the pharmaceutical industry. However, these methods do not reveal the ligand-binding site on the drug target and any structural information available is limited to the binding epitope of the small molecule ligand. In general, these methods are only for weaker ligands ($K_D \sim 10^{-7}-10^{-3}$ M) and compounds must be soluble in an aqueous buffer solution at concentrations of at least ~50–200 μM, which prevents the detection of ligands with high affinity and/or low solubility. In our experience, these screening methods are less robust and produce more false positives than 2D heteronuclear NMR screening for reasons such as non-specific binding and compound aggregation. However, many of these drawbacks can be overcome by combining ligand-observed NMR screening methods with competition binding experiments [24–28]. Therefore, we recently implemented a competition STD NMR method which can be used to identify ligands that bind to the same site as, for example, a natural substrate, a cofactor or a known inhibitor of a protein drug target [50].

STD NMR in Combination with Competition Experiments

A site-specific affinity marker is used in this experiment which binds weakly to an interesting subsite of the drug target (K_D typically in the tens-to-hundreds of μM range) and produces strong STD signals. Reduction or disappearance of the STD signal of the site-specific affinity marker upon addition of a compound mixture suggests the presence of at least one ligand in the mixture which competes with the marker for binding to the active site (Figure 2A). We have used this approach to screen a kinase-directed library of novel, chemically accessible cores against a variety of kinases. An example is shown in Figure 2B, in which we used ATP as a site-specific affinity marker in competition experiments (c-STD[ATP]). ATP binds this particular kinase with a K_D of ~30 μM and produces an STD signal for the H-2 proton of ATP at 8.30 ppm when 200 μM ATP are added to 5 μM of this kinase target. Addition of a sub-μM ligand which competes for binding to the ATP site completely removes the STD signal of ATP and this high-affinity binder does not produce an STD epitope itself. Addition of a ligand in the μM range still effectively competes with ATP, but now generates an STD epitope due to increased exchange between its bound and unbound states. A weaker binder in the tens of μM range only partially competes with ATP and produces an even stronger STD epitope due to increased exchange. This example illustrates that c-STD[ATP] can be used to (1) rapidly rank-order the affinity of ATP-competitive binders and (2) detect high-affinity ligands which would be missed in the simple STD NMR experiment.

This method can also be used to determine K_I's of high-affinity ligands which are in slow chemical exchange

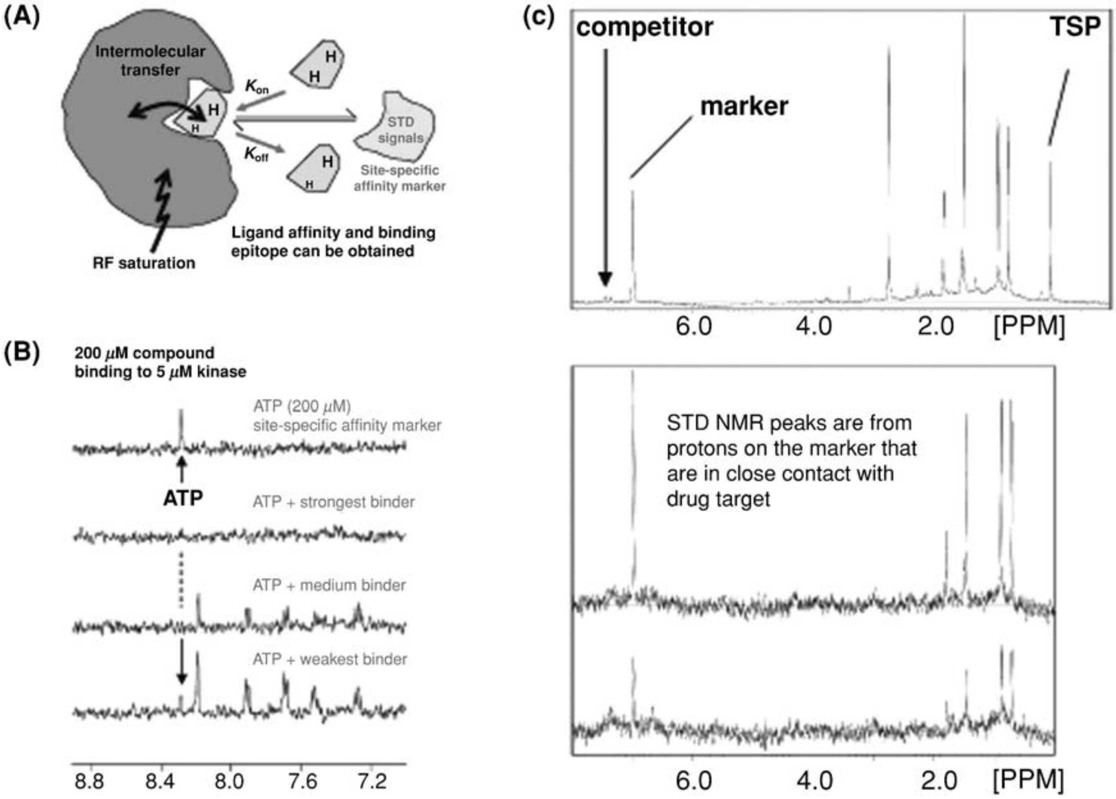

Fig. 2. 1D competition STD NMR [50].(A) A ligand which binds weakly to an interesting subsite of the drug target weakly (K_D typically in the tens-to-hundreds of μM range) and produces strong STD signals is used as a site-specific affinity marker. Reduction or disappearance of the STD signal of the site-specific affinity marker upon addition of a compound mixture suggests the presence of at least one ligand in the mixture which competes with the marker for binding to the same subsite. (B) c-STD[ATP] NMR spectra of a kinase (from top to bottom) in the absence of ligand and in the presence of a strong, medium and weak ATP-competitive binder at a concentration of 200 μM each (see text), illustrating its use to rapidly rank-order the affinity of ATP-competitive binders including high-affinity ligands which do not produce STD signals. (C) K_I's of high-affinity ligands which are in slow chemical exchange on the NMR time scale (K_D typically sub-μM) can also be determined with this method (see text). Addition of 140 μM of an active site-specific affinity marker (K_D[^{15}N-HSQC] = 60 μM) to 5.6 μM kinase produces strong STD signals in a reference spectrum (middle). Addition of 6.1 μM high-affinity inhibitor reduces the STD signals of the site-specific affinity marker (bottom). Based on this reduction and the experimentally determined ligand concentration relative to an internal standard TSP (top) yielded a K_I of 330 nM for the high-affinity ligand.

on the NMR time scale; this cannot be achieved with HSQC-based NMR titration experiments. Recently, we used this method in a drug discovery program to determine the K_I's of sub-μM NMR-derived lead inhibitors. An active site-specific affinity marker with a K_D[^{15}N-HSQC NMR] of 60 μM was used which produced strong STD signals in a reference spectrum (Figure 2C). Addition of small amounts of the high-affinity inhibitor then reduced the STD signals of the site-specific affinity marker. Based on this reduction and the experimentally determined ligand concentration relative to an internal standard (TSP) yielded a K_I of 330 nM for the high-affinity ligand. A second experiment with a different site-specific affinity marker (K_D of 120 μM) gave a similar K_I of 360 nM for the high-affinity ligand (data not shown), which was in good agreement with the IC_{50} of 500 nM from a homogenous time-resolved fluorescence (HTRF)-based enzymatic assay.

NMR–Based Screening Applied to Drug Targets

We have used NMR to assist lead generation in a number of difficult drug discovery programs in which HTS of large chemical libraries identified either no, or only a few, suitable leads for chemical optimization (Table 1) [51]. NMR-based screening (previous section) of customized libraries containing several hundred to several thousand small molecules identified multiple weak hits to active-site regions of these drug targets in the μM–mM range. Some of these initial hits were followed-up through the evaluation of analogs by a combination of NMR, X-ray crystallography and bioassays to derive SAR and 3D structural data. Interesting scaffolds were subsequently either linked, or further optimized by the parallel synthesis of a large number of analogs, or used as templates for structure-based inhibitor design to develop novel lead series against a variety of these targets.

A critical step in these fragment-based methods [2,3,10], which take a modular approach to drug design, is the optimization of weak NMR hits ($K_D \sim \mu$M–mM range) into potent leads ($K_D < \mu$M) using chemistry guided by 3D structural data. However, such information cannot always be obtained easily. We have, therefore, developed novel tools, which utilize protein CSP data, generated in HSQC-based NMR screens, to rapidly provide an accurate structural representation of protein-ligand complexes under conditions unfavorable for traditional structural work using X-ray crystallography and/or solution NMR [48,49]. These tools use the CSP data in a more quantitative manner than the traditional “chemical shift perturbation mapping” widely used to qualitatively map

Table 1: NMR-based screening applied to drug discovery targets

Drug targets	MW (kDa)	# HTS leads	# compounds screened	# NMR hits to active site(s) [affinity range]	# NMR hit-to-lead [affinity/activity range]	# sub-sites	X-ray structure with NMR hit	Chemistry approach [lead activity]
CNS	46	0	10,100 HSQC	10 [30 μM–mM]	6 series [15–100 μM]	3	yes	• structure-based • directed libraries on-going [<0.03 μM]
Cancer	13	0	6750 HSQC	62 [<700 μM]	3 series [1–100μM]	4	no	• link • directed libraries [<0.05 μM]
Cancer	37–40	1	Hundreds (in progress) HSQC/STD	>20 [5–500 μM]	4 series (in progress)	1	One	• Directed libraries on-going [<0.6 μM]
HCV NS3 protease—NS4A	20	0	3639 HSQC	16 [100 μM–10 mM]	5 series [100 μM–mM]	3–5	No	• Directed libraries • Link [0.8 μM]
HCV NS3 helicase	15/30/49	0	6006 HSQC	19 [mM range]	5 series [100 μM–mM]	3	Yes	• Structure-based • Directed libraries [3.0 μM]

Cancer	42	Few	Hundreds (in progress) c-STD [ATP]	>60 [0.4–500 μM]	7 series (in progress)	>2	One	Being initiated
Cancer	48	Few	Hundreds (in progress) c-STD [ATP]	>60 [<0.7–500μM]	Not initiated	>2	No	Not initiated
Anti-infective	41	0	3647 HSQC	13 [~mM]	3 series [50 μM–mM]	3	Yes	Not initiated

molecular interfaces, and hence, they allow rapid determination of the ligand-binding site with much higher precision [7] (Figure 1). By carefully comparing CSP data of closely related analogs, these methods also often enable an unambiguous determination of the binding mode of a small molecule ligand.

The following sections describe our application of target-detected NMR approaches to assist the discovery of leads against the HCV NS3 protease [46] and HCV NS3 helicase [51] domains. Table 1 lists additional programs in which target- or ligand-detected NMR-based screening was used as a primary assay and the chemistry approaches that were applied to develop leads from the NMR-derived hits [51].

NMR-Derived Competitive Non-Peptide Inhibitors of the HCV NS3 Protease

The RNA virus hepatitis C (HCV) has chronically infected an estimated 170 million people worldwide, of whom 10–20% will ultimately develop cirrhosis and 1–5% will develop liver cancer [52]. The HCV NS3 protein is a 631 amino acid residue bifunctional enzyme with a serine protease localized to the N-terminal 180 residues and an RNA helicase located in the C-terminal 451 residues [53], and represents an attractive molecular target for drug development [54]. Both protease and helicase domains retain their *in vitro* activity [55] and structural integrity [56] when expressed separately. Due to the importance of the NS4A cofactor for efficient catalytic activity and structural integrity [57] of the NS3 protease domain, we used a single chain HCV NS3 protease/NS4A complex (ns4a-ns3p) [58] for our NMR-based screens.

From a customized small molecule library, 3639 compounds were screened against uniformly ^{15}N-labeled ns4a-ns3p protein using 2D ^{15}N-^{1}H HSQC NMR identifying sixteen small molecule hits that bound weakly ($K_D \sim$ 100 μM–10 mM) to substrate binding sites of the NS4A-bound HCV NS3 protease. Analogs for five classes of NMR hits were evaluated by a combination of NMR and biochemical data yielding SAR and, in most cases, optimized hits with improved potencies ($K_D \sim K_I \sim 40\ \mu$M–1 mM). However, we were unsuccessful in determining X-ray crystal structures of complexes between the optimized NMR hits and ns4a-ns3p. Therefore, we used NMR CSP data to establish the binding location and orientation of the active site directed scaffolds in these five analog series (Figure 3A). Based upon the NMR-derived binding mode we produced models of linked molecules in which the S2' binding NMR hits were tethered with the S1-S3 binding NMR hits through various linkers.

Two of these scaffolds, which bind the enzyme at the proximal S1-S3 and S2' substrate binding sites, were linked together producing competitive inhibitors of the HCV NS3 protease with potencies in the μM range (Figure 3B). The linked molecule, SCH-414352, and its diester derivative (SCH-414351) showed competitive inhibition with K_I values in the μM range when tested in the biochemical assay. Thus, the linked compounds are approximately 200-fold and 1000-fold more potent than the individual unlinked NMR-derived scaffolds. This shows that much more potent inhibitors against the HCV protease can be obtained by linking weaker NMR hits based on the NMR data, which was first demonstrated by Fesik and co-workers in their pioneering work on stromelysin [35]. Moreover, SCH-414352 showed sufficient solubility in the aqueous NMR buffer for NMR binding studies. The pattern of CSP values observed for the linked compound was consistent with the proposed model. However, the complex between SCH-414352 and ns4a-ns3p was unstable over a period of days to weeks (slow complex precipitation out of solution) precluding attempts to determine its 3D structure by NMR and/or X-ray crystallography. This example illustrates that the low MW scaffolds discovered from NMR-based screening can be optimized with focused structure-guided chemistry to produce potent non-peptidic small molecule inhibitors of the HCV NS3 protease.

NMR-Derived Lead Inhibitors of the HCV NS3 Helicase

The HCV NS3 helicase is an enzyme which unwinds double-stranded RNA in a NTP-dependent fashion. *In vitro* this activity is stimulated by the addition of single-stranded (ss) nucleic acid. Most RNA helicases are grouped into two major superfamilies based on the occurrence of 7–8 conserved motifs which are implicated in the function of the enzyme. Residues in those motifs contribute to either NTP or RNA binding or couple the energy of NTP hydrolysis to dsRNA unwinding activity. These conserved motifs are localized within the two N-terminal subdomains and line the interfaces between the three subdomains of the HCV NS3 helicase domain. To simplify structural work and target-based NMR screening we optimized the 49 kDa HCV NS3 helicase domain as well as truncated protein versions containing subdomains 1 and 2 either linked or separated as individual subdomains [59]. Because the NS4A-bound protease may affect helicase activity [60], we used the bifunctional enzyme in complex with NS4A co-factor peptide in functional assays to test the inhibitory activity of NMR derived inhibitors.

Using 2D ^{15}N-^{1}H HSQC NMR we screened 6006 compounds from a custom-built small molecule library against an engineered ~30 kDa protein construct containing subdomains 1 and 2 ($d_{1,2\Delta}$–HCVh) in which the NTP binding site, part of the nucleic acid binding surface and all the sequence motifs conserved between SFI and SFII helicases are retained. Nine, eight and two small molecule NMR hits were identified which bound weakly

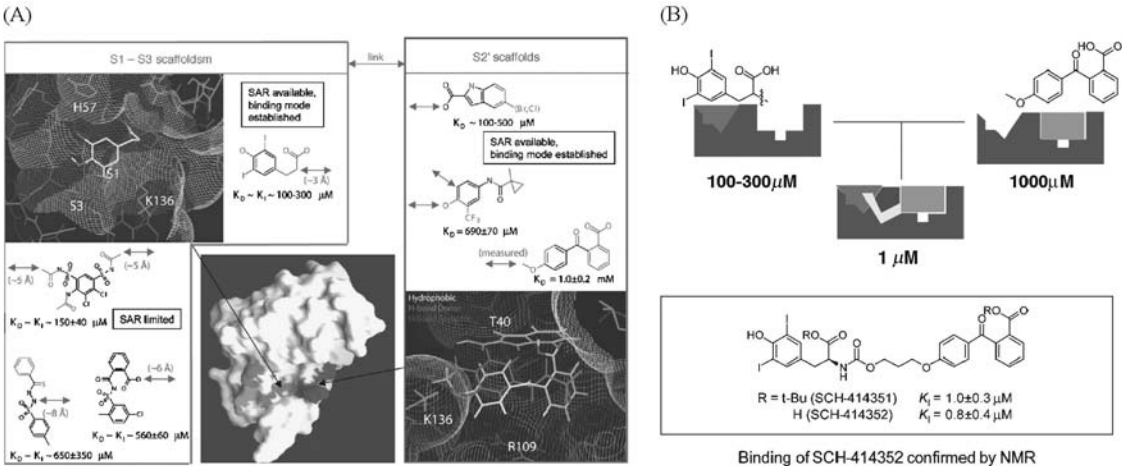

Fig. 3. NMR-derived competitive non-peptide inhibitors of the HCV NS3 protease. (A) NMR-derived binding orientation of optimized NMR hits to proximal substrate binding sites of the ns4a-ns3p [46]. Shown in green parentheses are the approximate distances which would have to be spanned by an appropriate linker in order to connect the S1-S3 scaffolds with the S2′ scaffolds at the respective sites (indicated with green arrows). Red highlights indicate those parts of the chemical structures for which detailed SAR is available. (B) Linking of two NMR-derived scaffolds which weakly bind the enzyme at the proximal S1-S3 and S2′ substrate binding sites yields competitive inhibitors with approximately 200- to 1000-fold increased potencies. (See also Plate 112 on page XXIV in the Color Plate Section.)

($K_D \sim 100\ \mu$M–10 mM) to $d_{1,2\Delta}$–HCVh near the TxGx motif, the NTP binding site, and motif IV, respectively, as judged by the induced protein CSP (Figure 4A). Binding of the NMR hits to the various motifs was confirmed by interaction with the full-length HCV NS3 helicase domain. Four NMR hits to the TxGx motif were followed-up by evaluating related compounds to derive SAR and 3D structural information. Hits to this site were targeted to potentially develop specific and selective HCV helicase inhibitors, since residues in and near this motif are implicated in the function of the enzyme [61,62], involved in ssDNA binding [63], highly conserved across all HCV genotypes, but nevertheless unique to a subgroup of SFII helicases [64].

Two of the NMR-detected hits could be soaked into crystals of the HCV helicase (Figure 4A). The x-ray crystal structure of SCH-482932 in complex with the enzyme (Figure 4B) was used as a starting point in the structure-guided design of lead inhibitors and the construction of focused chemical libraries using high-throughput synthesis methods. NMR-derived SAR showed that the carboxylate is required for binding of SCH-482932 to the HCV helicase domain, the 3-acetic acid and the 5-bromine are optimal, and the framework can be extended at the indole nitrogen to gain affinity. The 3D structure of the SCH-482932/HCV helicase complex suggested that this chemotype could be extended at the N1-position into two nearby conserved binding pockets through a suitable linker X (Figure 4B). Twenty-eight compounds were synthesized based on the 5-bromo-indole-3-actic acid scaffold which contained extensions at the indole nitrogen using either flexible alkyl linkers (3), or more rigid linkers such as amide (3), benzyl (3), benzoyl (1), urea (2), and phenyl (16). Several of these compounds showed K_D and IC_{50} values in the single digit μM range. Interestingly, the phenyl intermediate, SCH-529963, showed ~10-fold improvement in potency over the starting fragment, SCH-482932, and simple substituents at the *ortho* position on the phenyl ring increased its affinity another ~10-fold (Figure 4C). Importantly, the resulting compounds are small, lead-like [65] and suitable for high-throughput chemical library construction to efficiently explore the two nearby binding pockets of the HCV helicase domain.

Conclusion

We have used NMR-based screening as a reliable primary assay which provides chemists with good starting points for the structure-guided development of viable leads that are active-site directed and validated using fragment-based approaches. Focus was placed on targets for which HTS failed to identify suitable leads. NMR-based screening was carried out on a diverse set of targets to identify and optimize novel scaffolds, which subsequently were either linked, or further optimized by the parallel synthesis of a large number of analogs, or used as templates for structure-based inhibitor design. A critical step in these fragment-based methods, which take a

(See also Plate 113 on page XXV in the Color Plate Section.)

modular approach to drug discovery, is the optimization of the often weak NMR hits ($K_D \sim \mu$M–mM) into potent leads ($K_D < \mu$M) using chemistry guided by 3D structural data and SAR. We have implemented a number of NMR-based tools which are designed to facilitate this process.

In addition, we have used the NMR methods described in this report in several programs to validate hits from other sources and rapidly assist the project team chemists in selecting candidate leads for synthetic efforts. In this respect, NMR-derived information often helps to eliminate false positives hits early in the drug discovery process.

NMR and Structural Genomics in the Pharmaceutical Sciences

Maša Čemažar and David J. Craik*
Institute for Molecular Bioscience, University of Queensland, Brisbane 4072, Queensland, Australia

Introduction

Structural genomics (or more correctly structural proteomics) involves the high-throughput determination of protein structures on a genome-wide scale. It is a new field of research that has the potential to add substantial value to the sequence information becoming available from genome projects. The purpose of structural genomics is to accelerate protein structure determination so as to obtain structural examples of all available protein folds. The derived information will be essential in providing new insights into relationships between protein sequence, structure, and function.

There have been a large number of structural genomics consortia established in recent years in many countries. In addition to their primary purpose of generating large numbers of protein structures many of these consortia are developing and improving techniques for high-throughput structure determination. Together with X-ray crystallography, NMR is one of the two main structure determination methods. The two techniques are complementary and have advantages over one another in the specific ways that they can be applied to the problem of structure determination. In the pharmaceutical sciences structural genomics is beginning to play an important role in drug design strategies. This chapter reviews current progress and trends in structural genomics, with an emphasis on NMR structure determination.

Strategies and Targets in Structural Genomics

The present stage of structural genomics has been referred to as the "low-hanging fruit" phase [1]. Presently the proteins that are being tackled mostly express well in *E. coli* in a soluble form, can be purified easily, and either crystallize readily or give high-quality NMR spectra. The structure determination of these proteins does not require any conceptual or technical advances, although such advances are being made and will accelerate progress. The reason for the choice of the "low-hanging fruit" is that researchers in the field are still seeking to improve the downstream technology, i.e. high-throughput data collection, processing, and structure determination, and to develop automated procedures for many of the steps before embarking on more extensive programs involving more challenging targets.

Table 1 lists some of the major structural genomics initiatives around the world that are using X-ray crystallography or NMR spectroscopy or, in a majority of cases, both techniques. There are several resources on the World Wide Web where links to the details of these initiatives can be found, including for example http://www.rcsb.org/pdb/strucgen.html#Worldwide. Many targets chosen by these initiatives are either from model organisms such as *E. coli*, *S. cerevisiae*, *C. elegans*, or are human proteins that have important functions in essential cell processes such as signal transduction or nucleic acid binding.

Sequence alignment strategies are frequently used to predict the folds of proteins from related families with high sequence homology from across different genomes. However, sometimes even though the homology between two sequences is rather low, they might have a high similarity in their folds and vice versa, so at the moment predictive methods have not replaced the need for experimental structure determination. Even in cases where the predictions of the fold work well, the atomic resolution of the predicted structures may not be sufficient for some applications. In particular, for pharmaceutical applications there is still often a need to experimentally determine the high-resolution structure of a particular target to be able to predict and study the interactions of this protein with ligands for drug design.

Advantages and Disadvantages of NMR for Structural Genomics

From a structural proteomics perspective, NMR studies are mostly limited because of the size of the proteins that can be successfully tackled and by the lengthy data collection and analysis steps. Even with recent developments in the field, complete structure determination of monomeric proteins has still not been pushed beyond the

Table 1: Summary of global structural genomics initiatives[*]

Initiative	Full name	Location	Target genomes and/or proteins	Techniques used
BIGS	Bacterial targets Informatiom Genomique et Structurale	France	*Escherichia coli,* rickettsia, gram-positive, and gram-negative bacteria	X-ray crystallography
BSGC	Berkley Structural Genomics Centre	USA	Genomes of *Mycoplasma genitalium* and *M. pneumoniae*	NMR and X-ray crystallography
BSGI	Bacterial Structural Genomics Initiative	Canada	*E. coli*	NMR and X-ray crystallography
CESG	Centre for Eukaryotic Structural Genomics	USA	Eukaryotic proteins, arabidopsis	NMR and X-ray crystallography
ISPC	Israel Structural Proteomics Centre	Israel	Human health and disease-related proteins	X-ray crystallography
JCSG	Joint Centre for Structural Genomics	USA	Prokaryote *Thermotoga maritima* and eukaryote *Caenorhabditis elegans*	X-ray crystallography
MCSG	Midwest Centre for Structural Genomics	Worldwide	Unknown folds and proteins from disease-causing organisms	X-ray crystallography
MSGP	Marseilles Structural Genomics Program	France	Bacterial, viral, and human ORFs of (un)known function	X-ray crystallography
NESG	Northeast Structural Genomics Consortium	USA, Canada	*S. cerevisiae, C. elegans*, and *D. melanogaster* as well as homologs from the human genome	NMR and X-ray crystallography
NYSGRC	New York Structural Genomics Research Consortium	USA	Proteins from humans and model organisms	X-ray crystallography
OCSP	Ontario Centre for Structural Proteomics	Canada	*E. coli*, *Methanobacterium thermoautotrophicum*, *T. maritima*, *S. cerevisiae*	NMR and X-ray crystallography
OPPF	Oxford Protein Production Facility	UK	Human proteins and those of human pathogens	X-ray crystallography
PSF	Protein Structure Factory	Germany	cDNA clones from German Human Genome Project	NMR and X-ray-crystallography
RIKEN	RIKEN Structural Genomics Initiative	Japan	Human, mouse, and plant proteins	NMR and X-ray crystallography
S2F	Structure to Function	USA	*Haemophilus influenzae*	
SECSG	Southeast Collaboratory for Structural Genomics	USA	Eukaryotic *C. elegans*, *Homo Pyrococcus furiosus*	NMR and X-ray crystallography
SGPP	Structural Genomics of Pathogenic Protozoa	USA	*Leishmania major*, *Trypanosoma brucei*, *Trypanosoma cruzi*, and *Plasmodium falciparum*	X-ray crystallography
SPINE	Structural Proteomics in Europe	Europe	Bacterial pathogens, viral pathogens, and human proteins from fundamental processes and disease	NMR and X-ray crystallography
TB	Tuberculosis Structural Genomics Consortium	Worldwide	*Mycobacterium tuberculosis*	NMR and X-ray crystallography
YSG	Yeast Structural Genomics	France	*S. cerevisiae*	NMR and X-ray crystallography
SGC	Structural Genomics Consortium	UK, Canada	Chemical transformation of human metabolites, signal transduction, membrane receptor/channel signaling, and human parasitic disease	NMR and X-ray crystallography

[*] A selection of the largest structural genomics initiatives is shown, with their abbreviated name, main focus and/or target organisms and the preferred structural determination technique(s) used.

molecular mass limit of around 50 kDa. On the other hand, NMR has a great advantage over X-ray crystallography because it does not require crystals and the experiments are conducted in aqueous solution. Thus NMR can complement X-ray crystallography in providing structural determination for proteins that do not crystallize. Disordered and flexible regions within a protein may limit its "crystallizability", but a thorough NMR analysis using relaxation techniques and heteronuclear NOE measurements can detect and quantify the motions in flexible regions. Membrane proteins are particularly hard to crystallize and although NMR still has some major technical barriers to overcome, there have been some recent positive developments in the field of NMR structure determination of membrane proteins [2,3]. An approach that has been particularly successful is the use of detergent micelles to solubilize membrane proteins, as exemplified by recent studies on the structures of a series of *E. coli* outer membrane proteins, including OmpX, OmpA, and PagP in DHPC, DPC, and *n*-octyl-β-D-glucoside micelles, respectively. The micelle complexes of these β-barrel proteins are in the size range 50–70 kDa [3].

In X-ray crystallography the screening for suitable samples represents a real bottleneck as there is still no predictability about whether the sample will crystallize and if so, how fast. NMR has an advantage in that it can be used as a fast screening method for suitable samples that can be later subjected to structural determination. After successful purification, ^{15}N labeled protein samples can be screened using ^{1}H-^{15}N HSQC spectroscopy, in which exactly one backbone amide peak is expected for each of the non-proline residues, providing a diagnostic fingerprint of the protein. Since there may be correlations between the "foldedness" of a protein and its crystallizability, data from such an NMR screen can support efforts to make samples for a successful crystallographic analysis [4].

Although the acquisition of preliminary screening data can be quite fast in NMR, for example 10–30 min for a 2D HSQC spectrum on a 50 μM sample, the time for collection of an entire set of data is still slow (2–4 weeks) compared to crystallography, where the time from a diffracting crystal to structure can be sometimes hours. Whereas crystallography continues to struggle with the unpredictable rate-determining step of producing diffracting crystals, NMR struggles with months-long periods of more or less manual assignment and structural determination. This timescale is not compatible with many structural genomics initiatives objectives, which for example aim for 100–200 structures per year from each of the NIH-sponsored pilot centers [5].

As already mentioned, the size of proteins that can be studied by NMR is one of its greatest limitations. An analysis of the sizes of the proteins in the Protein Data Bank (PDB, http://www.rcsb.org/pdb/) shows that until now the median size of all proteins solved by NMR was approximately 7 kDa [6], which is substantially less than the median size of proteins solved by X-ray crystallography. Although NMR has solved many proteins larger than 7 kDa, the PDB statistics provide a clear reminder of where the "market" for NMR structures has been in the past.

Figure 1 summarizes the way the size limit has been pushed higher over recent years by the development of novel NMR techniques and improvements in the sensitivity of spectra by technological advances in NMR instrumentation. Proteins larger than 7–10 kDa need to be isotopically labeled with ^{15}N and/or ^{13}C and subjected to 3D or 4D experiments, whereas proteins below approximately 7 kDa can be structurally characterized using traditional 2D homonuclear (^{1}H–^{1}H) techniques based on NOE distance restraints, torsion angles, and inferred H bonds. Transverse relaxation optimization techniques (TROSY) have been a major development in pushing the limit of protein sizes to about 50 kDa when combined with appropriate labeling strategies [7]. It seems likely that this limit will be pushed higher still in coming years, at least from the perspective of deriving structurally informative data from spectra, if not full three-dimensional structures. In an exciting recent development informative solution spectra of a GroEl/GroEs protein complex of about 900 kDa [8] were obtained using TROSY/CRINEPT methods at high magnetic field. Another approach that has been successfully used in recent years is the domain-targeted approach that overcomes the size problem when the structural determination of the whole protein is not feasible. [9]. The average domain size of encoded proteins is approximately 150–175 amino acids, which is well within the NMR size limit [4,10]. Large, multidomain proteins sometimes exhibit interdomain flexibility, which complicates or prevents crystallization, so NMR can be particularly suitable for their structure determination, especially if specific domains can be selectively labeled in turn using intein technology [11,12].

An example of an ongoing structural genomics project on non-membrane proteins of the archeon *M. thermoautotrophicum* provides some typical numbers for the success rates of a high-throughput approach that involves the complementary use of NMR and X-ray crystallography [13]. At target selection, proteins are divided into larger/smaller molecular weight categories (>20 kDa or <20 kDa) that are earmarked for X-ray or NMR, respectively. Interestingly the statistics for successful expression rates hardly differed for them, at 93 and 94%, respectively. At the purification stage, small proteins had a better success rate, 32% vs. 21% for larger proteins. In the end, however, NMR provided an overall success rate for structures of smaller proteins of 5%, whereas X-ray crystallography was successful with 3% of larger proteins and an additional 0.5% of smaller proteins that had HSQC

Fig. 1. NMR structural information and biomolecular size limits. A schematic representation of the relationship between various NMR structural determination techniques and biomolecular size limits. For each size range an example of a protein structure is given: 3 kDa macrocyclic peptide kalata B1, 8 kDa antimicrobial protein MiAMP1 from the nut kernel of *Macadamia integrifolia* [32], 20 kDa granulocyte colony stimulating factor [33], the 40 kDa complex of maltodextrin binding protein with β-cyclodextrin [34], and the 900 kDa complex of GroEl/GroEs [14]. On the right hand side of the figure the NMR techniques that can be applied to the specific mass range are summarized. So far full 3D structures have been determined up to the size limit of ~50 kDa, but this limit is set to expand over the coming years. (See also Plate 114 on page XXVI in the Color Plate Section.)

spectra that were judged too poor to allow NMR structure determination. It is useful to point out just what a central role HSQC spectra play in structural genomics programs. For proteins that are soluble and purifiable, HSQC spectra can be categorized as good, promising, or poor (or “none” for those where protein had been lost during the concentration procedure) and appropriate decisions made as to whether to proceed with structure determination [13]. A graphic representation of the distribution of spectral types is shown in Figure 2. The exact distribution varies for different organisms but the result is illustrative of general findings. It shows that almost half of the small (<20 kDa)

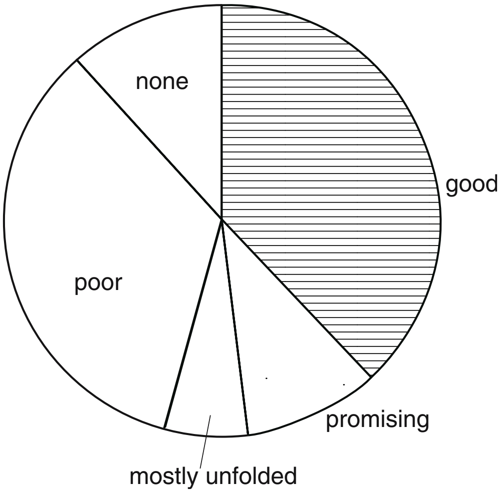

Fig. 2. Distribution chart for the HSQC classification of soluble, purifiable proteins. Spectra can be classified as good, promising, mostly unfolded, poor, or none (for those cases where no HSQC could be obtained). The chart shows the distribution obtained for the archeon *M. thermoautotrophicum*. Data are taken from Yee *et al.* [13].

proteins have potential for NMR structure determination. A key downstream application of NMR in structural genomics with particular relevance to the pharmaceutical sciences is in screening for ligand interactions, especially for those ligands that bind weakly to the protein target, an area where many conventional screening methods fail. In the same way, NMR is useful in screens for protein–protein interactions. Perturbations of specific peaks in an HSQC spectrum identify regions of contact, whereas recently developed residual dipolar coupling (RDC) methods [14,15] can be used to define the relative orientation of associated proteins, including the relative orientation of loosely associated domains in multidomain proteins [16,17]. Compared to conventional approaches, NMR significantly reduces the time for identification and optimization of novel ligands. As noted above, this is usually done by studying changes in ^{15}N/^{1}H chemical shifts of the protein resonances to identify binding ligands from a library of compounds [18].

Advances in NMR Instrumentation and Methodology

In recent years there have been a number of technological improvements in NMR that are being driven in part by structural genomics initiatives. The pharmaceutical sciences will particularly benefit from these advances. As targets move from well-studied and conventional systems to the more challenging systems that are usually more relevant as medicinal targets, high-throughput techniques in NMR will become increasingly important. The advances in NMR in recent years can be divided into advances in instrumentation, methods, data analysis, and sample preparation, as described below.

In terms of instrumentation, the introduction of cryogenic probes probably represents the greatest quantum leap in technology. In these, the traditionally low sensitivity of NMR has been improved by using radio frequency coils that are cooled to about 25 K [19]. This is an important advantage for structure genomics high-throughput methods as cryogenic probes decrease the time of data sampling by factors from 4 to 16. In addition to this new probe technology, the trend towards developing magnets of higher fields has continued incrementally, resulting in further improvements in the sensitivity and resolution of NMR spectra. As of 2004, 900 MHz is the highest commercially available field strength. 800 MHz systems are widely used in structural genomic programs and 900 MHz systems are beginning to come on-line in such programs.

New methods play an important and complementary role to new instrumentation. As already mentioned, the TROSY technique has been developed to be used with higher magnetic fields to give better spectral resolution so that large protein complexes can be tackled [20]. A development that might be especially important for future high-throughput analysis in structural genomics involves the collection of a single set of triple-resonance data from ^{15}N-, ^{13}C-labeled samples in isotropic and liquid crystalline media to provide a rapid low-resolution view of a protein fold [21].

The bottleneck of structural genomics with NMR is still the analysis of NMR data and there is much effort currently been directed towards automation. These efforts have produced several programs [22–26] that can successfully assign well-resolved spectra, but there is scope for future improvement in this area for more robust peak-peaking algorithms that can better distinguish artifacts and noise from real peaks. Another recent development in data analysis has been to include restraints other than the short range ones, particularly RDCs, in the calculation of structures, providing information about long-range order in macromolecules [21,27,28].

Several developments on the protein expression side also have important impacts on high-throughput structural analysis. Especially important are cell-free or *in vitro* expression systems, which now produce yields suitable for structural studies (mg/ml) [29]. These approaches have several advantages over the traditional *in vivo* expression systems, amongst them the fact that some proteins, that are prone to aggregation in the cell or have toxic properties, may now be produced without the need of cloning genes into expression systems. Another advantage of this approach is that labeling of specific amino acids can be introduced because they are additionally supplemented to the reaction mixture. Other resolution-enhancing methods such as encapsulation of proteins in inverted micelles in low-viscosity solvents lead to rapid tumbling and hence to narrower resonances in the spectra [30].

Outlook and Conclusions

From an analysis of current structural genomics initiatives, it has been estimated that on average about 4.7 out of 100 cloned proteins are expected to yield crystal structures and about 5 out of 100 protein NMR structures [31]. These statistics however do not reflect the number of solved structures in a given time frame, since X-ray crystallography is substantially faster. Overall only about 17% of all deposited protein structures in the PDB have so far been determined by NMR methods. On the other hand, NMR can tackle a number of proteins that might are not accessible for crystallization, and about 75% of NMR structures in the PDB do not have corresponding crystal structures. Overall, it is clear that NMR is a viable and economic strategy for structural genomics and will continue to be successfully used for drug design and screening strategies.

Subject Index

A

- α-synuclein, protein misfolding disease and, 1389
- Γ method, quantitative, 1249
- ε186–θ complex, 1263, 1266
  - diamagnetic, 1264
  - paramagentic, 1264
- 1D ^{1}H MRS
  - single- and multi-voxel based, 1161
- 1D NMR
  - based screening, 1393
- 2,2,2-trifluoroethanol. *See* TFE
- 2D ^{1}H MRS, 1173
- 2D heteronuclear NMR-based screening, 1420
- 2D j-resolved MRS, 1174
- 2D MAS experiments, 1016
- 2D MRS, 1015, 1024
  - advantages in human biopsies, 1016
  - artefacts in localized, 1180
  - CT-COSY, 1173
  - CT-PRESS, 1173
  - JPRESS, 1173
  - L-COSY, 1174
  - multi-voxel based, 1180
  - SECSY, 1173
  - single volume localized, 1175
- 2D NMR, 1015
  - applications to cells and tissues, 1016
- 2D TOCSY, 1242
- 3-FABS
  - high-throughput screening and, 1393
- *A. hydrophila*, 1341, 1342
- abscess, 1021
- absolute quantitation, 1021, 1110
- acquiring spectra method
  - global, 986
  - local, 986
- active-site metals, 1334
- adenosine diphosphate (ADP), 1146
- adsorption, gas. *See* gas adsorption
- *Aeromonas hydrophila*, 1331
- alignment media
  - organic molecules structure determination, 1280
- alignment tensor, 1279
- aloe metabolites, 1232
- amide protons, H-bonded, 1369
- amide resonances, backbone, 1332
- amyloid precursor protein, 1388
- antimicrobial peptides, structural
  - characterization of defensins, 1315
  - dimerization properties, 1318
  - disulfide cross-linking, 1319
  - hepcidin, 1319
  - microcin J25, 1319
  - NMR for, 1315
  - NOESY, 1319
  - NOESY NMR, 1318
  - orientation in bilayers (magainin 2), 1320
  - protegrin-1, 1320
  - solid-state NMR experiments, 1320
  - solution structures of, 1315
  - TOCSY, 1315, 1318
  - unusual linkages characterization, 1317
- apodization, human biopsies and, 997
- aqueous fraction, 1146
- ARIA, 1244
- arteriovenous malformation (AVM), 1072
- *Aspergillus spp*, 1008
- assignments
  - human biopsies, 1032
  - pharmaceutical sciences, NMR in, 1239
- astrocytoma, 1030, 1056
- ATP, 1143
- automated protein structure determination, 1243
- AUTOPSY, 1242

B

- B0 field, 1077
- B1 field, 1163
- B1 homogeneity and SNR
  - local rf coils, 1170
- B1 homogeneity versus SNR, 1166
- backbone amide resonances, 1332
  - inhibitor binding and, 1332
- backbone RDC
  - protein NMR and, 1287
- backbone torsion angle
- *Bacteroides fragilis*, 1331
- basic fibroblastic growth factor (bFGF), 1130
- benign prostatic hyperplasia, 1051, 1058
- bicelle
  - isotropic, 1273
  - magnetically aligned, 1275
  - membrane systems, phospholipid, 1271
  - phospholipid, 1272
- bifunctional contrast agent, 1093, 1095
- bilayer systems
  - magainin 1315
  - peptide orientation in, 1320
- binding activities, DNA. *See* DNA-binding activities (hTRF1and hTRF2 with hTRF2 mutants)
- biochemical applications (cryogenic NMR probe technology), 1207
- bioinformatics, intraoperative MRI and, 1075
- biomolecular NMR, 1305
- biopsy
  - ^{31}P MRS and, 1077, 1078
  - human. *See* human biopsies
  - tissue, 1078
- *Blastomyces dermatitides*, 1008
- blood oxygen level dependent. *See* BOLD imaging
- BMRB, 1242
- BOLD contrast, 1029. *See also* contrast agents
- BOLD imaging 1037. *See also* functional MRI phMRI
- *Bombina maxima*, 1317
- bone, 1115
- borate complexes, 1347
- brain. *See also* infective brain lesions
  - HRMAS MAS analysis, 1051
  - surgical specimens, 1051
- breast. *See also* MR-mammography
  - HRMAS MAS of, 1061
  - MRS, 1127
- breast cancer
  - MRS and, 1077
- breast cancer, in vivo MRS, 1077
  - ^{1}H MR spectroscopy, 1079
  - ^{1}P MR spectroscopy, 1078
  - future aspects, 1084
  - localization in MRS, 1077
  - methodological issues related to proton in vivo MRS, 1079
  - normal and malignant, 1082
- broadband decoupling, 1101
- Bruker single-sided NMR device, 1873

C

- ^{13}C excitation and detection, in vivo^{13}C MRS, 1102
- ^{13}C NMR
  - in vivo, 1099
- ^{113}C spectrum, thiomandelate binding effect, 1335
- CABINET, 1174

calar coupling, 1015
cancer pathology determination, 1038
CANDID, 1244
CANDID algorithm, 1244
Candida spp, 1008
CCPPA. *See* coupled-cluster polarization propagator
cell labeling

APPLICATIONS IN MATERIALS SCIENCE

Foreword 1437

- **Acoustically Stimulated NMR Relaxometry: Application to the Study of Molecular Dynamics in Liquid Crystalline Materials,** *E. Anoardo and F. Bonetto* 1439
- **Characterization of Elastomers Based on Monitoring Ultraslow Dipolar Correlations by NMR,** *Farida Grinberg* 1445
- **Correlating Molecular and Macroscopic Properties of Elastomers by NMR Relaxometry and Multi-pulse NMR Techniques,** *S. Stapf, S. Kariyo, and B. Blümich* 1455
- **Determining Structural and Dynamic Distribution Functions from Inhomogeneously Broadened NMR Spectra: The Conjugate Orthogonal Functions Approach,** *Marcel Utz and Magesh Nandagopal* 1463
- **Fluid Diffusion in Partially Filled Nanoscopic and Microscopic Porous Materials,** *I. Ardelean, G. Farrher, C. Mattea, and R. Kimmich* 1471
- **Gas Adsorption on Carbon Nanotubes,** *Tanja Pietraß* 1479
- **Magnetic Resonance Studies of the Heterogeneous Rotational and Translational dynamics in Disordered Materials,** *R. Böhmer, G. Diezemann, G. Hinze, K.R. Jeffrey, and M. Winterlich* 1487
- **Nuclear Magnetic Resonance in Ferromagnetic Multilayers and Nanocomposites: Investigations of Their Structural and Magnetic Properties,** *C. Mény and P. Panissod* 1493
- **^{1}H Solid-State NMR of Supramolecular Systems,** *Ingo Schnell and Hans Wolfgang Spiess* 1499
- **Quadrupolar NMR of Inorganic Materials: The Multiple-Quantum Magic Angle Spinning Experiment,** *Stephen Wimperis* 1507
- **Rheo-NMR Spectroscopy,** *Claudia Schmidt* 1515
- **Advances in Single-Sided NMR,** *J. Perlo, F. Casanova, and B. Blümich* 1523
- **Site-specific Characterization of Structure and Dynamics of Complex Materials by EPR Spin Probes,** *Dariush Hinderberger and Gunnar Jeschke* 1529
- **NMR of Organic Semiconductors,** *Magesh Nandagopal, Mathew Mathai, Fotios Papadimitrakopoulos, and Marcel Utz* 1539
- **Solid State NMR of Xerogels,** *J.L. Yarger, D.A. Buttry, and G.P. Holland* 1547
- **Solid-State ^{17}O NMR Spectroscopy of High-Pressure Silicates,** *Sharon E. Ashbrook* 1551
- **The Structure of Oxide Glasses: Insights from ^{17}O NMR,** *Philip J. Grandinetti and Ted M. Clark* 1563
- **Studies of the Local Structure of Silk Using Solid-State NMR,** *Jacco D. van Beek, Lilyane Beaulieu and Beat H. Meier* 1569
- **Velocity Imaging of Granular Materials,** *Siegfried Stapf, A. Khrapitchev, C. Heine and Bernhard Blümich* . 1581

Preface

It is a great pleasure for me to Introduce the handbook of Modern Magnetic Resonance, MMR. The various techniques which comprise MMR derive essentially from three sources, all of which were produced by physicists. Today they are widely used by scientists working in many diverse areas such as chemistry, biology, materials, food, medicine and healthcare, pharmacy and marine studies.

The first source of MMR studies is nuclear magnetic resonance, NMR. This provides details on the relative positions of nuclei, i.e. atoms, in a molecule. Consequently NMR provides structural information on samples which may be in the solid, liquid or gaseous state. Nuclear relaxation data yield dynamic information on the sample and the topology of the dynamic processes if the sample is undergoing a molecular change. Thus high and low resolution NMR studies provide information on all interesting aspects of molecular science. The protean nature of NMR is reflected in its many applications in chemistry, biology and physics which explore and characterize chemical reactions, molecular conformations, biochemical pathways and solid state materials, to name a few examples.

Magnetic resonance imaging, MRI, is the second source of MMR data. MRI provides a three-dimensional image of a substance, and is consequently widely employed to assess materials both *in vitro* and *in vivo*. The importance of MRI studies in many areas of science and medicine is shown by the recent award of the Nobel Prize to Lauterbur and Mansfield.

The third source of MMR results is due to electron spin resonance, ESR. This is a technique for detecting unpaired electrons and their interactions with nuclear spins in a given sample. Thus ESR data are often used to complement the results of NMR experiments.

Taken together NMR, MRI and ESR comprise the field of MMR, recent years have witnessed the fecundity of these techniques in many scientific areas. The present three volumes cover applications in most of these areas. Part 1 deals with Chemical Applications, Biological and Marine Sciences. Medical and Pharmaceutical Sciences are covered in Part 2. Part 3 provides examples of recent work in the Materials Science and Food Science.

I wish to express my gratitude to all of the Section Editors and their many contributors for their hard work and dedication in the creation of MMR. My thanks also go to Emma Roberts and the production staff at Springer, London, for their assistance in the realization of these volumes.

Part III, Section 1: Applications in Materials Science

Foreword to Applications in Materials Science

After unsuccessful experiments by Gorter in the early 1930s, the principle of magnetic resonance was first applied experimentally to atomic nuclei in 1938 by Rabi and coworkers in a molecular beam experiment. Their purpose was to determine the magnitude and, in particular, the sign of the nuclear gyromagnetic ratio [1]. It is noteworthy that none of their papers of that period mention the possibility to use magnetic resonance to study anything but the magnetic properties of atomic nuclei. This situation did not change 10 years later with the work in the groups of Purcell [2] and Bloch [3,4] who, thanks to advances of radio-frequency electronics during World War II, were able to directly detect the induction signal due to magnetic resonance in bulk condensed samples. It was only the discovery of the chemical shift around 1950 by Gutowsky and Hoffmann [5], that opened the door for wider applications, forming the basis for the success of nuclear magnetic resonance as a tool of chemistry, biology, medicine and materials science. In parallel, electron paramagnetic resonance became available after 1945 [6–8]. Its wider benefits were more immediately clear, due to the direct involvement of the electrons in the formation of chemical bonds.

Chemistry and biology have benefitted greatly from advances in solution-state NMR spectroscopy (and imaging), whereas the development of high-resolution solid-state NMR spectroscopy has been particularly important for materials science. While the analytical power of solid state NMR spectroscopy rests on many incremental improvements and discoveries, too numerous to list exhaustively, a few noteworthy milestones should not go unmentioned. These include the introduction of magic angle spinning by Andrew *et al.* [9], the discovery of cross-polarization by Hartmann and Hahn [10], and the combination of the two to study low-gamma, low-abundance nuclei [11,12]. The development of multi-pulse homonuclear decoupling sequences [13], combined with multi-dimensional NMR [14] has made it possible to separate different nuclear spin interactions in different spectral dimensions. More recently, the multiple-quantum magic angle spinning methods first introduced by Medek and coworkers [15] have greatly facilitated high-resolution spectroscopy of half-integer quadrupolar nuclei, which represent the majority of elements in the periodic table. This success story provides a striking example for the importance of free research, solely driven by the challenge of the unknown and the quest for fundamental understanding.

The present volume is dedicated to the application of magnetic resonance techniques in the context of materials science. Bridging fundamental concepts of condensed matter physics with problems of engineering and technology, materials science plays a crucial role in reaping practical benefits from scientific advances. Throughout human history, technological progress has been intimately linked to the availability of materials with favorable combinations of properties. While the 19th and early 20th centuries have seen great advances in the quality and availability of metallic materials, the focus of innovation has shifted towards “soft” materials in the more recent past. Their properties in many ways resemble those of structural substances found in plants and animals: they are often based on organic compounds, processed at relatively low temperatures, and integrate themselves well into living environments. A particularly striking example of what is ultimately possible in this direction is provided by spider silk, which is an amazing material, admirably adapted to its application: It exhibits a very high ultimate tensile strength, combined with enormous toughness, to withstand wind forces and the attempts of caught prey to escape, and resists air humidity and rain water without deterioration of its properties. In addition, depending on the particular application either as tangential or radial net thread, or as drag line, its surface is modified to provide the right amount of tackiness. All of this is achieved with a small number of amino acids as building blocks, which are not specific to this application, but form the basis of all known forms of life. The silk is synthesized and processed by the spider on demand, in real time, in a gland that is only a few hundred μm in size, at ambient temperature. Contrast to this with the production of aramid fibers, which are the only man-made material to rival the mechanical properties of spider silk: They are synthesized using toxic precursor compounds, and processed by high-temperature spinning with concentrated mineral acids as solvents. Obviously, there are still many things that human technology can learn from nature.

This, however, requires experimental tools that provide structural and dynamic information on all length scales, down to atomic dimensions. The development of metallic and ceramic materials has benefitted enormously from experimental techniques that rely on diffraction to provide structural information, such as electron microscopy or X-ray scattering. Although such techniques are extremely powerful in crystalline solids, they are much less useful in the context of soft organic materials, where crystalline order is the exception rather than the rule. For this rapidly evolving class of materials, magnetic resonance provides an extremely flexible and powerful tool of investigation, as is amply illustrated in the articles of this volume.

Given the growing diversity of modern materials, the flexibility of magnetic resonance techniques is a major asset. It is difficult to find two contributions in the present volume that utilize the same pulse sequences and data acquisition techniques. Similarly, the materials that are investigated vary widely, including synthetic and natural polymers, organic semiconductors, inorganic glasses, glass-forming fluids, magnetic materials and xerogels, to just name a few. Finally, the information provided by magnetic resonance is diverse also, ranging from structural data to relaxation times and transport properties.

On the one hand, the flexibility to taylor the experimental approach to the research question to be answered is a great strength of magnetic resonance techniques. On the other hand, the resulting complexity of experimental techniques and data interpretation makes it unlikely that magnetic resonance spectroscopy will evolve into a "black box" tool that the materials scientist will be able to apply without thoroughly understanding its inner workings. Therefore, it will remain necessary for materials scientists to work closely with spectroscopists in order to generate meaningful results. On each part, this requires a certain level of understanding of the other field. It is my sincere hope that the present volume will facilitate this interaction.

I am grateful to the main editor, Professor Graham Webb, for the opportunity to serve as section editor, and for his patience, support and guidance. This volume, of course, would not have been possible without the authors of the individual articles, and it is a great pleasure to acknowledge their contributions.

Acoustically Stimulated NMR Relaxometry: Application to the Study of Molecular Dynamics in Liquid Crystalline Materials

E. Anoardo and F. Bonetto

Facultad de Matemática, Astronomía y Física, Universidad Nacional de Córdoba—Ciudad Universitaria,
X5016LAE Córdoba, Argentina

Introduction

Field-cycling NMR relaxometry represents a powerful approach for investigating the spin–lattice relaxation times within the lowest Larmor frequency window. With sophisticated electronic manipulation, i.e. precise control of the current through non-mobile, very special electromagnets, magnetic field switching rates may be made as fast as 0.5 T/ms, allowing to extend relaxation experiments involving relaxation times of the order of 1 ms within a typical proton Larmor frequency range starting from local field frequencies up to 20 MHz. In this particular case, we refer to fast-field-cycling (FFC) [1, 2, 3]. The technique was successfully applied in recent years mainly for the study of the molecular dynamics in polymer and liquid crystals (LCs) [4], confined LCs [5], in the development of contrast agents for magnetic resonance imaging [6] and the study of biomolecules containing paramagnetic centers [7].

By comparing the characteristic Larmor frequency (ν) relaxation dispersions, FFC allows to gain a better understanding of the involved molecular dynamics. This can be interpreted as a superposition of different contributions, provided that in some cases a time scale separation may be applied. For instance, collective contributions due to order fluctuations in a nematic LC specimen can be usually separated from fast individual molecular motions. Therefore, a clear limitation of the FFC technique appears when both, collective and individual motions, contribute to the dispersion with similar frequency dependences. In this case, unless one of these processes can be filtered or enhanced, the mentioned discrimination becomes impossible. In this brief chapter we deal with this problem, particularizing the discussion to smectic organizations.

Why Field-Cycling Experiments in Liquid Crystals?

Relaxation features due to order director fluctuations (ODF) were first worked out for the nematic phase by Pincus [8]. His model predicted a characteristic $\nu^{1/2}$ Larmor frequency dependence for the spin–lattice relaxation time T_1. In the following years, several attempts were reported insinuating the finding of this frequency dependence by using standard non-cycled magnetic field apparatus within the MHz frequency range. However, it was not until 1975 when Wölfel *et al.* [9], using the FFC method, clearly showed for the first time that Pincus' prediction was correct. The ODF mechanism is usually manifested predominantly within the kHz frequency range, absolutely inaccessible by conventional methods (including rotating frame relaxation, see ref. [10] for a better understanding), where a concomitant degradation of the signal-to-noise ratio limits the quality of the experiments. Since then, FFC relaxometry was applied to the study of many different bulk and confined liquid crystalline compounds, mainly in the isotropic (I), nematic (N) and smectic A (SmA) phases.

Distinguishing features of FFC as a unique NMR tool for the study of LC, polymers and confined systems are: (a) the noticeable T_1-relaxation dispersion shown by these materials, (b) the strong differences shown-up by the corresponding T_1 dispersions in different mesophases, and (c) the remarkable sensitivity to a minimum spatial confinement. On these grounds, a further development of the technique is mandatory.

Relevant Properties of Liquid Crystals

In the following, we briefly discuss relevant properties of the nematic and smectic phase that are important for the interpretation of relaxation dispersion experiments. For further details the reader can refer to some of the specialized books about the matter [11, 12, 13].

The nematic phase is characterized by a molecular orientational correlation over macroscopic distances, while lacking molecular positional order. The orientational order defines a director field $\widehat{n}\left(\vec{r},t\right)$ that indicates the molecular average orientation within a certain region [14]. The free energy of the N phase due to elastic distortions

Graham A. Webb (ed.), Modern Magnetic Resonance, 1439–1444.
© 2008 *Springer.*

of the media can be expressed as:

$$F = \int \frac{d^3r}{2}\left[K_1\,(\nabla.n)^2 + K_2\,(n.\nabla \times n)^2 \right.$$
$$\left. + K_3\,(n \times \nabla \times n)^2\right], \tag{1}$$

where K_1, K_2 and K_3 are the elastic constants associated with the splay, bend and twist deformations, respectively. The elastic constants strongly depend on temperature and, as the elastic free energy is small compared with thermal energy, relatively weak external forces can easily distort the molecular arrangement.

In addition to the orientational order present in nematics, smectic phases exhibit layered structures. In the SmA phase, no long range positional order is shown inside each layer and the director is perpendicular to the smectic planes.

The order parameter for the SmA phase is defined as the amplitude of a one-dimensional density wave whose wave vector points along the director [12,15]:

$$\rho\left(\overrightarrow{r}\right) = \rho_o\left[1 + \frac{1}{2}\,|\Psi|\cos(q_o z + \varphi)\right], \tag{2}$$

where $|\Psi|$ is a measure of the strength of the smectic order, ρ_o is the average density, $q_o = 2\pi/d$ is the wave vector of the density wave (being d the interlayer distance), φ is an arbitrary phase, and z is the coordinate perpendicular to the planes.

For an ideal SmA phase, twist and bend elastic distortions are forbidden [15]. For an undistorted smectic, only the splay term of the nematic elastic free energy survives. Besides this term, the smectic free energy term f_{sm} and the corresponding one to the smectic–nematic interaction should be included in the free energy density expression [12,16]. Then:

$$f = f_{\text{nem}} + f_{\text{sm}} + f_I, \tag{3}$$

where,

$$f_{\text{sm}} = \alpha(T)\,|\psi|^2 + \beta(T)\,|\psi|^4 + \ldots$$
$$f_I = \left(\nabla + iq_s\overrightarrow{\delta n}\right)\psi * \frac{1}{2M}\left(\nabla - iq_s\overrightarrow{\delta n}\right)\psi, \tag{4}$$

here, α and β are coefficients in the f_{sm} expansion in powers of ψ. M is a mass tensor with two main components, along ($M_{//}$) and normal ($M_\perp$) to the layers, and $\overrightarrow{\delta n} = \widehat{n}\left(\overrightarrow{r}\right) - \widehat{n}_o$, being $\widehat{n}_o$ the unperturbed director.

Order Director Fluctuations

Due to the long range orientational order characteristic of liquid crystals, the molecules around a given spatial position (defined by $\overrightarrow{r}$) tend to align parallel to an average direction defined by an unitary vector $\widehat{n}\left(\overrightarrow{r}\right)$ called "director". The existence of thermal fluctuations cause the director to fluctuate around $\widehat{n}_0\left(\overrightarrow{r}\right)$, turning it dependent on the time t. These fluctuations of collective nature are called order director fluctuations (ODF), being effective to scatter light (a reason for the turbid appearance of the nematic phase) [17].

NMR relaxation due to ODF originates in the modulation of the dipolar interaction between spin pairs due to the presence of hydrodynamic modes [8,18–20]. In the following, we briefly discuss the basic arguments of this theory.

Let us consider a nematic sample in presence of a magnetic field along the z direction. Then $\widehat{n}(\overrightarrow{r}, t) = \widehat{n_0} + \overrightarrow{\Delta n}(\overrightarrow{r}, t)$, with $\overrightarrow{\Delta n}(\overrightarrow{r}, t) = n_x(\overrightarrow{r}, t)\widehat{i} + n_y(\overrightarrow{r}, t)\widehat{j}$. and $\widehat{n_0}$ the average director parallel to the z direction.

According to equation (1), the change in the free energy caused by these distortions will be (neglecting the magnetic term):

$$F = \frac{1}{2}\int\left\{K_1\left(\frac{\partial n_x}{\partial x} + \frac{\partial n_y}{\partial y}\right)^2 + K_2\left(\frac{\partial n_y}{\partial x} - \frac{\partial n_x}{\partial y}\right)^2\right.$$
$$\left. + K_3\left[\left(\frac{\partial n_x}{\partial z}\right)^2 + \left(\frac{\partial n_y}{\partial z}\right)^2\right]\right\}. \tag{5}$$

Expanding in Fourier series and rotating the coordinate system, it is possible to write the last equation in terms of two uncoupled modes (n_1, n_2):

$$F = \frac{1}{2}\sum_{\overrightarrow{q}}\sum_{\beta=1}^{2} K_\beta\left(\overrightarrow{q}\right)\left|n_\beta\left(\overrightarrow{q}\right)\right|^2 \tag{6}$$

where $K_\beta(\overrightarrow{q}) = K_\beta q_\perp^2 + K_3 q_{\backslash\backslash}^2$, $\langle|n_\beta(\overrightarrow{q})|^2\rangle = \frac{K_B T V}{K_\beta(\overrightarrow{q})}$, K_B is the Boltzmann constant and T is the temperature.

It is well known from different relaxation theories [21–23] that spin lattice relaxation time T_1 due to dipolar coupling interaction is given by:

$$\frac{1}{T_1} = \frac{9}{8}\gamma^4\hbar^2\left[J_1(\omega_L) + J_2(2\omega_L)\right], \tag{7}$$

where $J_q(\omega) = \int_{-\infty}^{\infty} g_q(\tau)e^{-i\omega\tau}d\tau$, $q = 1, 2$, being $g_q(\tau)$ the correlation function for a given dynamic process, ω is the Larmor frequency, γ is the spin gyromagnetic ratio and $\hbar$ is the Planck constant over 2π.

For the ODF process, under the low angle approximation ($|\overrightarrow{\Delta n}(\overrightarrow{r}, t)| \ll |\widehat{n_0}|$), it can be demonstrated that

$J_2(2\omega_L) \ll J_1(\omega_L)$, and:

$$J_1(\omega) = 3\frac{K_B T}{16\pi^3}\sum_{\alpha=1}^{2}\int_q \frac{d^3q}{\left(K_\alpha\left(\overrightarrow{q}\right)\right)^2 + \eta_\alpha^2\omega^2}, \tag{8}$$

where η_α are viscosity constants. Due to the anisotropic nature of nematics, the integration should be made over a cylindrical or ellipsoidal volume. Considering that the minimum wavelength is associated with molecular dimensions:

$$\int_q d^3q \rightarrow \int_0^{2\pi} d\phi \int_0^{q_{zh}} dq_z \int_0^{q_{\perp h}\sqrt{1-\frac{q_z^2}{q_{zh}^2}}} q_\perp dq_\perp, \tag{9}$$

where q_{zh} and $q_{\perp h}$ are the parallel and perpendicular associated cut-off wavelength, and ϕ is the azimuthal angle.

Integration of equation (8) conduces to a general expression [24] that, in the simplified nematic one constant approximation (isotropic viscoelastic properties) and assuming $(K/\eta)\,q_h^2 = \omega_h \gg \omega$ (i.e. within a Larmor frequency window far below from the high frequency cut-off), the result reduces to the Pincus' law for nematic dispersion: $T_1^{ODF}(\omega) \propto \sqrt{\omega}$.

The SmA phase can be approximated from the nematic formalism assuming the extreme anisotropic condition $K_3 \ll K_1 = K_2$. Under this assumption, the model reduces to a linear frequency dependence [24] $T_1^{ODF}(\omega) \propto \omega$. The same frequency dependence may be obtained from the assumption that only the splay term and the local fluctuation of the layers are present in the SmA elastic free energy [25].

A more refined model for the SmA phase can be obtained by including all terms in the SmA free energy (see equation (3)). In this case [26]:

$$T_1^{DF}(\omega) \propto \left(\frac{\eta_1}{D^{1/2}K_1^{3/2}}Y_1 + \frac{\eta_2}{D^{1/2}K_3^{1/2}K_2}Y_2\right)^{-1}, \tag{10}$$

with

$$Y_1 = \frac{B}{D}\int_0^1 \frac{dx}{x\left(\frac{B}{D}\left(1-x^2\right)+\frac{K_3}{K_1}x^2\right)^{3/2}\sqrt{1+\sqrt{1+\frac{1}{x^4}\left(\frac{\omega}{\omega_{s1}}\right)^2}}},$$

$$Y_2 = \frac{1}{\sqrt{1+\sqrt{1+\left(\frac{\omega}{\omega_{s2}}\right)^2}}},\ B = \frac{\psi_0^2 q_s^2}{M_{//}},\ D = \frac{\psi_0^2 q_s^2}{M_\perp},$$

$$\omega_{s1} = \frac{D}{\eta_1}$$

and $\omega_{s2} = \frac{D}{\eta_2}$; being ψ_0 the equilibrium value of the smectic order parameter. In contrast with the simplified models conducing to a linear dependence, in this case the resulting dispersion ranges from ω^0 to $\omega^{1/2}$.

Self Diffusion

Self diffusion is a relevant intermolecular relaxation mechanism for mesomorphic materials [27]. The theory of translational diffusion for isotropic liquids [28] was directly used in the analysis of the relaxation dispersion in LCs [29,30]. Later, modified versions of Torrey's model were proposed for nematics [31] and SmA structures [32]. Both models predict a flat dispersion in a frequency range where $\omega\tau \ll 1$, being τ the correlation time associated with the self diffusion process.

Molecular Reorientations

The influence of molecular reorientations in the spin–lattice of isotropic liquids is well known [23]. In liquid crystals, the unique relevant difference remains in connection with the anisotropic nature of the media, which usually demands to consider more than one correlation time for a given process. Internal motions and configurational molecular fluctuations are mainly due to molecular flexibility and rotations of chain groups. These processes are in general fast and usually manifest in the relaxation dispersion at high frequencies. At the simplest case, these contributions may be represented by a sum of BPP-type terms with their associated correlation times [33]. In the SmA phase, free rotation of the whole molecule about the long molecular axis is less probable than in nematics due to the layered packing [34].

Proton FC Relaxometry in Liquid Crystals

Proton spin–lattice relaxation time in liquid crystals is basically determined by both, collective fluctuations and individual molecular motions like self diffusion or molecular reorientations. If a time scale separation is feasible at correlation function level, collective and individual molecular dynamics may be assumed statistically independent. This may not be the case between translational and rotational diffusion. In turn, such individual contributions may be hardly identifiable in the relaxation dispersion unless the explored frequency range is extended up to a Larmor frequency well above the inverse of the involved correlation times. Consequently, the effective relaxation rate can be, at least, considered as the sum of two different contributions: $(T_1)^{-1} = \left(T_1^{ODF}\right)^{-1} + \left(T_1^{IM}\right)^{-1}$, where T_1^{IM} stands for the individual molecular dynamics.

In nematics, the typical $\omega^{1/2}$ law was observed for the first time in p-azoxyanisole PAA [9]. This study was later extended to very low frequencies as well as other compounds [29,35–38]. However, the relevance of local magnetic fields and hardware setting was only better understood in recent times [4,39,40]. Summarizing these experimental results:

- The typical square root law (Pincus' model) is found to be dominant in the T_1 dispersion within the kHz frequency range.
- In the MHz range, individual molecular motions dominate T_1.
- The change in tendency of the dispersion within the kHz region depends on different parameters related to the hardware setting and the nature of the local fields.
- The low frequency plateau is mainly due to the unavoidable presence of the local fields.

In the SmA phase, the typical relaxation dispersion looks nearly flat till a minimum frequency of about 20 kHz, where a noticeable steep down dispersion appears up to a low frequency plateau. The steep dispersion was currently attributed to ODF through a ω^1 dispersion law, while the low frequency plateau, usually between 300–800 Hz, interpreted in terms of the cut-off of the ODF modes. At higher frequencies than the starting point of the steep decay (30 kHz–10 MHz), the T_1 frequency dependence is minor. This behavior was normally explained in terms of individual motions with a dominant role of the translational diffusion, although this interpretation is based on the ω^1 law for T_1 due to ODF.

By means of two independent experiments, it has been recently shown that the strong dispersion observed in the low frequency regime in the SmA phase is not due to ODF, but a conjunction of experimental pitfalls and the strong local fields present in smectic phases [41].

When equation (10) is used to explain the contribution of ODF in the SmA phase, the frequency dependence of T_1^{ODF} becomes very similar to the diffusive one, thus turning difficult the identification of each of them. Lately, studies of relaxation dispersions under sonication shed light on this topic [42].

Ultrasound Induced Relaxometry

When sound is applied to a mesomorphic specimen, the acoustic perturbation induces density fluctuations. A coupling is established between ODF and the acoustic field through this process. A new free energy term associated with molecular reorientation in uniaxial mesophases was recently proposed on experimental [43] and theoretical grounds [44]. In the following, the problem we will consider concerns how relaxation dispersions due to ODF can be modified under the influence of sonication. For the sake of simplicity, only ultrasonic waves parallel and perpendicular to the director will be treated. Henceforth, signs between parenthesis stand for perpendicular waves.

The interaction energy between an acoustic wave and the director $\widehat{n}$ is given by [43,44]:

$$f_a = \frac{1}{2} a^2 \left(\widehat{s}.\widehat{n}\right), \tag{11}$$

where a^2 depends on the acoustic intensity, the ultrasound velocity, the average of the sample density, the magnitude of the ultrasound wave vector and the director-density coupling. In the last equation, $\widehat{s}$ represents the ultrasound wave unitary vector and $\widehat{n}$ the director. The last equation results after averaging over fast oscillations of the ultrasonic waves [44].

If an ultrasound wave propagates across the liquid crystalline media parallel (perpendicular) to the magnetic field, the fluctuations of the local director decrease (increase) f_a by:

$$\Delta f_a = -(+)\frac{1}{2} a^2 \left(n_x^2 + n_y^2\right). \tag{12}$$

Adding this free energy term to the equation (5), a closed expression for the modified dispersion ($T_1^{ODF+S}(\omega)$) can be obtained [45]. In the simplified nematic one constant approximation, this result reduces to [43,45]:

$$T_1^{ODF+S}(\omega) \propto \frac{\sqrt{\sqrt{1+(\omega\tau_0)^2} - (+)\,1}}{\sqrt{\tau_0}}, \tag{13}$$

while for the smectic simplified case ($K_3 \ll K_1 = K_2$), the following expression is obtained:

$$T_1^{ODF+S}(\omega) \propto \sqrt{1+\frac{1}{(\omega\tau_0)^2}} \times \frac{\omega}{\pi + (-)\,2\arctan\left(\dfrac{\dfrac{1}{\omega\tau_0}}{\sqrt{1+\dfrac{1}{(\omega\tau_0)^2}}}\right)}. \tag{14}$$

In the last two equations, $\tau_0 \equiv \frac{\eta}{a^2}$.

When the acoustic term is considered in the model where the coupling between smectic order with director fluctuations is taken into account, the expression obtained for $T_1^{DF+S}(\omega)$ becomes very complex [42,45]. Main remarks about the results of the model are:

- In the limit of zero acoustic intensity ($a \to 0$, $\tau_0 \to \infty$), the three results tend, respectively, to the Pincus' model, the linear model and equation (10).
- Parallel sound waves enhance the relaxation by ODF, while the opposite behavior is observed for normal incidence.
- More remarkable changes (respect to the non-sonicated case) manifest at lower frequencies.
- Main assumptions of the model are (a) the existence of a preferential macroscopic orientational order induced by the magnetic field, (b) time averaging over fast oscillations of the density and (c) the sound power (in the case of parallel irradiation) is low enough to prevent a violation of the low angle approximation.

This model has already been successfully contrasted with experimental data in nematics [43,46] as well as in SmA compounds [42]. Typical results of relaxometry experiments using the field cycling technique under the simultaneous irradiation with ultrasonic waves can be observed in Figures 1 and 2. Experimental data and model fitting (or simulations) are shown for nematic and smectic compounds at both, in the presence and absence of sonication.

The ultrasound-induced changes in the T_1 dispersion observed in nematics can be characterized by:

- A decrement in the characteristic slope of the dispersion (as observed in the logarithmic plots). The effect is stronger within the lower frequency range and for higher ultrasonic powers.

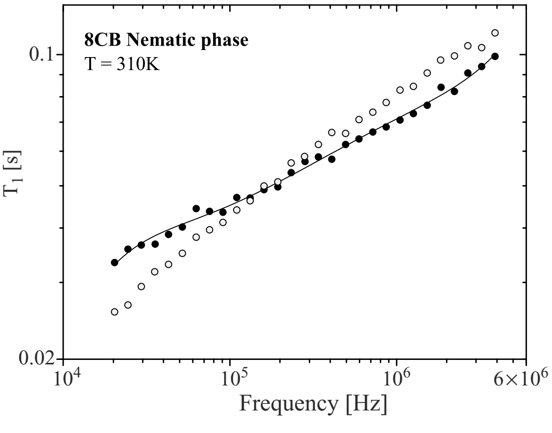

Fig. 1. Frequency dependence of T_1 in nematic 8CB at 310K in the absence (hollow circles) and the presence (filled circles) of ultrasonic waves. The fitting curve corresponding to the later case is also shown.

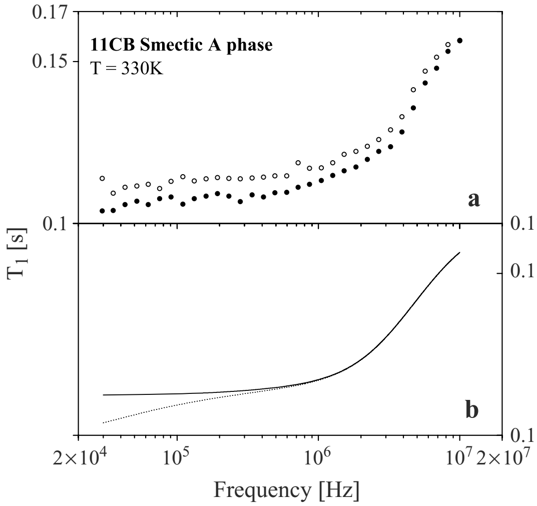

Fig. 2. T_1 dispersion experimental data (a) and simulated curves (b) for 11CB at the smectic temperature of 330K in the presence (filled circles and dotted line) and the absence (hollow circles and solid line) of ultrasonic waves.

- A nearly uniform relaxation enhancement within the whole observed Larmor frequency window.

Only the first effect is predicted by the model. The second effect may be a consequence of changes in the viscoelastic properties induced by the sound [46]. A similar behavior was encountered in the SmA phase.

Most notably, in cases where the smectic ODF relaxation model (and not the simplified versions) has to be considered, an enormous dilemma comes up [42]. The similitude between ODF frequency dependence with those contributions due to individual relaxation mechanisms has an ominous consequence for standard relaxometry: collective and individual processes cannot be identified in the dispersion. The matter can be fortunately circumvented by the fact that only ODF couple with the sonic field, allowing the selective enhancement of its relative contribution and changing the associated frequency dispersion. Consequently, both contributions can be separated. Unlike the nematic case, the T_1 relaxation dispersion in the SmA phase of cyanobiphenyls seems to be mainly driven by individual motions. For this reason, the observed sound-induced changes are less important than in nematics.

Outlook

The study of NMR relaxation with simultaneous sonication provides a new tool for the investigation of collective dynamics in mesomorphic systems. A topic of high interest is, for instance, how a sonic field can be used to influence an ordered molecular arrangement thus changing the rheological properties of the assembly. Within this picture, NMR relaxometry can be used to monitor sound-induced dynamical features that take place at microscopic level, as a means of achieving a comprehensive description of the involved processes. The main advantage of this newly proposed method relays in the possibility of disentangling between different mechanisms that cannot be identified in a simple T_1 dispersion experiment. From a technical standpoint, the evolution of this *acoustically stimulated relaxometry* technique encourages further instrumental development. A challenging task is, for instance, the design of special combined NMR and sonication probes, allowing to scan the acoustic frequency, while keeping a precise control of the involved acoustic parameters. On a different way, the study of other NMR relaxation parameters like T_{1D} or $T_{1\rho}$ under sonication looks appealing for many reasons. Firstly, it may allow to display the involved information in terms of a different spectral density set. Secondly, with a careful experimental management, individual and collective contributions may be selectively filtered out. A deeper discussion on this topic is left for future work as being matter of current active development.

Acknowledgment

The authors are indebted to Professor Rainer Kimmich (Ulm University, Germany) for fruitful discussions and for a successful scientific collaboration. Characterization of Elastomers Based on Monitoring Ultraslow Dipolar Correlations by NMR

Farida Grinberg
Universität Leipzig, LinnéStraße 5, D-04103 Leipzig, Germany

Introduction

Owing to enormous industrial use, elastomers remain an important field of intensive NMR studies [1–15] since more than three decades. The major goal is to establish a correlation between the molecular structure, molecular dynamics and the macroscopic mechanical properties of final materials. On this basis, material properties can be tailored using an optimization of the technological procedures and an application of cross-linking agents and special additives [16,17].

Undisputable advantage of NMR in comparison to other conventional methods of material characterization (like swelling or stress–strain measurements [16,17]) is that it is fully non-destructive and does not require any special sample treatment. Various NMR methods proposed as the characterization tools are based mainly on probing stochastic molecular motions via the measurements of the line shapes, nuclear magnetic relaxation rates and translational displacements.

At room temperatures, the NMR response of elastomers is predominantly determined by the so-called residual dipolar couplings (RDCs). Finite RDCs are characteristic of many "soft" materials like liquid crystals or polymers in which molecular motions are restricted by anisotropic molecular alignment or topological constraints [18,19]. In isotropic non-viscous liquids, in contrast, dipolar interaction are averaged out completely [20,21]. In polymers, restrictions to chain re-orientations arise owing to the excluded volume effects or "entanglements". The constraints of this art can also be produced artificially by confining polymeric materials in the nanoscopic pores [22,23]. In rubber, especially severe constraints on isotropic chain re-orientations are imposed by chemical cross-links. The consequence is that any fast chain fluctuations between the cross-links remain strongly anisotropic in the time scale of typical NMR experiments and cannot completely average out the secular part of the dipolar Hamiltonian. This feature is exploited in various experimental NMR approaches deployed in study of elastomers.

The influence of topological constraints on "residual" dipolar fluctuations was elaborated many years ago in works by Cohen-Addad [1–4]. In these works, a given chain is assumed to have a mean position in space which is determined by the cross-links and/or the constraints formed by the so-called chain entanglements. The chain is described in terms of N freely jointed Kuhn (or statistical) segments of length b. If chain meshes between the cross-links are not too long, an end-to-end vector $\boldsymbol{R}$ is determined mainly by the two adjacent cross-links. In the time scale of typical NMR pulse sequences, the mean orientation of the end-to-end vector can be considered as constant, whereas fast intrachain fluctuations tend to be anisotropically restricted in space. Averaging over fast fluctuations with respect to a local symmetry axis determined by the fixed vector $\boldsymbol{R}$ gives for the "residual" dipolar coupling constant in elastomers [4]:

$$\overline{\Omega}_d \approx \Omega_0 \frac{\boldsymbol{R}^2}{N^2 b^2}(1 - 3\cos^2\theta), \qquad |\boldsymbol{R}| = \boldsymbol{R} \ll Nb, \qquad (1)$$

where $\Omega_0 = 3\mu_0\gamma^2\hbar/(8\pi r_{kl}^3)$, r_{kl} and α_{kl} are polar coordinates of the internuclear vector, θ is the angle between the magnetic field and the vector $\boldsymbol{R}$.

Depending on the strength, the RDCs affect many measurable NMR variables in various ways. Interpretation in terms of RDCs was undertaken for experimental NMR line shapes and relaxation properties in cross-linked elastomers [5,24–26]. Later, a "sine" correlation echo function was suggested in Ref. [27] for monitoring weak residual dipolar interactions in stretched rubbers and "entangled" polymeric liquids [28]. Recently, elegant though more sophisticated approaches based on elucidation of multiple-quantum coherences were successfully explored both theoretically and experimentally for various elastomers [9,13]. A combination of frequency-dependent relaxometry with double quantum spectroscopy was elaborated in Ref. [15]. Some recent advances in studies of polymer chain dynamics with help of field-cycling NMR relaxometry and field-gradient NMR diffusometry were outlined in Ref. [22].

This review will concentrate on a simple efficient method usually referred to as the dipolar correlation effect (DCE) [29] and it's application to polymer elastomers [30–32]. The DCE arises in macro and microscopically

Graham A. Webb (ed.), Modern Magnetic Resonance, 1445–1453.

anisotropic liquids like liquid crystals, biological membranes, polymer melts and elastomers. Motions like ultra-slow orientational director fluctuations in liquid crystals [29,33,34] or reorientations of long chain backbones in polymer melts [35,36] can be probed via the DCE. In rubbers, molecular motions of this sort are associated with slow reorientations of long chain backbones spanned by the adjacent cross-links. The DCE proved to provide a valuable tool for materials characterization. In particular, it was shown to be sensitive to cross-link density in the series of synthetic elastomers and in natural rubber materials [30–32]. A new imaging procedure permitting one to directly visualize the mean squared dipolar fluctuation (MSDF) in spatially resolved maps [37] was developed on the basis of the DCE.

Background of the Dipolar Correlation Effect

The DCE [29,36] represents a specific relaxation mechanism produced essentially by modulations of RDCs due to ultra-slow anisotropic molecular motions. The relevant time scale of motions in question is that of the order of the interpulse spacings in the stimulated echo pulse sequence, that is, between a few microseconds and a few seconds in the case of protons. The upper limit is ultimately determined by spin–lattice relaxation and represents the longest time scale accessible to NMR techniques in general.

We consider systems where dipolar couplings of spin pairs represent dominating internal interactions. The aim is to monitor the effects of RDCs on the stimulated and primary echoes generated by a standard sequence of three 90°-radio frequency pulses [38,39]:

$$90^\circ - \tau_1 - 90^\circ - \tau_2 - 90^\circ. \tag{2}$$

The time intervals τ_1 and τ_2 denote the interpulse spacings between the first two and between the second and the third pulses, respectively.

A residual dipolar coupling constant (in angular-frequency units)

$$\Omega_d = \Omega_0 \langle (1 - 3\cos^2 \alpha_{kl}) \rangle \propto 1 - 3\cos^2 \theta, \tag{3}$$

remains after averaging pair dipolar interactions over motions fast on the time scale $t \ll \tau_1, \tau_2$. The brackets in Equation (3) denote the average with respect to the local symmetry axis of the system persisting on the much longer time scale. The quantity Ω_d in Equation (3) has then a finite value determined by an angle between an external magnetic field and that direction. In the case of elastomers, the local symmetry axis is determined by the vector connecting the two adjacent cross-links, so Ω_d becomes identical with $\overline{\Omega}_d$ in Equation (1).

In contrast to non-viscous liquids, where any dynamical motions are very fast, the RDCs in soft materials tend to additionally be modulated on the time scale of the interpulse intervals by much slower motions. Examples of such ultra-slow motions are given by orientational director fluctuations in liquid crystals [18], the "reorientaions mediated translational diffusion" mechanism in geometrically confined liquids [36] or cross-link fluctuations in rubber materials. The effects produced on echo amplitudes by this kind of motions is referred to as the DCE.

Experimentally, the DCE is elucidated by measuring the quotient of amplitudes of the stimulated, A_{st} and the primary, A_{pr}, echoes at the time points $2\tau_1 + \tau_2$ and $2\tau_1$ of their maximal refocusing, respectively. The quotient

$$\frac{A_{\mathrm{st}}(2\tau_1 + 2\tau_2)}{A_{\mathrm{pr}}(2\tau_1)} = Q_{\mathrm{dc}} \tag{4}$$

is then usually analyzed as a function of τ_1 for a constant value of τ_2. Varying τ_2 as a parameter then produces a set of the experimental curves $Q_{\mathrm{dc}}(\tau_1, \tau_2)$.

Equation (4) implies that ultra-slow dipolar fluctuations of interest are statistically (quasi)-independent of those due to fast internal molecular motions, that is, motions with correlation times short on the time scale determined by the pulse sequence (2). The parts of the transverse relaxation due to slow and fast types of fluctuations are then factorized. The attenuation factors associated with fast fluctuations (that is, "ordinary" relaxation dominating in non-viscous liquids) consequently cancel in the quotient since they are equal for both the primary and the stimulated echoes. The longitudinal relaxation depends only on the time interval τ_2 and does not affect $Q_{\mathrm{dc}}(\tau_1)$ normalized for $\tau_1 \to 0$. Equation (4) further anticipates a validity of quasi-static conditions for a coherence evolution due to single particle local resonance offsets. That is, spins are assumed to experience the same local resonance offsets during the initial and the final evolution intervals providing a complete refocusing of echoes at the times of their maximal amplitudes. This requires in practice that magnetic field inhomogeneities are sufficiently small in order to ignore effects of translational molecular or spin diffusion [40,41]. As mentioned above, pair dipolar couplings are assumed to dominate all other internal interactions, so that any cross-relaxation [21,42,43] processes between chemically in-equivalent local environments are also of negligible importance (or compensated otherwise).

The DCE manifests itself as an attenuation of the dipolar-correlation quotient $Q_{\mathrm{dc}}(\tau_1)$, Equation (4). Given a Gaussian distribution of resonance frequencies the latter takes a form [29]

$$Q_{\mathrm{dc}} = \exp\left\{-\frac{1}{4}\left\langle\delta\Omega_d^2\right\rangle C_1\right\} \left(1+\overline{\cos(\langle\Omega_d\rangle\tau_1)}\exp\left\{-\frac{1}{2}\left\langle\delta\Omega_d^2\right\rangle C_2\right\}\right). \quad (5)$$

Here $\delta\Omega_d$ is the part of "residual" dipolar coupling constant, Ω_d, fluctuating on the time scale of the experiment about its mean value, $\langle\Omega_d\rangle$,

$$\delta\Omega_d(t) \equiv \Omega_d(t) - \langle\Omega_d\rangle. \quad (6)$$

Coefficients C_1 and C_2 are functions of the time intervals τ_1 and τ_2 and of the characteristic times of dipolar correlations. In the case of an exponential correlation function

$$g(t) \equiv \frac{\langle\delta\Omega_d(0)\delta\Omega_d(t)\rangle}{\left\langle\delta\Omega_d^2\right\rangle} = e^{-|t|/\tau_c}, \quad (7)$$

with the correlation time, τ_c, these coefficients read [29]

$$C_1 = \tau_c^2\left(e^{-\tau_1/\tau_c}-1\right)^2\left(1-e^{-\tau_2/\tau_c}\right) \quad (8)$$

$$C_2 = \tau_c^2\left(e^{-\tau_1/\tau_c}-1\right)^2 e^{-\tau_2/\tau_c}. \quad (9)$$

The analytical expressions for C_1 and C_2 for other types of correlation functions can be found in the literature [29,35].

The mean coupling constant has a finite value proportional to the order parameter

$$\langle\Omega_d\rangle \propto \langle 1-3\cos^2\theta(t)\rangle. \quad (10)$$

The bar over the cosine term in Equation (5) denotes the average over all orientations of local directors. In macroscopically ordered uniform systems in which the order parameter does not vary over space, it can be omitted. The attenuation curves in such systems are then subject to oscillations [29] with a frequency proportional to the macroscopic order parameter. In non-stretched polymer systems like rubber, orientations of local "directors" with respect to the external magnetic field are distributed in space. For the most common spherical distribution, the average $\overline{\cos(\langle\Omega_d\rangle\tau_1)}$ vanishes and Equation (5) reduces to

$$Q_{\mathrm{dc}} = \exp\left\{-\frac{1}{4}\left\langle\delta\Omega_d^2\right\rangle C_1\right\}. \quad (11)$$

More complicated situations are observed in systems in which RDCs are still finite but relatively weak. If chemical shift differences are of the same order of magnitude, the situation becomes favorable for cross-relaxation processes. These processes then easily give rise to additional undulations of spin echo amplitudes as a function of τ_1 [44,45]. Two mechanisms then interfere and the quotient of the stimulated echo and the primary echoes takes the form [31,44]

$$\frac{A_{\mathrm{st}}(2\tau_1+\tau_2)}{A_{\mathrm{pr}}(2\tau_1)} = Q_{\mathrm{dc}}A_{\mathrm{off}}, \quad (12)$$

where Q_{dc} is given by Equation (5) and A_{off} is the factor modulating amplitudes of the stimulated echo due to spin exchange

$$A_{\mathrm{off}}(2\tau_1+\tau_2) = 1-2P_aP_b(1-\cos(\Delta\omega\tau_1)) \times\left(1-e^{-\frac{\tau_2}{\tau_{ex}}}\right). \quad (13)$$

Here $\Delta\omega$ is the total frequency (chemical shift) difference between two spin states, P_a and P_b are the relative spin fractions in these states ($P_a+P_b=1$), and τ_{ex}^{-1} is the exchange rate depending on the efficiency of "residual" dipolar interactions. Equation (13) anticipates a "two-site" exchange model.

Undulations of the attenuation curves according to Equations (12) and (13) complicate the evaluation of the quantitative parameters of the DCE. This problem, however, can be overcome using a special modified pulse program [30,31] with the additional 180°-pulses permitting one to refocus any single particle local field offsets and cancel the modulation effect of spin exchange.

The DCE in Elastomers

In elastomers, the DCE was experimentally illustrated for a series of cross-linked synthetic poly-(styrene-butadiene) (SBR) networks [30] and natural rubber (NR) [31,32] as a strong attenuation of the quotient $Q_{\mathrm{dc}}(\tau_1)$. The influence of the cross-link density, swelling degree and the carbon black content was examined.

Besides the DCE, attenuation curves $A_{\mathrm{st}}(2\tau_1+\tau_2)$ as a function of τ_1 were affected by an additional strong modulation mechanism. The undulations of echo amplitudes observed in dry SBR and NR series could not be ascribed to any (macroscopic) ordering effects predicted by Equation (5), see cosine term, since investigated non-stretched rubber samples were macroscopically disordered. The latter was easily proven by the absence of any dipolar splitting in the corresponding proton spectra of the investigated samples. This obviously means that the macroscopic average $\overline{\cos(\langle\Omega_d\rangle\tau_1)}$ in Equation (5) vanishes. The observed undulation mechanism in both investigated sample series was actually identified with the cross-relaxation (spin exchange) between chemically in-equivalent protons of polymer chains.

In the case of NR samples, the oscillating behavior of the stimulated echo could be described on the basis of a simple two-site exchange model, Equation (13). The comparison of fitted values of $\Delta\omega$ with the chemical shifts observed in spectra permitted one to conclude that spin exchange occurs between CH and CH_3 (and/or CH_2) groups of polyisoprene chains. The exchange time was fitted to approximately 0.04 s. At the same time, the attenuation curves in swollen NR were free of any undulations. This indicates that spin exchange in swollen samples slows down drastically compared to that in dry materials as RDCs become much weaker.

In order to separate the contributions due to the DCE and spin exchange, a second experiment was performed using the modified pulse sequence [30,31]. The modified pulse sequence contains two additional π-pulses inserted in the middle of each free-evolution τ_1 intervals. Provided that spin exchange in the short τ_1 intervals is negligible, π-pulses refocus the phase shifts produced by spin interactions except those having a bilinear form. Spin exchange in the long interval $\tau_2 \gg \tau_1$ then does not affect the formation of the stimulated echo so that undulations described by Equation (13) vanish. The remaining attenuation of the dipolar-correlation quotient is due to the DCE only. This permits one to evaluate its quantitative characteristics by fitting the theoretical expressions to the experimental attenuation curves. An alternative approach permitting one to avoid spin exchange effects implies performing the experiments in low magnetic fields (see below).

In SBR samples, the theory, Equation (11), based on a power–law dipolar correlation function [30] was proved to provide reasonable fits to the attenuation curves of $Q_{\rm dc}(\tau_1)$. Before forming the quotient, the long-time tails of the individual (primary and stimulated) echo attenuation curves had to be subtracted. The observed tails were attributed to free chain ends or low-molecular weight constituents with a maximum percentage of 20%. This type of long tails was not detected in dry NR samples but showed up again when these samples were let to swell. In fact, there could be several reasons for the appearance of “slow” components in elastomers, see for instance Ref. [46] and references cited therein. This components are irrelevant for the DCE caused by slow re orientations of chain meshes. In this context one only needs to remember that attenuation curves consisting of two components must be decomposed in individual components before the quotient is formed. Ignoring this circumstance may produce strong distortions of $Q_{\rm dc}(\tau_1)$.

The exponent of the power-law correlation function was fitted in SBRs to ≈ 1.5 in coincidence with the previous finding for a melt of linear high molecular weight poly(ethylene oxide) [35]. The existence of ultraslow dynamics was supported by the results of the field-cycling relaxometry [36,47]. This powerful method permits one to probe molecular motional modes on the shorter ($t \ll 10^{-3}$ s), however, complementary time scale and can favorably be combined with the DCE. In combination, these two methods probe molecular motions on the time scale covering eight orders of the magnitude.

In NR samples, the best fits of Equation (11) to experimental attenuation curves, $Q_{\rm dc}(\tau_1)$, were obtained when using an exponential correlation function, see Equations (7–9). The experimental curves together with their fits are shown for four differently cross-linked samples in Figure 1. The samples are differentiated using the values of added sulfur, P_s. The cross-link density defined as the inverse of the number of segments $\tilde{N}$ between the nearest

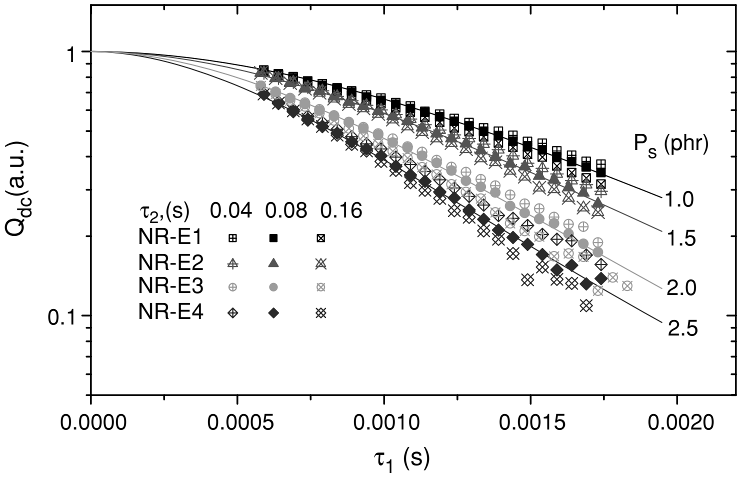

Fig. 1. Dipolar–correlation quotient, $Q_{\rm dc}$ of the stimulated and the primary echo amplitudes in samples of NR as a function of τ_1. The graph shows four sets of curves referring to the samples NR-E1—NR-E4 with different cross-link densities proportional to the sulfur content, P_s, as indicated. Each set contains three experimental curves measured at $\tau_2 = 0.04$, 0.08 and 0.16 s and fitted at one time. Solid lines are fits of Equations (11,8) to experimental data sets. Each solid line represents a corresponding set of three fitted curves which cannot be differentiated visually in a given graphic scale. The fit parameters were $\langle\delta\Omega_d^2\rangle$ and τ_c. The fitted values are listed in Table 1. All curves are normalized in the limit $\tau_1 \to 0$. (See also Plate 115 on page XV in the Color Plate Section.)

Table 1: Parameters of the Equations (11, 8) fitted to the experimental attenuation curves in dry and swollen samples of NR

	Dry	Dry	Swollen	Swollen
Sample	$\langle\delta\Omega_d^2\rangle$ $[10^6\text{rad}^2/\text{s}^2]$	τ_c[ms]	$\langle\delta\Omega_d^2\rangle$ $[10^6\text{rad}^2/\text{s}^2]$	τ_c[ms]
NR-E1	2.1 ± 0.4	4.2 ± 0.4	3.3 ± 0.2	1.3± 0.1
NR-E2	2.9 ± 0.2	3.3 ± 0.3	6.5 ± 0.3	1.3± 0.1
NR-E3	4.4 ± 0.3	2.6 ± 0.3	7.8 ± 0.5	1.5± 0.1
NR-E4	6.1 ± 0.8	2.0 ± 0.2	11.5 ± 0.1	1.2± 0.2

neighbour cross-links is proportional to added amounts of sulfur, P_s, [48], that is, $\tilde{N}^{-1} = \alpha P_s$ where α is the coefficient depending on a technological procedure and vulcanizing agents used. (Note that $\tilde{N}$ here refers only to the chemical cross-links and is not quite identical to N in Equation (1)). The four measured samples refer to different values of P_s equal to 1.0, 1.5, 2.0, and 2.5 given in mass fractions relative to the amount of polymer (or "rubber") used, that is, in "phr = parts per hundred rubber". In Table 1 these samples are denoted as NR-E1, NR-E2, NR-E3, NR-E4, respectively.

The curves in Figure 1 were measured using the modified pulse sequence and turned out to be completely free of any undulations. For each sample, a set of the curves was measured for several values of τ_2 ranging from 0.04 to 0.16 s. The fits were applied simultaneously to the whole set of the curves using just two fitting parameters, $\langle\delta\Omega_d^2\rangle$ and τ_c. The fitted values for dry and swollen samples are represented in Table 1.

The values of τ_c were fitted to a few milliseconds. This finding complies with the fact that the attenuation of the dipolar–correlation quotient tends to be independent of τ_2 since for $\tau_c \ll \tau_2$ the dependence of Q_{dc} on τ_2 in Equations (11,8) virtually vanishes. This is not true, as shown in Ref. [32], as soon as the measured range of τ_2 becomes shorter, below 10 ms, so that the condition $\tau_c \ll \tau_2$ does not hold. In this case a dependence of the dipolar–correlation quotient on τ_2 is distinct Ref. [32]. Again, the fits were applied simultaneously to the whole set of the curves using only two fitting parameters. This actually allowed one to confirm that a simple exponential correlation function complies indeed very well with the experimental data. Worth noting is that in materials in which a longitudinal relaxation is longer than a transverse one the application of the pulse sequence (2) has an essential advantage over the two pulse sequences. In the pulse sequence (2), two time variables τ_1 and τ_2 can be varied independently extending the overall time scale in which molecular motions can be probed.

The values of τ_c tend to decrease with increasing the cross-link density, that is, from sample NR-E1 to NR-E4. The correlation times in swollen samples were two to three times shorter than in dry rubber indicating much faster mesh chain fluctuations due to presence of small solvent molecules.

A strong dependence on the cross-link density was found for the second moment of the dipolar fluctuation $\langle\delta\Omega_d^2\rangle$. Both in dry and swollen samples, this quantity increases by a factor of ≈3 with increasing the cross-link density by a factor of 2.5. A similar effect was observed also for dry SBRs [30]. The carbon black used as a filler on the contrary does not seem to affect slow anisotropic chain modes in the elastomer: increasing of carbon black content by a factor of 2 did not produce any measurable effect on the attenuation of the dipolar–correlation quotient [31].

These findings comply with the results of Ref. [49]. In that work, effects of swelling, stretching and filling on molecular dynamics of NR samples were studied with help of the field-cycling relaxometry. It was shown that the dispersion curves of longitudinal relaxation rates alter significantly upon swelling and a uniaxial deformation. At the same time an addition of filler particles to the material was found to produce practiclly no effects on measured relaxation rates and thus underlying molecular dynamics at least at room temperatures.

As mentioned above, the DCE observed in elastomers is caused by the fluctuations of the chain meshes on the time scale exceeding $\approx 10^{-4}$s. It is reasonable to assume that on the time scale of the pulse sequence each given cross-link may undergo only small fluctuations around its mean position. The fluctuation of the residual coupling constant $\delta\Omega(t)$ then corresponds to the fluctuation of the mesh chain end-to-end vector around the average angle θ described in the "Introduction" Section. The characteristic time constant of this process in materials under consideration is thus estimated to be of the order of a few milliseconds.

The dependence of the MSDF, $\langle\delta\Omega_d^2\rangle$, on the number of segments between cross-links N can be estimated in two limits. If the meshes were completely stretched, that is, $|R| = R = Nb$, so that all Kuhn segments were parallel to R, the residual dipolar coupling constant and its mean squared fluctuation would be independent of N. The other limit is given by $R \ll Nb$. Using Equations (1) and (6) the mean squared fluctuation of the dipolar coupling constant reads [30]

$$\left\langle\delta\Omega_d^2\right\rangle \equiv \langle(\Omega_d(t) - \langle\Omega_d\rangle)^2\rangle \approx \Omega_0^2 \frac{R^4}{(N^2b^2)^2} \langle[(1 - 3\cos^2\theta) - \langle 1 - 3\cos^2\theta\rangle]^2\rangle. \quad (14)$$

If the dependence of $\langle[(1 - 3\cos^2\theta) - \langle 1 - 3\cos^2\theta\rangle]^2\rangle$ on N in Equation (1) is considered to be minor, the relation between $\langle\delta\Omega_d^2\rangle$ and N is determined simply by the function $R(N)$. The end-to-end distance of a random coil is distributed according to a Gaussian function. In the case of a freely jointed chain of Kuhn segments, the root mean square end-to-end distance is then given by $\sqrt{\bar{R^2}} \approx b\sqrt{N}$. In this case, the MSDF scales proportional to $1/N^2$, i.e.

$$\left\langle\delta\Omega_d^2\right\rangle \propto \frac{1}{N^2}. \tag{15}$$

The experimental findings in works [30,31] were compared to these limiting predictions. In the case of SBRs, the quantity $\langle\delta\Omega_d^2\rangle$ scales in the investigated cross-link density range as $\propto \frac{1}{N^{0.75}}$. For dry NR, the scaling exponent was considerably bigger, that is, $\langle\delta\Omega_d^2\rangle \propto \frac{1}{N^{1.3}}$ but still much smaller than that predicted by Equation (15). The conslusion was that mesh chains in both materials are more stretched than expected for a freely jointed mesh chain conformation. Scaling exponents observed for dry and swollen rubber appeared to be practically equal. This result was somewhat surprising considering that meshes in swollen rubber are expected to be more stretched than in dry.

The prediction for the MSDF as a function of the cross-link density was refined in Ref. [32]. It was demonstrated that the effects of topological constraints other than chemical cross-links must be taken into account. In Ref. [30,31] the comparison of the experimental findings with Equation (15) was done relying on the condition $P_s \propto \frac{1}{N}$, that is, only chemical cross-links were taken into account. Relevant for the DCE experiments, however, are not only chemical cross-links but also topological constraints that prevent a complete averaging of dipolar interactions on the experimental time scale.

The inverse value of N in rubber samples was tentatively decomposed into two contributions according to [50–52]

$$N^{-1} = \breve{N}^{-1} + \tilde{N}^{-1} = \breve{N}^{-1} + \alpha P_s \tag{16}$$

where $\breve{N}^{-1}$ is the density of the constraints other than chemical cross-links effective for the DCE. From Equations (15) and (16) it follows that

$$\sqrt{\left\langle\delta\Omega_d^2\right\rangle} \propto \breve{N}^{-1} + \alpha P_s = \sqrt{\left\langle\delta\Omega_d^2\right\rangle}_{P_s\to 0} + \tilde{\alpha} P_s \tag{17}$$

where $\tilde{\alpha}$ is a numerical coefficient, $\sqrt{\langle\delta\Omega_d^2\rangle}_{P_s\to 0}$ denotes $\sqrt{\langle\delta\Omega_d^2\rangle}(P_s)$ at $P_s \to 0$. Figure 2 shows the experimental results for $\sqrt{\langle\delta\Omega_d^2\rangle}$ as a function of $P_s \propto \frac{1}{N}$. A remarkable finding was that not only was the fitted value of $\sqrt{\langle\delta\Omega_d^2\rangle}_{P_s\to 0} = (1.65 \pm 0.3) \times 10^3$ rad/s finite but also it was approaching the value of $\sqrt{\langle\delta\Omega_d^2\rangle} = 1.97 \times 10^3$ measured for linear polyisoprene. In Figure 2 this value is represented by the point at $P_s = 0$. Linear highly viscous polyisoprene used in this study can be considered as a prototype of natural rubber at "zero" density of the chemical cross-links. The obtained results comply with the results obtained earlier for other linear polymer melts [28,35]. In that systems, the slow dipolar correlation effects are predominantly caused by the constraints due to topological constraints (excluded volume effects). The conclusion referring to rubber was that this kind of constraints is essential for slow dipolar fluctuations along with the chemical cross-links and that its contribution to the DCE is comparable to that in high molecular weight polymers.

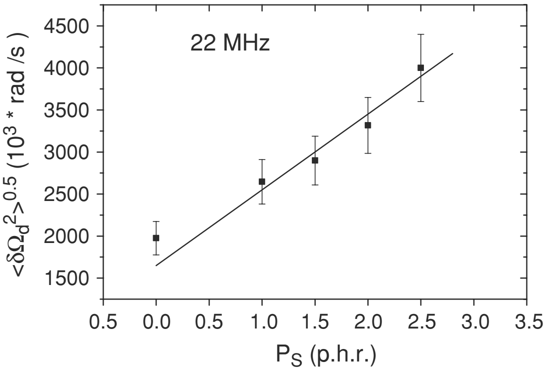

Fig. 2. Square root of the mean squared dipolar fluctuation, $\sqrt{\langle\delta\Omega_d^2\rangle}$, as a function of the amount of added sulfur, P_s. The cross-link density $1/\tilde{N}$ given by the number of segments per mesh is directly proportional to P_s. The solid line was fitted to the experimental data of rubber samples according to $\sqrt{\langle\delta\Omega_d^2\rangle} = K + \beta P_s$ with $K = (1.65 \pm 0.25) \times 10^3$ rad/sec and $\beta = (0.9 \pm 0.1) \times 10^3$ rad/(sec× phr).

A strong dependence of the DCE on the cross-link density of elastomers naturally suggests this method as a useful tool of a material characterization. On the other hand, the first works on the DCE in elastomers [30,31] were performed with a Bruker 300 and 400 MHz spectrometers not well suited for routine applications in industry because of high operating costs. Less expensive "mini"-spectrometers operating at much lower magnetic fields suggest a much better alternative for this purpose. Advantages and problems related with measuring the DCE in low magnetic fields was considered in Ref. [32]. One of the important issues that rises up in this context is the following. Although the DCE itself is virtually independent of the applied magnetic field, the relative contributions of other attenuation or undulation mechanisms may vary considerably with the external magnetic-flux density. This leads to certain peculiarities when performing the DCE experiment in low magnetic fields.

One of the findings of the study in Ref. [32] was that the low field DCE (at 0.52 T or 22 MHz) in dry NR measured using the standard pulse sequence (2) was not distorted by spin exchange modulations as it was the case with the high field measurements. The reason is that local resonance offsets due to chemical shifts scale linearly with the external magnetic-flux density. As a result, the corresponding period of modulations becomes much longer compared to the experimental range of τ_1 (limited by the transverse relaxation) and thus no modulation effects can be detected. Besides, this study revealed an advantage of having faster longitudinal relaxation compared to that in high magnetic fields. In NR for instance, the longitudinal relaxation time decreases from 800 ms at 400 MHz to 27 ms at 20 MHz. This permits one a reduction of the measuring time by more than one order of magnitude, which is greatly appreciated in the routine applications.

Imaging on the Basis of the DCE

NMR imaging is a well established tool in elastomer characterization [53–57]. An especially interesting application of the DCE in this context was demonstrated in Ref. [37], where the MSDF was used as a new parameter for NMR mapping.

The MSDF maps can be produced using the pulse sequence (2) combined with any scheme of the magnetic field gradients providing a spatial resolution (see, for instance, Refs. [53,36] or any other text books for NMR imaging). One of the appropriate pulse sequences is shown for example in Figure 3. The first 90°-pulse of the sequence might either be “hard” (if no slice selection is required) or “soft” (shaped) suited for selection of a particular sample slice.

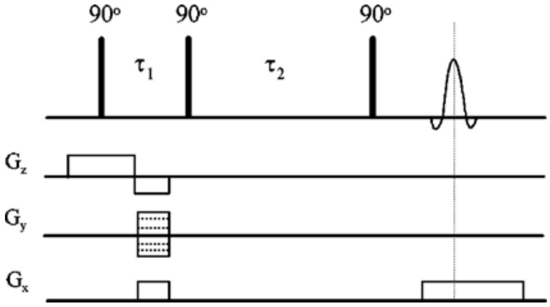

Fig. 3. Pulse sequence for measuring the MSDF maps. G_x, G_y and G_z denote the pulses of magnetic field gradients in X-, Y-, and Z- directions with Zeeman field applied along the Z-axis as usual. Signal amplitudes are acquired for the stimulated and primary echoes subject to maximal refocusing at $2\tau_1 + \tau_2$ and $2\tau_1$, respectively. In the case of the primary echo, τ_2 is set to zero and the third 90° pulse is omitted. The chemical-shift compensating version of the pulse sequence includes two additional 180°-pulses set in the middle of each τ_1-interval, that is, between the first two 90°-pulses and between the echo time and the preceding pulse.

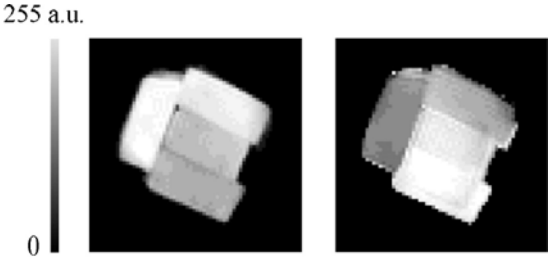

a) Relaxation weighted spin density image

b) $\langle \delta\Omega_d^2 \rangle$ - map

Fig. 4. RWSD image (a) and the MSDF map (b) of the sample consisting of four rubber stripes with different cross-link density. The RWSD image in (a) refers to the primary echo for $\tau_1 =$ 0.9 ms (echo time $2\tau_1 = 1.8$ ms). Each data matrix consists of 128×128 pixels. The in-plane pixel resolution is 78 μm in both directions. Field of view is 10 mm. The repetition time was 1 s. The range of the values measured for (a) the RWSD from 0 to 255 arbitrary units and for (b) $\langle \delta\Omega_d^2 \rangle$ from 1×10^6 to 5×10^6 rad^2/s^2 is displayed using the grey shade reference rulers shown on the left and on the right hand sides. The ruler assigns consistently decreasing grey shades (from black to white) to each of the 255 subsequent equidistant intervals covering the whole range of the measured values.

The primary and stimulated echo signals are acquired for a series of subsequently increasing τ_1-values, while τ_2 is kept constant. The dipolar–correlation quotients are formed to produce sets of values, $Q_{\mathrm{dc}}(\tau_1)$, for all pixels of the given map. The values of $\langle \delta\Omega_d^2 \rangle$ are evaluated for the individual pixels by fitting theoretical expressions, see Equation (5), to the obtained data sets. These values are then “visualized” in the grey shade or coloured MSDF maps.

Figure 4b demonstrates such an MSDF map of a composite sample consisting of the four rubber pieces with different cross-link density Ref. [37]. This sample models an inhomogeneous rubber object. The pixel values of the MSDF are “visualized” using grey shades related to the 255 equidistant intervals covering the whole range of the measured values. The values of $\langle \delta\Omega_d^2 \rangle$ evaluated for the corresponding areas of the map satisfactorily coincide with those found earlier for NR-E1—NR-E4 in the bulk measurements [31]. The regions with larger cross-link density (lower molecular mobility) are brighter according to their larger values of $\langle \delta\Omega_d^2 \rangle$, consider Equation (6). As it can easily be seen from Figure 4b, the MSDF map produces a clear contrast for the relevant regions.

Figure 4a shows for a comparison a conventional relaxation weighted spin density (RWSD) image of the same sample. It refers to the primary echo at echo time $2\tau_1 = 1.8$ ms. The RWSD images visualize the measured pixel signal intensity at this time point. It is proportional to initial magnetization attenuated by transverse relaxation. The contrast in the RWSD image in Figure 4(a) is obviously produced by the difference in the transverse relaxation rates of the different rubber stripes assuming that their initial magnetizations (proportional to proton density) are roughly equal. By the echo time, the corresponding magnetizations are attenuated stronger for the stripes with larger cross-link density resulting in darker regions. The contrast in the RWSD images depends on the experimental parameters (echo time in this case) as in any relaxation attenuated spin density images. On the contrary, single parameter MSDF maps enable one to visualize the areas with different orientational molecular mobility on the quantitative basis irrespective of the experimental parameters.

In studies of materials, the areas with reduced orientational mobility of molecules are quite often of a special interest. They may, for instance, indicate the aging processes in polymer elastomers. On the basis of the MSDF maps, the areas less mobile are favorably scaled up relative to more mobile regions. An additional advantage in the context of material characterization is that the DCE is not expected to be sensitive to the traces of low-molecular impurities or to motions like reorientations of the short free-end chains.

Worth noting is that in systems subject to slow correlated molecular motions, the overall transverse relaxation is generally not exponential [31]. Therefore, the conventional transverse-relaxation time (T_2) maps cannot be properly evaluated, as routinely done, on the basis of the Hahn echo attenuation curves. Mapping of the MSDF offers in such cases an alternative quantitative tool for the investigations of the heterogeneous objects exposed to ultraslow dipolar correlations.

Concluding Remarks

The experimental findings discussed in this paper suggest that the DCE represents an extremely useful tool of material characterization. In view of a strong dependence of the MSDF on the cross-link density of elastomers combined with the simplicity of performing the measurements with non-expensive low field NMR instruments, it can routinely be exploited for the determination of rubber cross-link density. The MSDF represents a new parameter of NMR mapping and can be used for visualizing material inhomogeneity and monitoring aging processes in rubber products. In studies of elastomer chain dynamics, the DCE is expected to be especially useful when favourably combined with other NMR methods like field-cycling relaxometry and field-gradient diffusometry.

Correlating Molecular and Macroscopic Properties of Elastomers by NMR Relaxometry and Multi-pulse NMR Techniques

S. Stapf, S. Kariyo and B. Blümich
Lehrstuhl für Makromolekulare Chemie, ITMC, RWTH Aachen, Worringerweg 1, D-52074 Aachen, Germany

Introduction

Making use of NMR techniques for the characterization of elastomers poses the problem of identifying a connection between a parameter accessible to NMR and the material property of interest. Due to the origin of interactions affecting the NMR signal, this provides a link between the molecular level and the macroscopic scale. Understanding these links, and developing suitable experimental techniques for their investigation, also addresses the fundamental issue of the dynamics of macromolecules which is still a topic of extensive research with many open questions remaining. However, encoding these molecular properties within an NMR imaging sequence eventually allows the generation of parameter maps, which can be used for quality control of technical elastomers in the production process or under external constraints (deformation, aging, failure).

Spectra and relaxation times represent the simplest parameters with which material properties of elastomers can be correlated. They relate to either static or dynamic molecular properties, or combinations thereof. Considerably more information is contained in parameter sets which include one further dimension; this might be a second encoding leading to a 2D spectrum, or the dependence of the relaxation process on a certain time or frequency scale. The term "relaxometry", sometimes used in the general sense of providing any kind of relaxation information of a sample, was initially coined for the interrogation of the relaxation *spectrum*, i.e. the dependence of the longitudinal relaxation time on the Larmor frequency, and hence magnetic field strength [1]. The shape of such a relaxation dispersion curve contains information about molecular dynamics over the covered frequency scale. Related, but different, information is retrieved from measurements of the transverse relaxation time with a time-axis added, such as obtained by a CPMG sequence with variable pulse separations.

A different, less easily defined microscopic property is the concept of "order". It includes both static and dynamic aspects, because order, usually attributed to the relative orientation of atoms or molecules, depends on the time scale which is interrogated. It is thus less suitable to provide absolute and intuitively interpretable results, but can be equally powerful as a contrast parameter.

Published works highlight different aspects of the microscopic/macroscopic link in the investigation of elastomers, hereby employing a broad range of experimental techniques which go beyond the simple analysis of spectra and lineshapes:

The incomplete averaging of the dipolar interactions which is brought about by the presence of entanglements and cross-links can be quantified by exploiting the time dependence of a particularly encoded parameter in a multi-pulse sequence. Cohen-Addad [2] has proposed to extract quantitative information about couplings from combinations of solid echo and FID decays; Callaghan and Samulski have developed a related sequence that directly visualizes dipolar couplings and suppresses Zeeman effects [3,4]. Grinberg *et al.* determined the dipolar correlation effect for long evolution times based on stimulated echoes [5]. Multi-quantum encoded signals were correlated with elastomer properties [6,7] and were combined with imaging [8,9] and low-field realizations [10]. Measurements of the transverse and longitudinal relaxation times [11–14] of elastomers focussed on the dynamical aspects of the molecular motions, and correlations with material properties were established [15]. First results of relaxation dispersions in permanent and thermoreversible networks were presented [16,17], and recent investigations were carried out on elastomers employing the frequency dispersion of T_1 [18,19] and $T_{1,\rho}$ [20,21].

This overview is by no means complete, but provides some ideas of the "NMR toolbox" being available to cover" questions related to the behavior and quality of rubbery materials.

Theoretical Background

A general formulation of the dependence of the longitudinal relaxation time on Larmor frequency ω can be written

Graham A. Webb (ed.), Modern Magnetic Resonance, 1455–1461.
© 2008 *Springer.*

as follows:

$$T_1^{-1}(\omega) = C[\mathcal{I}(\omega) + 4\mathcal{I}(2\omega)] \tag{1}$$

where the constant C depends on the kind of interaction, e.g. dipolar or quadrupolar. The equation is correct for quadrupolar interactions, and in the case of like spins for dipolar relaxation. It has to be modified for dipolar coupling between unlike spins or for other types of coupling. Similar expressions are found for the transverse relaxation time T_2, and the longitudinal relaxation time in the rotating frame $T_{1,\rho}$.

The frequency dependence is introduced by the spectral density function $\mathcal{I}(\omega)$ describing reorientational motions which are responsible for the relaxation process. $\mathcal{I}(\omega)$, in turn, represents the Fourier transform of the autocorrelation function $G(t)$:

$$\mathcal{I}(\omega) = \int_{-\infty}^{\infty} G(t)e^{-i\omega t} \ . \tag{2}$$

For the most important case of dipolar relaxation, $G(t)$ is obtained from the time-dependence of fluctuating functions describing the orientational dependence of the spin-operator components in the dipolar Hamiltonian [1]. It should be kept in mind that "motion" of a polymer or an elastomer is parametrized via the reorientation of its segments, while other methods, e.g. PFG NMR diffusometry, use the lateral displacement as a parameter. This can explain method-dependent differences in the description of the time-dependence of motion.

Most models, which had been developed for the segmental reorientation, avoid a detailed analysis of the dynamics on an atomic scale and consider the motion of segments like the *Kuhn segment* as a whole. This is justified for two reasons. First, the molecular structure itself influences only the absolute value of the relaxation time and its frequency dependence in a range, which is not of interest for understanding the dynamics of the chain molecule, and also often inaccessible by the experiment. Second, the mechanism of spin diffusion leads to an averaging of the magnetization of individual protons in one segment, so that an average T_1 is found for a microscopically homogeneous sample, which is subject to ensemble averaged reorientations of the segment. This is no longer true for microscopically heterogeneous samples (e.g. block copolymers) or for relaxation of deuterons, where spin-diffusion is inefficient, resulting in multi-component relaxation decays.

The simplest case of an autocorrelation function is an exponential with an average correlation time τ_c, $G(t) = \exp(-t/\tau_c)$. It describes well the rotational contribution to relaxation in liquids. Its Fourier transformation is the Lorentzian, $\mathcal{I}(\omega) = \tau_c(1 + \omega^2\tau_c^2)^{-1}$, containing a frequency-dependent term which becomes much smaller than unity for liquids of low viscosity, hence the absence of a frequency dispersion. This is, of course, no longer true for polymers and elastomers which are known to show a wide spectrum of motion as found with many experimental techniques. The description of molecular motion in elastomers starts from models for polymer melts and solutions where several theories are available. Examples are the well-known reptation approaches by de Gennes [22,23], Doi and Edwards [24], and the mode-coupling ansatz by Schweizer [25]. In a nutshell, they all predict characteristic power–law dependences of the mean-squared displacement on time, and similar power-laws were proposed and indeed measured for the spectral density function of nuclear relaxation [16,26,27]. From these works, power-law relations of $T_1(\omega) \propto \omega^\gamma$ with $\gamma = 0.5$, $\gamma = 0.2 \ldots 0.25$ and $\gamma = 0.45 \ldots 0.5$ are expected in a succession from high to low frequencies.

A detailed discussion of these different regimes is beyond the scope of this article. The phenomenological description serves mainly as a starting point to demonstrate how these relations are affected in an elastomer, and how experimental results can be employed for a characterization of material properties. In this sense, the elastomer is regarded not as a "soft solid", but as a melt with additional geometrical constraints in the shape of permanent cross-links. The consistency of the experimental results supports this notion.

Relaxometry Experiments

The determination of relaxation times over a wide range of frequencies almost always requires the use of a magnetic field of variable strength. This is particularly true for the low-field region ($B_0 \ll 0.1$T), where signal intensity becomes critical. In a so-called *field-cycling* experiment, polarization and detection occur at (not necessarily equal) high fields, and the sample is exposed to the desired lower field for the relaxation period in between these two stages. In principle, either the sample can be moved mechanically between regions of different fields [28], or the current in the magnet is varied directly [29,30]. The latter method usually allows faster field changes and consequentially the determination of shorter relaxation times, which is often crucial for elastomers. For the studies presented here, relaxometry measurements were performed on a commercial Stelar Fast Field Cycling Relaxometer (Stelar s.r.l., Mede, Italy) which allowed the determination of longitudinal relaxation times at ^{1}H Larmor frequencies between 5 kHz and 20 MHz, providing field switching times of 1.3 ms. Signal decays were found to be monoexponential over more than one decade; the relaxation times were reproducible within 1%, the temperature stability was ±0.1 K.

Figure 1 demonstrates the principle shape of the dispersion curves for isoprene rubber and butadiene rubber

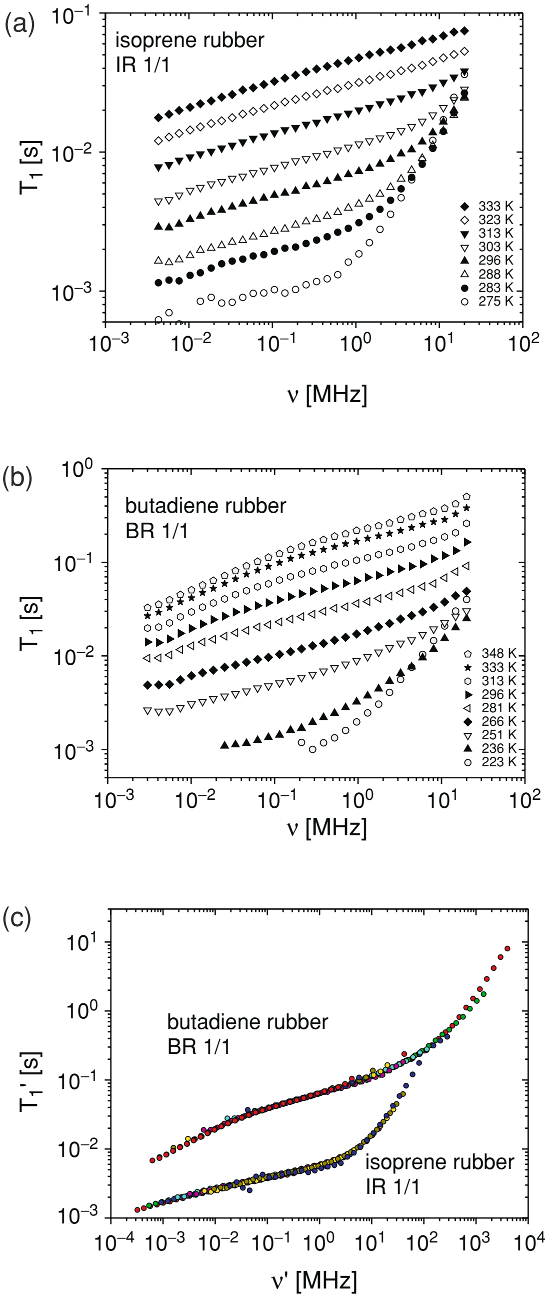

Fig. 1. Frequency-dependent relaxation times $T_1(\nu)$ for elastomers of low cross-link density as a function of temperature: (a) isoprene rubber; (b) butadiene rubber; (c) master curves relative to $T_0 = 296$ K derived from (a) and (b) applying shifts according to the WLF equation.

with low cross-link density (1 phr of sulfur and accelerator each, unfilled samples), and their dependence on temperature. It employs a double-logarithmic scale where a power–law relationship is identified by a line of constant slope γ. All dispersion curves can be approximated by a succession of power–laws. The changing shape of the curves with temperature can be explained by a shift along the frequency axis. Displacing the curves by empirically found shift parameters [31] according to the Williams–Landel–Ferry (WLF) equation

$$\log a_T = -C_1(T - T_0)/(C_2 + T - T_0) \,, \qquad (3)$$

where a_T is the shift factor relative to a reference temperature, T_0, one obtains *master curves* which cover a larger portion of the spectrum $\mathcal{I}(\omega)$. The master curves for the two different elastomers are compared in Figure 1c.

The data shown in Figure 1 for weakly cross-linked elastomers are qualitatively similar to those of the uncross-linked polymers (see [16,18]), only minor shifts relative to the melt relaxation curves are found but the exponents γ remain the same. One finds, in order from high to low frequencies, $\gamma \approx 1.15$, $\gamma = 0.24 \pm 0.01$ and $\gamma \approx 0.45$ for butadiene rubber (BR), and $\gamma = 1.23 \pm 0.07$ and $\gamma = 0.16 \pm 0.01$ for isoprene rubber (IR), respectively. The highest values are a consequence of semi-local (within the Kuhn segment) reorientations [18]; the small values observed for both elastomers describe frequency scales on which the fluctuation amplitude is sufficiently large to make geometrical constraints become effective for the individual chain; the lowest frequency range, only covered in part for BR (but reported for IR at higher temperatures [27,32]) denotes the onset to coherent chain motion. Only the latter is expected to be strongly affected by the presence of cross-links, but no clear evidence for such an effect has been found so far from the limited range of data of BR and polybutadiene melts. It should be noted that the particularly small value of $\gamma = 0.16$ found for IR is indeed a characteristic feature of the polyisoprene chain and has been investigated in some detail [18,19,33]. Like the other exponents, it is not changing due to cross-linking effects.

Note that the change of relaxation times in the low-frequency region is very sensitive to temperature changes, particularly so for IR. With the reproducibility of the data given above, this allows the indirect determination of temperature with a precision of 0.1–0.2 K from a single experiment, being improved by obtaining a full dispersion curve. This information is not available from high-field experiments where the temperature dependence of T_1 becomes much weaker. It is, however, accessible from T_2, and corresponding experiments of T_2 parameter images on rubber were suggested as a means of temperature mapping [34].

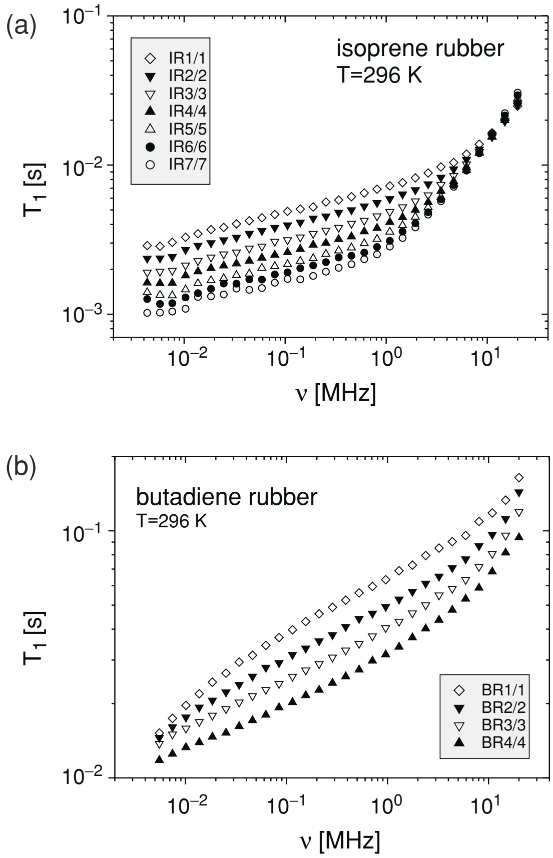

Fig. 2. Frequency-dependent relaxation times $T_1(\nu)$ at T $= 296$ K as a function of cross-link density (numbers indicate sulfur/accelerator content in phr): (a) isoprene rubber; (b) butadiene rubber.

The most important parameter for the characterization of elastomers is the cross-link density. Figure 2 shows the effect of increasing cross-link density at constant temperature for IR and BR. It is seen immediately that the relaxation times sharply decrease with increasing cross-link density. For IR, almost equidistant lines appear for relative sulfur concentrations between 1 and 7 phr. The dispersion curves, however, are not simply displaced vertically but follow the same WLF-type shift as observed from measurements at different temperatures. It is indeed possible to construct another master curve. The reason for this behavior is found in the dependence of the glass transition temperature, which enters into the WLF equation, on cross-link density. In a systematic investigation of several types of elastomers, Herrmann *et al.* have used the connection between glass temperature and T_2 at constant field for an estimation of cross-link densities [15]. From the dispersion data presented here and in [18,19], an estimated precision in the determination of the cross-linked sulfur of 0.1 phr or better seems feasible for IR. Regarding the absolute difference between T_1 values, the intermediate frequency range between 100 kHz and 1 MHz provides the best contrast as a function of cross-link density; this range is, in practice, only accessible by field-cycling relaxometry.

Once a correlation between relaxation times and cross-link density is established, one can continue with deforming the elastomer out of its equilibrium conformation. The first possibility is a static deformation experiment, i.e. stretching or compressing the sample. The deformation induces order on the molecular scale, which generates anisotropy in the spectral features. One can expect that relaxation itself also becomes angle-dependent, a fact that has been demonstrated for transverse relaxation times in stretched [10] and compressed samples [35]. Indeed, clear evidence for a possible angular dependence of T_1 was not found, but the dispersion curves obtained from IR samples deformed either parallel or perpendicular to the magnetic field axis show a surprising feature [18,19], see Figure 3. While T_1 values at high field remain indistinguishable, the curves diverge and stretching results in an increase in the value of the power–law exponent itself. The difference is small but significant, amounting to a change from $\gamma = 0.16$ to $\gamma = 0.24$ for IR stretched to $\lambda = 7$ and from $\gamma = 0.24$ to $\gamma = 0.28$ for SR for which extension was only obtained at $\lambda = 2$. The IR results indicate that the beginning of divergence is shifted to higher frequencies as temperatures are increased, making the difference more easily observable at low fields. From simple geometrical considerations, deformation of the local environment of the polymer chain should only affect the frequencies of transition between different power–law regimes, but not the statistical properties themselves. However, there are indeed strong indications that an actual change of the shape of the correlation function of reorientation, $G(t)$, can be made responsible for the observed effect.

Finally, the effect of the addition of solvents is demonstrated in Figure 4. Equilibrium swelling conditions have been reached for IR in different mixtures of a bad (ethanol-d6) and a good solvent (toluene-d8), being equivalent to weight increases between 4% and 439%. A gradual transition from a power–law behavior to Rouse dynamics, which is characterized by a logarithmic relation between T_1 and frequency [16], is found; the same qualitative observation has been made for polyisoprene melts with equivalent solvent contents (data not shown). Only at high degrees of swelling, the residual weak dispersion found for the elastomer becomes distinguishable from the solution where the frequency dependence of T_1 all but disappears. We present the results of Figure 4 mainly for pointing out the high sensitivity of the low-field relaxation

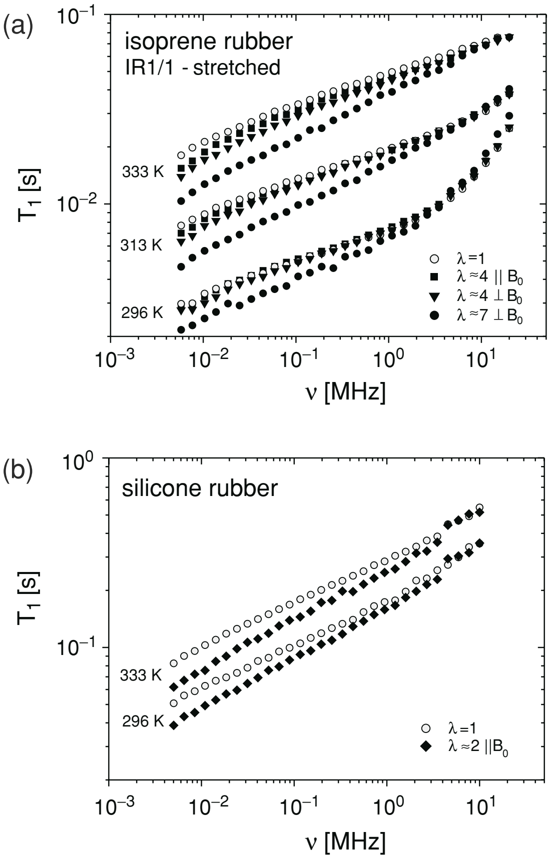

Fig. 3. Frequency-dependent relaxation times $T_1(\nu)$ at different temperatures for elastomer samples stretched parallel or perpendicular to B_0: (a) isoprene rubber IR1/1; (b) silicone rubber.

time to the presence of small amounts of solvent. Even for a weight increase of only 4%, T_1 increases for up to 30% at low fields so that the method allows, in principle, to determine solvent concentrations of well below 1%. A series of experiments with internal plasticizers as additives showed no measurable effect, but changed the behavior in T_2. The method can thus be useful for discriminating contaminants in elastomers at a low concentration.

Double Quantum Experiments

The determination of dipolar coupling constants provides further, and potentially complementary, information about the material properties of elastomers, and shall be presented briefly for comparison. Homonuclear (proton) dipolar couplings can be obtained, for instance, from double quantum (DQ) filtered spectra. The double-quantum coherences are encoded by at least two successive rf pulses and need to be reconverted into single-quantum (observable) coherences by a further pulse, with appropriate phase cycling selecting the correct coherence pathways to avoid "contamination" with unwanted signals. Apart from this basic three-pulse sequence [36,37], more advanced methods are in use which still consist of the basic scheme of encoding, evolution and reconversion (see, e.g. [7,9]). During the evolution period, the double quantum coherence builds up from the sum over proton spin pairs in the sample. For identical pairs, the dependence of the signal intensity is a well-defined quantity of the coupling strength expressed in frequency units, ω_D. In the presence of more than one possible combination of proton pairs, such as in IR, the interpretation is not as straightforward but the total evolution can be written in terms of an average coupling constant, $\overline{D}$. In order to obtain $\overline{D}$ from the experiment, the evolution time τ is varied and the initial slope of the resulting buildup curve is determined, which is proportional to $\overline{D}^2\tau^2$. For a more detailed description of the case of DQ encoding in elastomers, see [7].

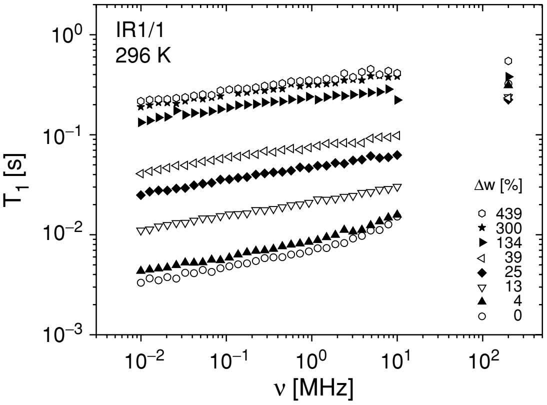

Fig. 4. Frequency-dependent relaxation times $T_1(\nu)$ as a function of weight increase (Δw) during swelling for isoprene rubber in a mixture of deuterated ethanol and toluene.

A complete averaging of dipolar couplings by fast and isotropic motion, such as in a low-viscosity liquid, does not allow the buildup of coherences between spin pairs. In a rigid solid, the coupling is strongest, and for substances such as elastomers, anisotropic motion of particular moieties and segmental motion add up to a reduced coupling strength which indicates an order parameter [6]. These residual couplings are employed as parameters to characterize the material properties on a microscopic level. In [7], it was already demonstrated that a strong correlation between $\overline{D}$ and the cross-link density exists. In [9],

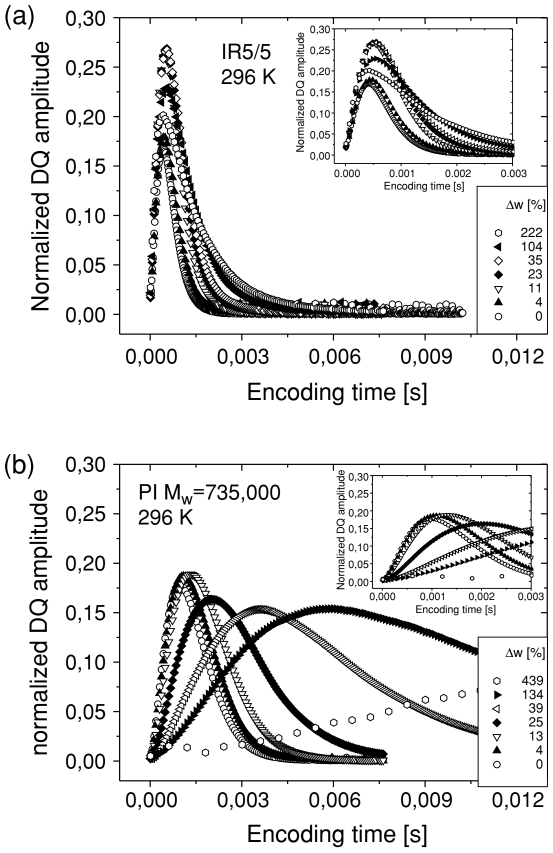

Fig. 5. Double quantum buildup curves as a function of encoding time τ for different weight increase Δw of solvent: (a) for isoprene rubber IR5/5, (b) for polyisoprene melt ($\overline{M_w} = 735000$).

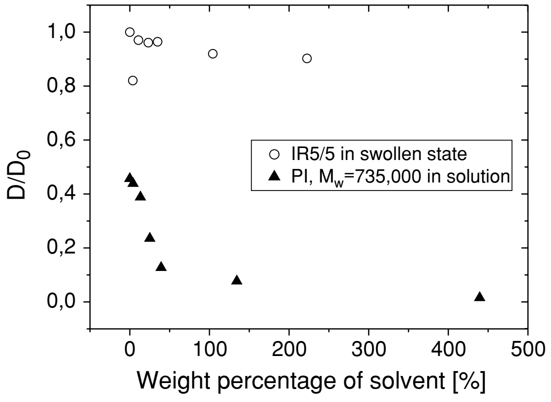

Fig. 6. Relative dipolar coupling constants obtained from the curves of fig. 5; data are normalized to the coupling constant for IR5/5 in the absence of solvent (D_0).

the dependence on the deformation ratio λ was shown, and indeed used in combination with imaging techniques to visualize the stress parameter distribution in a cut elastomer band. The increase of $\overline{D}$ with λ is intuitively understood from the preferential alignment of segments along the deformation axis, but it possesses the potential to quantify the affine or non-affine transformation of the macroscopic effect onto the molecular scale. Double-quantum experiments were performed for the stretched elastomers discussed above. However, we restrict ourselves to a demonstration of the effect of cross-links on the order parameter in the case of swelling. It becomes obvious by comparing the buildup curves of Figure 5 that the coupling behavior for cross-linked rubber changes only weakly even for the highest degree of swelling; the higher maximum value and the decaying part follow from a moderate increase in the transverse relaxation time, T_2 (data not shown). In contrast, uncross-linked polyisoprene in equivalent amounts of solvent shows a dramatic decrease of coupling strength, accompanied by a strong increase in T_2. A quantitative comparison between the coupling constants, determined as described above, is given in Figure 6. The effect of the cross-links is to maintain molecular order even under strong swelling. The order parameter in the uncross-linked melt is already lower by a factor of two, and drops significantly on addition of solvent. Thus, the presence of permanent cross-links has a pronounced influence on the order parameter as obtained from DQ experiments, but alters the longitudinal relaxation time dispersion only weakly. From a theoretical point of view, this can be explained by the different time scales and length scales involved: the change of the orientation of an internuclear vector affects relaxation but not necessarily the value of the coupling constant. By practical considerations, DQ encoding is demonstrated to be very sensitive to the detection of cross-links in general, but particularly in swollen samples. Its relatively simple use allows straight forward combinations with imaging techniques, thus providing spatially resolved maps of the order parameter.

Summary

The use of frequency-dependent relaxometry in combination with double quantum spectroscopy for the characterization of elastomers subject to different constraints has been presented. Relaxation dispersion master curves can be reconstructed from experiments performed in a limited frequency range, and feature a sequence of power–law regimes characteristic to the elastomer type. The exponents of this dispersion are the same for melts and corresponding elastomers; the dependence of the glass transition temperature is reflected in the shift of the dispersion curves. Both effects point to the high sensitivity of the low-field relaxation measurements to either temperature or cross-link density. At the same time, internal plasticizers or high concentrations of fillers hardly affect the relaxation behavior, making the method insensitive to these properties. Deformation, on the other hand, was shown probably to change the spectrum of segmental motions itself. A similar, but much stronger effect is observed for swelling of the elastomer, making only small amounts of solvents indirectly detectable via the elastomer relaxation. Finally, double quantum encoding is likewise sensitive to the cross-link density, and even more so in the presence of mobile components such as solvents. Provided that a sufficiently precise calibration has been established, a comparison of the experimental results for samples of different properties facilitates the choice of experimental conditions for achieving optimal contrast. The large potential of low field (<0.1 T) NMR in general, and low field imaging in particular, for the investigation of elastomer properties and their spatial distribution in heterogeneous samples has been demonstrated.

Acknowledgments

The authors are grateful to Dr. V. Herrmann, Dunlop GmbH, for kindly providing the IR and BR samples, and to M. Adams, K. Kupferschläger and G. Schroeder for continuous support throughout this study. Financial support from the Deutsche Forschungsgemeinschaft DFG (Sta 511/3) is gratefully acknowledged.

Determining Structural and Dynamic Distribution Functions from Inhomogeneously Broadened NMR Spectra: The Conjugate Orthogonal Functions Approach

Marcel Utz and Magesh Nandagopal
Department of Physics, Institute of Materials Science, University of Connecticut, Storrs CT 06269,USA

Introduction

The structure and dynamics of amorphous solids are difficult to characterize. On the one hand, the absence of structural coherence makes most experimental techniques, such as X-ray scattering and NMR spectroscopy more challenging due to line broadening effects, which degrade the available signal to noise ratio. On the other hand, the presence of structural and dynamic inhomogeneity means that a complete characterization of the sample involves the determination of distributions of structural and dynamic parameters [1,2].

Many NMR techniques exist that map a distribution of parameters such as molecular orientation [3–9], dihedral angles [1,10–12], bond distances and angles [13,14], or reorientation flip angles and rates [15–19], as well as structural relaxation times [20,21] onto an inhomogeneously broadened NMR spectrum. In all of theses cases, the underlying disorder is reflected in the intensity distribution in the resulting spectrum, whereby each molecular segment makes an additive contribution both the distribution to be determined and to the spectrum.

In most cases, the relationship between the structural or dynamic parameter under study and the resulting contribution to the observed NMR spectrum is not straightforward. This leads to an inverse problem, which is often ill-posed, particularly in the presence of experimental noise.

In this article, a general approach to inverse problems of this type is discussed. It is based on the representation of the mapping of the distribution function onto the observable spectrum as a linear integral operator. This leads to two conjugate sets of orthogonal functions, one in the distribution domain, and one in the spectral domain, which can be used to decompose the experimental data. The orthogonal functions in the distribution domain emerge as eigenfunctions of the linear integral operator associated with the spectral technique. As shown in the following, the corresponding eigenvalues provide useful information on the sensitivity of the experimental method to noise.

The problem of finding the distribution function from experimental data can be cast in the form of a Fredholm integral equation of the first kind. A large number of other physical inverse problems also lead to equations of this type, e.g. diffraction-limited imaging [22], the determination of particle size distributions from elastic [23] and inelastic [24] light scattering, measurement of radial distribution functions from EXAFS spectra [25], or the determination of potential energy surfaces from time-resolved probing of chemical reactions [26], just to name a few. As is well known, Fredholm equations of the first kind are ill-posed, and special care is required in order to ensure the stability of their solutions. McWhirter and Pike have discussed the extraction of information from Laplace transforms and similar integral equations using an eigenfunction analysis of the Laplace operator [27].

In the following, the theoretical framework for the conjugate orthogonal functions (COF) approach will be briefly reviewed, and its application to the determination of orientational distribution functions by rotor-synchronized magic angle spinning spectroscopy will be discussed as an example. A more complete discussion of the COF theory can be found in Ref. [1].

Conjugate Orthogonal Functions

Under the assumption that each structural element in the sample makes an additive contribution to both the spectrum $S(\omega)$ and the distribution $P(\Gamma)$, the spectroscopic method can be represented by a linear operator $\mathcal{S}$, and we can formally write

$$\mathcal{S}P(\Gamma) \mapsto S(\omega). \tag{1}$$

It should be noted that both Γ and ω need not be single scalars, but may represent, e.g. a set of Euler angles and a set of spectral frequency domains, respectively. The (hypothetical) spectra associated with single structural elements, for which Γ has a unique value, are called elementary spectra. They are obtained by applying $\mathcal{S}$ to Dirac

Graham A. Webb (ed.), Modern Magnetic Resonance, 1463–1469.
© 2008 *Springer.*

delta functions, such that

$$S_{\Gamma_0} = \mathcal{S}\delta(\Gamma - \Gamma_0). \tag{2}$$

The set of N elementary spectra $\{S_\Gamma\}$ can be viewed as a complete representation of $\mathcal{S}$. If $S_\Gamma(\omega)$ is known for all Γ, the spectrum that results from distribution function $P(\Gamma)$ can be calculated as

$$S(\omega) = \int_{\mathcal{D}_{\Gamma'}} P(\Gamma')\ S_{\Gamma'}(\omega)\ \mathrm{d}\Gamma', \tag{3}$$

In practice, one has measured a spectrum $S(\omega)$ and would like to calculate $P(\Gamma)$. It will become clear in the following that this problem is equivalent to finding the solution of a Fredholm integral equation of the first kind [28]. Its inversion is an ill-posed problem, since the information that is contained in the distribution function may not entirely be transferred to the experimentally accessible spectrum. Typically, infinitely many distribution functions provide approximate solutions to the inverse problem within experimental precision. Thus, the determination of a distribution function P from spectral data must be done in two steps. The first, which can be done rigorously, consists in finding the space of distribution functions that are compatible with the experimental data. Then, a decision must be made which function inside this space is a reasonable estimate of the "true" distribution function. This second step invariably involves the use of heuristic arguments or *a priori* information.

By multiplying Equation (3) with an elementary spectrum $S_\Gamma(\omega)$ and integrating over the frequency domain, one obtains

$$A(\Gamma) = \int_{\mathcal{D}_\Gamma} G(\Gamma, \Gamma')\ P(\Gamma')\ \mathrm{d}\Gamma', \tag{4}$$

where we have used the abbreviations

$$G(\Gamma, \Gamma') := \int_\omega S_\Gamma(\omega)\, S_{\Gamma'}(\omega)\ \mathrm{d}\omega \tag{5}$$

and

$$A(\Gamma) := \int_\omega S(\omega)\, S_\Gamma(\omega)\ \mathrm{d}\omega. \tag{6}$$

The kernel G defines a compact symmetric integral operator $\mathcal{G}$ acting on $P(\Gamma)$. $\mathcal{G}$ is a complete representation of the spectroscopic method. Unlike $\mathcal{S}$, it is symmetric, which allows it to be decomposed into a set of eigenfunctions $\phi_n(\Gamma)$ and real eigenvalues λ_n [28,29]:

$$\int_{\Gamma'} G(\Gamma, \Gamma')\phi_n(\Gamma')\ d\Gamma' = \lambda_n\ \phi_n(\Gamma). \tag{7}$$

In the following we will make use of the customary conventions that the eigenvalues λ_n be arranged in decreasing order and repeated according to their multiplicity. Moreover, for degenerating eigenvalues $\lambda_k \cdots \lambda_{k+m}$, the eigenfunctions $\phi_k \cdots \phi_{k+m}$ shall be chosen such that the ϕ_n form a complete orthonormal set.

It can be shown that the operator $\mathcal{G}$ is bounded, which means that its largest eigenvalue must be finite. In addition, $\mathcal{G}$ is positive semi-definte [1], i.e. all its eigenvalues are positive or zero. Furthermore, it follows from the theory of linear integral operators that $\lim_{n\to\infty} \lambda_n = 0$. The eigenvalues λ_n therefore decay monotonously from the largest value λ_1 to zero. The rate of decay of the λ_n provides a valuable measure of the sensitivity of the spectroscopic method under study.

Due to the linearity of $\mathcal{S}$, the mean square deviation between two spectra that corresponds to two different distribution functions P_1 and P_2 depends only on the difference $p = P_2 - P_1$. It is easily shown that the deviation can be obtained from the correlation kernel G as

$$\chi^2[p] = \int_{\Gamma,\Gamma'} p(\Gamma)G(\Gamma, \Gamma')p(\Gamma')\,\mathrm{d}\Gamma'\,\mathrm{d}\Gamma. \tag{8}$$

This simple relation is very useful when discussing the sensitivity of the spectroscopic method to experimental error.

The *eigenspectra* $\psi_n(\omega)$ result from application of $\mathcal{S}$ to the eigenfunctions $\phi_n(\Gamma)$:

$$\psi_n(\omega) = \mathcal{S}\phi_n = \int_\Gamma \phi_n(\Gamma)S_\Gamma(\omega)\,\mathrm{d}\Gamma. \tag{9}$$

They are orthogonal in the sense that

$$\int_{\mathcal{D}_\omega} \psi_n\, \psi_m\, \mathrm{d}\omega = \lambda_n \delta_{mn}. \tag{10}$$

The diagonalization of the kernel G thus leads to a set of orthogonal basis functions, not only in the structural domain $\mathcal{D}_\Gamma$, but also in the spectral domain $\mathcal{D}_\omega$. With the eigenspectra ψ_n known, the analysis of measured data becomes very simple. It is sufficient to decompose the measured spectrum into the set of eigenspectra $\{\psi_n\}$ in order to find the expansion coefficients p_n:

$$p_n = \frac{1}{\lambda_n} \int_{\mathcal{D}_\omega} S(\omega)\psi_n(\omega)\,\mathrm{d}\omega. \tag{11}$$

In practice, any spectroscopic measurement produces data that is contaminated with noise. Therefore, two measured spectra can only be regarded to be *significantly* different if their spectral deviation exceeds the threshold

$$\xi^2 = F\ \left(\chi^2_{\min} + W\sigma^2\right) \tag{12}$$

where $\chi^2_{\min}$ is the spectral deviation between the experimental spectrum and the best possible representation by an infinite number of eigenspectra, accounting for systematic errors. σ^2 represents the mean square noise spectral density, and W is the relevant spectral area. F is a statistical significance factor of order unity. It is easily shown that a change in a particular expansion coefficient, Δp_n, is detectable if it satisfies the condition

$$\Delta p_n^2 \geq \frac{\xi^2}{\lambda_n}. \tag{13}$$

Hence, the error margins associated with the expansion coefficients p_n of a distribution function P that has been measured spectroscopically are given by $\Delta p_n = \pm \xi \lambda_n^{-1/2}$.

The expansion coefficients p_n represent moments of the distribution function $P(\Gamma)$ with respect to the eigenfunctions of the spectroscopic mthod, and one can formally write $p_n = \langle \phi_n \rangle$. Since their error margins are well defined, they can be compared to the same moments resulting from a theoretically predicted distribution. This provides a rigorous, "model-free" approach to decide whether experimental results contradict or support a given theory.

As an illustration, consider a hypothetical spectroscopic method sensitive to a single scalar structural parameter $\gamma \in [0,1]$. The elementary spectra consist of a single normalized Gaussian peak, centered at $\omega_0 = \alpha\gamma$. The width of the elementary spectra, and thus the spectral resolution of the method, is given by a parameter β. The eigenvalues of the correlation kernel associated with these elementary spectra, $\mathcal{G}$, calculated numerically for different values of β, are plotted in Figure 1. The larger the width of the elementary spectra β, the faster the eigenvalues decay. As expected, the information content, measured by the number of eigenvalues above a certain threshold, increases with spectral resolution. However, the *type* of information is almost independent of β, as the eigenfunctions, some of which are shown in Figure 2, are very similar for all values of β.

In practice, due to the fact that the eigenvalues λ_n decay rapidly towards zero, the error bars Δp_n diverge for large values of n. Mathematically, this reflects the ill-posed nature of the inversion of Fredholm equations of the first kind. If a representation of the full distribution $P(\Gamma)$ is desired, rather than just its moments $\langle \phi_n \rangle$, *a priori* information and heuristic arguments must be used in order to select from the infinitely large space spanned by the set of coefficients $\{p_n \pm \Delta p_n\}$ a point which is a plausible approximation to the "true" underlying distribution function, a process is often referred to as regularization. In the simplest case, only the coefficients p_n up to a limit $n_{\max}$, are used, and the solution is given as a truncated series [30]

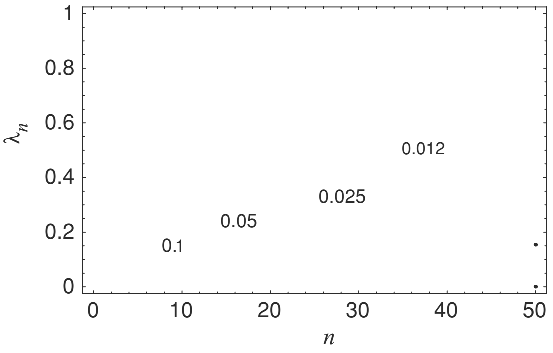

Fig. 1. The first 50 eigenvalues of the operator $\mathcal{G}$ corresponding to a hypothetical spectroscopic method. It is assumed that the elementary spectra consist of a single Gaussian peak whose position depends linearly on a structural parameter. Four different cases are shown, corresponding to elementary spectra with widths β indicated in the figure. The better the spectral resolution of the spectroscopic method, the slower the eigenvalues decay.

$$P(\Gamma) \approx \widetilde{P}(\Gamma) = \sum_{n=1}^{n_{\max}} p_n \, \phi_n(\Gamma). \tag{14}$$

As the eigenfunctions become more and more oscillatory for larger n, this is equivalent to restricting the solution to be smooth, which is a reasonable assumption in many cases. As a method of regularization of the solution of Fredholm equations, truncation of the eigenfunction expansion has been shown to be equivalent to weighting the residual with a smoothness functional [27,30], such as the Tikonov functional [31] or the entropy functional [32].

It must be noted, though, that any finite series approximation of $P(\Gamma)$ cannot be guaranteed to be positive. In particular, sharply peaked distribution functions typically have ripples in their truncated series approximations. If a sufficient number of coefficients p_n can be determined to good precision, $\widetilde{P}(\Gamma)$ will nevertheless be a useful approximation to the "true" distribution function $P(\Gamma)$.

Several numerical strategies can be employed to find a distribution function that is both positive, and compatible with the measured moments $p_n \pm \Delta p_n$. One possibility is to do a Monte Carlo optimization of the functional $\int (P - |P|)^2 d\Gamma$. This is easily implemented in the space of the expansion coefficients p_n.

Orientational Order

As an illustration for the COF approach, we discuss its application to the determination of orientational order in

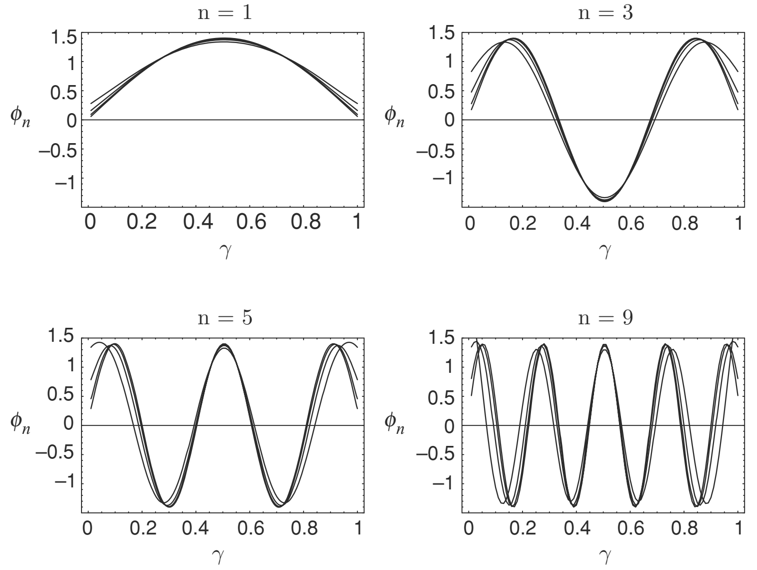

Fig. 2. The eigenfunctions associated with hypothetical elementary Gaussian spectra with line widths $\beta = 0.1$, 0.05, 0.025, 0.012.

amorphous solids. It has been shown by Harbison *et al.* that the orientational distribution function in disordered polymers can be quantified by a two-dimensional rotor synchronized magic angle spinning (MAS) experiment [5,9]. This method makes use of the fact that the spinning sidebands associated with a chemical shielding anisotropy (CSA) tensor are phase-modulated depending on the relative orientation of the principal axes frame of the CSA tensor with respect to the magnetic field and the spinner axis at the beginning of the acquisition. If many transients are added without rotor synchronization, this modulation is lost, and a purely absorptive sideband manifold results. The same happens if the orientational distribution of the molecular segments is isotropic, even if the acquisition is rotor-synchronized. By acquiring a series of transients with different rotor orientations at the beginning of the acquisition and taking the Fourier transform with respect to the rotor phase, Harbison *et al.* obtained a pure-phase two-dimensional sideband manifold, which quantitatively reflects the deviation of the orientational distribution from isotropy.

In the following, we consider a variant of this experiment that makes use of the Deuterium quadrupolar splitting, instead of the ^{13}C chemical shift. This has a number of advantages: the anisotropy of the ^{2}D quadrupolar coupling is usually large compared to the spin–spin relaxation rate, which allows a very sensitive measurement of orientation. In addition, the orientation of the principal axes of the quadrupolar interaction with respect to the molecular frame is usually known quite well. Of course, a major drawback lies in the necessity of isotopic labeling.

The expression given by Harbison *et al.* for the intensity of the sideband of order M, N (where N denotes the order with respect to the free evolution domain, and M is the order with respect to the rotor phase) is easily adapted to the quadrupolar interaction of ^2D. One finds

$$I_{M,N}(\beta,\gamma) \propto e^{iN\gamma}\left[\int_0^{2\pi} e^{i(N-M)\psi}F(-\gamma-\psi)\mathrm{d}\psi \int_0^{2\pi} e^{-iN\theta}F(\theta)\mathrm{d}\theta + \int_0^{2\pi} e^{i(N-M)\psi}F(\gamma+\psi)\mathrm{d}\psi \int_0^{2\pi} e^{iN\theta}F(\theta)\mathrm{d}\theta\right], \qquad (15)$$

where

$$F(\theta) = \exp(iA_2 \sin 2\theta + iA_1 \sin\theta); \qquad (16)$$

with

$$A_1 = -\frac{\sqrt{2}}{\omega_r}\delta \sin\beta\cos\beta;$$

$$A_2 = -\frac{1}{4\omega_r}(3\cos^2\beta - 1)\delta, \qquad (17)$$

where δ denotes the aniosotropy of the axially symmetric quadrupolar coupling tensor, and $\omega_r = 2\pi\nu_r$ is the angular velocity of the rotor. The relation between the

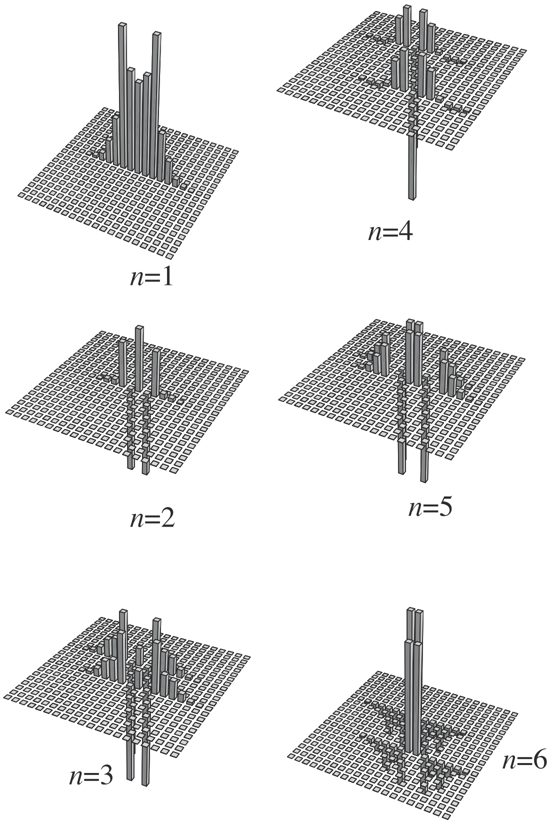

Fig. 3. Eigenspectra of a rotor-synchronized MAS experiment. The sideband intensities are indicated by the height of the bars; the main sideband index N increases to the right, whereas the secondary index (associated with the rotor phase) M increases to the back. The ratio of the quadrupolar anisotropy to the rotor speed was $2\pi\delta/\omega_r = 5$. (See also Plate 116 on page XV in Color Plate Section.)

orientation of a molecular segment (represented by the two polar angles β and γ orienting the unique axis of the quadrupolar tensor in the rotor frame) and the contribution to the spectrum $I_{M,N}$ is not straightforward at all. However, as will be shown in the following, COF analysis makes it easy to get a feel for the information content of the method.

As an example, the first six eigenspectra and eigenfunctions of this method are shown in Figures 3 and 4. As in the hypothetical Gaussian line example above, the first eigenfunction is almost a constant, whereas higher eigenfunctions are increasingly oscillatory.

The sideband intensities depend on the ratio between the quadrupolar anisotropy δ and the rotor speed ω_r. Slower rotor speeds lead to a larger number of sidebands. One would therefore intuitively expect that slower rotation speeds provide more information on the orientational distribution function. As will become clear in the following, this is not entirely true, since the total spectral intensity remains the same: more sidebands also mean a lower signal/noise ratio. An optimum value for ω_r can easily be found through the COF framework.

Figure 5 shows the eigenfunctions if only sidebands with $M = 0$ are taken into account. This corresponds to taking a conventional, one-dimensional spectrum without rotor synchronization. In this case, the anisotropy with respect to the circumferential polar angle γ is averaged out by the sample rotation. However, the distribution of polar angles β between the axes of the quadrupolar tensor and the rotor still influences the intensity distribution in the sideband pattern. This is directly seen in the eigenfunctions in Figure 5: they only depend on β (radial variation), but are symmetric with respect to rotation around the spinner axis.

While the eigenfunctions provide details of the *kind* of information provided by the spectroscopic method under study (e.g. its symmetry), the eigenvalues are useful to quantify *how much* of this information is contained in a spectrum with a given signal to noise ratio. As an

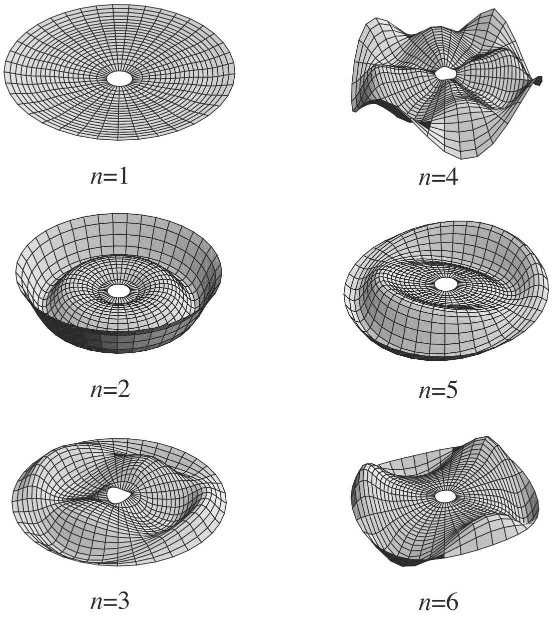

Fig. 4. Eigenfunctions $\phi_n(\beta, \gamma)$ of the rotor-synchronized MAS experiment with $\delta/\nu_r = 5$. The functions are shown in a stereographic projection, with the angle β varying from 0 to $\pi/2$ from the center to the outside of the graphs. The center point corresponds to the rotor axis direction. (See also Plate 117 on page XV in the Color Plate Section.)

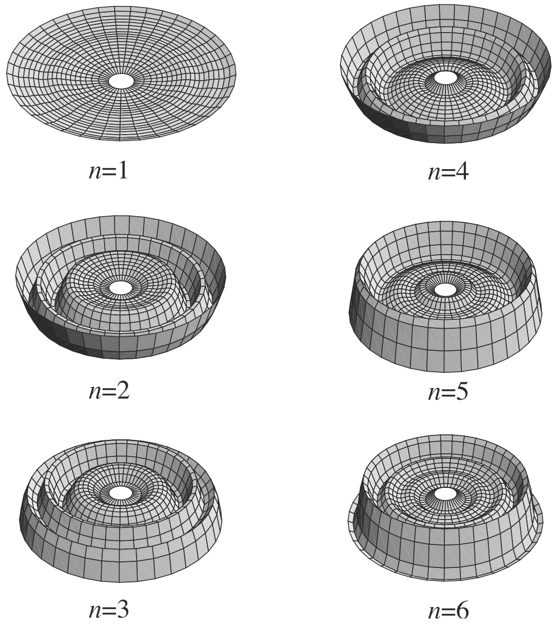

Fig. 5. Eigenfunctions $\phi_n(\beta, \gamma)$ of the rotor-synchronized MAS experiment, with only sidebands with $M = 0$ taken into account. The method is insensitive to the polar angle γ, but remains sensitive to the first polar angle β (cf. text). (See also Plate 118 on page XVI in the Color Plate Section.)

example, consider the eigenvalues of the ^{2}D rotor-sync MAS method shown in Figure 6 depending on the ratio between the quadrupolar anisotropy and the rotor speed δ/ν_r. This ratio essentially corresponds to the number of observable sidebands in a one-dimensional MAS spectrum, while the number of sidebands that can in principle be observed in a rotor-synchronized MAS experiment are proportional to $(\delta/\nu_r)^2$. As Figure 6 shows, the eigenvalues λ_n decay exponentially as a function of n. As expected, more observed sidebands lead to a slower decay.

Which spinning speed should be chosen in order to maximize the information content of the method? Answering this question requires consideration of the amount of noise that is included in the analysis. Assuming a constant spectral density of noise, the total mean-square noise introduced into the projections of the experimental spectra is proportional to the number of sidebands considered. The absolute limit of detection, given by the maximum tolerable error bar, is obviously a matter of choice. Setting the limit (arbitrarily) to $\lambda_n \geq 1$ for a ratio $\delta/\nu_r = 5$ (center panel in Figure 6), the first 22 coefficients are detectable. Decreasing the rotor speed to $\delta/\nu_r = 10$ results in a increase of the number of sidebands by a factor of 4. Therefore, at the same spectral noise density, the limit of detection increases to $\lambda_n \geq 4$. The bottom panel in Figure 6 shows that the first 26 coefficients can be detected in this case. The increase in information content over the faster rotor speed is therefore quite modest. By contrast, increasing the rotor speed to $\delta/\nu_r = 2$ (which is unrealistic in practice, since δ is of the order of 150 kHz) would lead to a very rapid decay of the eigenvalues, as seen in the top panel of Figure 6. In spite of the corresponding decrease in the limit of detection, the information content would be reduced to less than 10 coefficients.

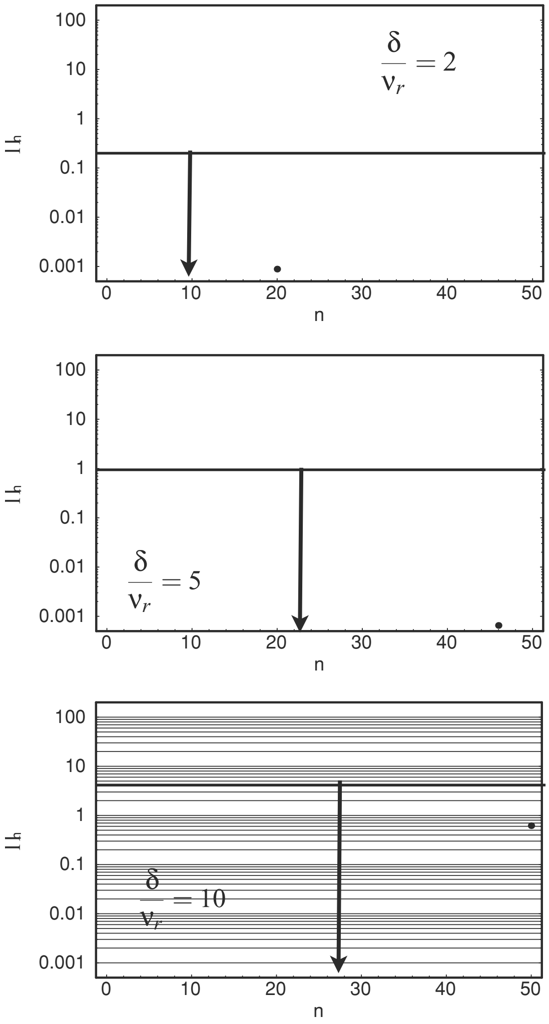

Fig. 6. Eigenvalues of the ^{2}D rotor-synchronized MAS experiment for different ratios between the quadrupolar anisotropy δ and the rotor speed ν_r. (See also Plate 119 on page XVI in the Color Plate Section.)

Conclusions

The conjugate orthogonal function approach provides a coherent framework for dealing with the inverse problem of extracting structural or dynamic distributions from inhomogenously broadened NMR spectra. It provides a rigorous and convenient method to obtain moments of the desired distribution with respect to a set of orthogonal eigenfunctions. Experimental spectra are decomposed by projection onto a conjugate set of orthogonal eigenspectra, rather than by an iterative fitting procedure. The experimental errors of the resulting moments depend on the spectral noise density in a well-defined manner. The set of moments $\langle \phi_n \rangle \pm \Delta p_n$ represents *all* the information on the distribution that is contained in an experimental spectrum with a particular signal-to-noise ratio. If a sufficient number of the moments $\langle \phi_n \rangle$ can be determined, they may be used to reconstruct the underlying distribution function.

The orthogonal eigenfunctions and eigenspectra also provide useful information on the spectroscopic method, and can be used to optimize experimental parameters for maximum sensitivity, as well as to compare the merits of alternative experimental approaches.

Abstract

The contribution of the vapor phase to molecular diffusion in porous silica glasses with nanometer (Vycor) and micrometer (VitraPor #5) pores partially filled with water (polar) or cyclohexane (nonpolar) was investigated with the aid of field-gradient NMR diffusometry. The effective diffusion coefficient of water in nanometer pores (Vycor) decreases with decreasing filling factor, whereas that of cyclohexane increases due to the vapor phase contribution without exceeding its bulk liquid value. On the other hand, the effective diffusion coefficient of cyclohexane in micrometer pores (VitraPor #5) was up to ten times larger than the bulk liquid value. This is in contrast to the effective diffusion coefficient in water which first decreases and then increases upon reduction of the pore space filling factor. A general two-phase liquid/vapor exchange model is presented that is accounting well for all experimental diffusion features. The dependence of the effective diffusion coefficient on the pore filling factor is strongly related to the pore dimension and the polar character of the fluids.

Introduction

Field-gradient NMR diffusometry studies of fluids partially filling porous materials suggested effective self-diffusion coefficients enhanced due the vapor phase contribution relative to the bulk liquid phase [1–7]. The explanation is the exchange between the liquid and vapor phases. The bulk diffusivity at room temperature in the gas phase is four orders of magnitude larger than in the liquid phase. Consequently, the root mean squared displacement of a molecule entering the gas phase will be two orders of magnitude bigger than in the liquid phase for a given diffusion time. In some experimental situations, this can compensate for the three orders of magnitude smaller density in the vapor phase as compared with the liquid phase. The exchange between the two phases on the time scale of the experiment thus leads to an average diffusivity enhanced by the vapor phase whereas the NMR signal is still dominated by the liquid phase.

In the following, the contribution of the vapor phase to molecular diffusion in silica glasses with nanometer (Vycor; mean pore diameter 4 nm) and micrometer (VitraPor #5: mean pore diameter 1 μm) pores partially filled with water (polar) or cyclohexane (nonpolar) is investigated with the aid of the field-gradient NMR diffusometry technique represented by the pulse scheme shown in Figure 1A. The experimental results will be discussed in the frame of a general two-phase exchange model [6] that is based on a two-region approximation [8]. The general results of the theoretical model will be further analyzed into “fast” and “slow” molecular exchange limits between the liquid and vapor phases.

The Two-Phase Exchange Model in NMR Diffusometry

In completely filled pore spaces, the transport properties of filling fluids are predominantly affected by the geometrical restriction, i.e. the tortuosity and the interaction with the surface. According to Archie’s law, $D = \Phi_{\mathrm{t}}^{m} D_0$, the effective diffusion coefficient in the pore space, D, is reduced by tortuosity effects by a factor Φ_{t}^{m} relative to its bulk value, D_0 [2,9]. The quantity $\Phi_{\mathrm{t}} = V_0/V_{\mathrm{t}}$ represents the total porosity of the sample. V_{t} is the total volume including the matrix and the pore space, V_0 is the pores space volume and m is an empirical exponent.

In an unsaturated porous sample with polar inner surfaces, the liquid and the vapor phase form two interpenetrating systems of different geometry and porosity. Polar and nonpolar adsorbates such as liquid water and cyclohexane, respectively, tend to be distributed in a different way in the pore space depending also on the imbibing degree [10]. In any case, the remainder of the pore volume is filled by air saturated with the respective vapor phase. In this case, we have to consider two interpenetrating pore systems of different effective porosities $\Phi_{\mathrm{l}} = V_{\mathrm{l}}/V_{\mathrm{t}}$ and $\Phi_{\mathrm{v}} = (V_0 - V_{\mathrm{l}})/V_{\mathrm{t}}$ for the liquid and vapor phases, respectively (the subscript l stands for liquid and v for vapor).

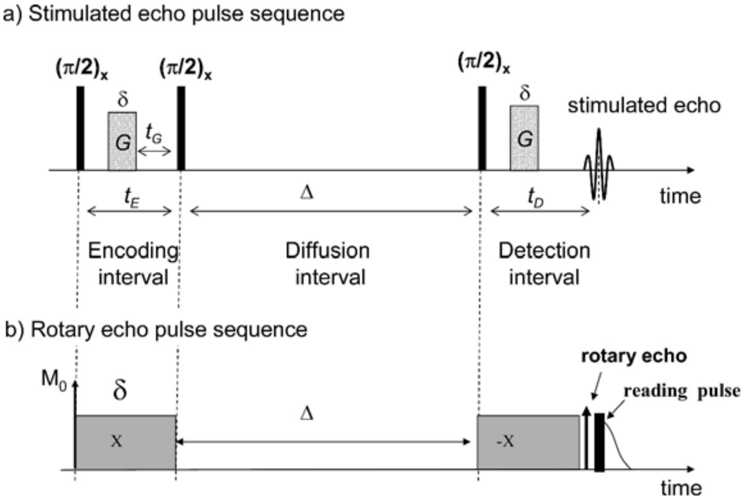

Fig. 1. (a) Schematic radio frequency (RF) and field-gradient pulse sequence for the stimulated echo variant of field-gradient NMR diffusometry. *G* represents the spatially constant field gradient along the *z* axis. (b) The rotary echo pulse sequence that was used in test experiments for the evaluation of internal gradient effects. The gradient of the RF amplitude B_1 was created with a conic coil [12].

Assuming Archie's law again, the reduced diffusion coefficient in the liquid phase can be written in the form [5]

$$D_\mathrm{l} = \Phi_\mathrm{l}^{m_\mathrm{l}} D_{\mathrm{l},0} = \Phi_\mathrm{t}^{m_\mathrm{l}} \left(\frac{V_\mathrm{l}}{V_0}\right)^{m_\mathrm{l}} D_{\mathrm{l},0} = \Phi_\mathrm{t}^{m_\mathrm{l}} f^{m_\mathrm{l}} D_{\mathrm{l},0}, \tag{1}$$

where $f = V_\mathrm{l}/V_0$ is the filling factor and m_l is an empirical exponent specific for the liquid phase and depends both on the sample geometry and the wetting properties of the liquid. The diffusion coefficient in bulk liquid is designated by $D_{\mathrm{l},0}$. Equation (1) thus links the porosity effective for the liquid phase, Φ_l, to the sample porosity, $\Phi_\mathrm{t} = \Phi_\mathrm{l} + \Phi_\mathrm{v}$.

Diffusion in the vapor phase is governed by collisions among the diffusing molecules themselves (Einstein diffusion) or with the pore walls (Knudsen diffusion). The term "wall" may refer both to liquid–vapor interfaces and to inner surfaces of the solid matrix. Taking Knudsen diffusion into account, the effective vapor diffusion coefficient inside a porous system can be derived by adding the diffusion resistances associated with these two types of collisions, i.e. molecule–wall and molecule–molecule [11]:

$$\frac{1}{D_\mathrm{v}} = \frac{1}{D_\mathrm{K}} + \frac{1}{D_\mathrm{E}} \tag{2}$$

D_K and D_E are the Knudsen and Einstein diffusivities, respectively. Note that D_v approaches D_K in the Knudsen limit, $D_\mathrm{K} \ll D_\mathrm{E}$, when molecule–wall collisions dominate. It becomes equal to D_E in the Einstein diffusion regime, $D_\mathrm{K} \gg D_\mathrm{E}$, where molecule–molecule collisions prevail [11].

Anticipating Archie's law again, the quantities D_K and D_E can be represented in terms of effective tortuosity factors as above, in order to relate the diffusivities in reduced pore spaces and in "bulk," i.e.

$$\begin{aligned} D_\mathrm{K} &= \Phi_t^{m_{\mathrm{v,K}}} (1-f)^{m_{\mathrm{v,K}}} D_{K,0}; \\ D_\mathrm{E} &= \Phi_t^{m_{\mathrm{v,E}}} (1-f)^{m_{\mathrm{v,E}}} D_{\mathrm{v},0}. \end{aligned} \tag{3}$$

The diffusivities in the "bulk" vapor phase are given by $D_{\mathrm{V},0}$ and $D_{\mathrm{K},0}$ in the Einstein and Knudsen diffusion limits, respectively. The exponents $m_{\mathrm{v,K}}$ and $m_{\mathrm{v,E}}$ account for tortuosity effects in the Knudsen and Einstein regimes and may consequently also deviate from each other [11].

If we assume that wetting liquids are distributed at the pore walls in the form of a hollow cylinder [2], the diameter of the vapor phase domains can be expressed as a function of the filling factor and the reference Knudsen diffusion coefficient can be written as [2,5]

$$D_{\mathrm{K},0}(f) = \frac{1}{3} d (1-f)^{\frac{1}{2}} \sqrt{\frac{8 k_\mathrm{B} T}{\pi M_0}}. \tag{4}$$

Here k_B is the Boltzmann constant, T is the absolute temperature, M_0 is the molecular mass, and d is the mean pore diameter. Note that the reference Knudsen diffusion coefficient is related to the pore shape but may also be different for different chemical species such as water and cyclohexane due to their different wetting properties.

In the following, we consider the pulse sequence in Figure 1A where we neglect diffusion, relaxation, and exchange phenomena during the encoding interval and assume the spoiling of the transverse magnetization component in the diffusion interval. The combined effect of diffusion, relaxation, and exchange on the modulated longitudinal magnetization in the diffusion interval can be evaluated on the basis of a set of "Bloch/Torrey/McConnell equations" (BTC) introduced in Ref. [6]:

$$\begin{aligned}\frac{\mathrm{d}M_{z,\mathrm{l}}(z,t)}{\mathrm{d}t} &= D_\mathrm{l}\frac{\mathrm{d}^2M_{z,\mathrm{l}}(z,t)}{\mathrm{d}z^2} - \frac{M_{z,\mathrm{l}}(z,t) - M_{0,\mathrm{l}}}{T_{1,\mathrm{l}}} \\ &\quad - \frac{M_{z,\mathrm{l}}(z,t)}{\tau_\mathrm{l}} + \frac{M_{z,\mathrm{v}}(z,t)}{\tau_\mathrm{v}}, \\ \frac{\mathrm{d}M_{z,\mathrm{v}}(z,t)}{\mathrm{d}t} &= D_\mathrm{v}\frac{\mathrm{d}^2M_{z,\mathrm{v}}(z,t)}{\mathrm{d}z^2} - \frac{M_{z,\mathrm{v}}(z,t) - M_{0,\mathrm{v}}}{T_{1,\mathrm{v}}} \\ &\quad - \frac{M_{z,\mathrm{v}}(z,t)}{\tau_\mathrm{v}} + \frac{M_{z,\mathrm{l}}(z,t)}{\tau_\mathrm{l}}. \end{aligned} \tag{5}$$

$T_{1,\mathrm{l}}$ and $T_{1,\mathrm{v}}$ are the longitudinal relaxation times in the liquid and vapor phase, respectively, in the absence of exchange. $M_{0,\mathrm{l}}$ and $M_{0,\mathrm{v}}$ are the corresponding equilibrium magnetizations. The mean lifetimes the adsorbate molecules spend in the liquid and vapor phases are denominated by τ_l and τ_v, respectively. Analogously, we allocate effective self-diffusion coefficients D_l and D_v to the two fluid phases, as given by Equations (1) and (2).

The first terms on the right-hand side of Equation (5) describe molecular transport inside the individual phase, the second terms are accounting for longitudinal relaxation in the absence of exchange, and the other terms represent molecular interphase exchange rates. As a strong simplification, the BTC equations anticipate that both phases are spread uniformly to the entire pore space. That is, mutual exchange between the two phases can occur at any position z without prior need to diffuse to an interface.

The mean lifetimes τ_l and τ_v are effective quantities determined by the extensions of the two-phase regions and the molecular mobilities therein. Additional transport resistances at the interfaces may also play a role. The mean lifetimes are related to the relative number (mass fraction) of molecules in the ith phase region, p_i, by

$$p_i = \frac{\tau_i}{\tau_\mathrm{l} + \tau_\mathrm{v}} \quad (i = \mathrm{l}, \mathrm{v}) \tag{6}$$

in a similar way as described in Ref. [8]. They can be expressed as a function of the filling factor $f = V_\mathrm{l}/V_0$ and of the respective mass densities, ρ_l and ρ_v, as follows:

$$p_l = \frac{f}{f + (1-f)(\rho_\mathrm{v}/\rho_\mathrm{l})} \quad \text{and} \quad p_\mathrm{v} = 1 - \rho_\mathrm{l}. \tag{7}$$

The general solution of BTC Equation (5) which can provide us the amplitude of the stimulated echo, has a generally complicated form (see Ref. [8]), and is not given here. It can be simplified in some experimental limits to be described in the following.

The General Liquid/Vapor Exchange Limit

For vapor/liquid phase systems we always have

$$p_\mathrm{v} \ll p_\mathrm{l}; \quad D_\mathrm{v} \gg D_\mathrm{l}; \quad T_{1,\mathrm{v}} \gg T_{1,\mathrm{l}}, \tag{8}$$

and the stimulated echo amplitude obeys [6]

$$\frac{A_\mathrm{STE}(k,\Delta)}{A_\mathrm{STE}(0,\Delta)} = \exp\left[-k^2\left(D_\mathrm{l} + \frac{p_\mathrm{v}D_\mathrm{v}}{k^2\tau_\mathrm{l}p_\mathrm{v}D_\mathrm{v} + 1}\right)\Delta\right]. \tag{9}$$

Here $k = \gamma G\delta$ represents the "wave number" of the modulated magnetization that is produced by the gradient pulses of strength G, and duration δ and γ is the gyromagnetic ratio. The relaxation term has been discarded in the above expression because in experiments with constant intervals but variable gradient strength, it does not affect the echo attenuation curve apart from a constant reduction factor. Note that the same expression was obtained by Kärger for the attenuation of the Hahn echo using a different approach [8]. An interesting feature of Equation (9) is that the mean lifetime, τ_l, the molecules spend in the liquid phase can be determined on this basis.

Equation (9) suggests that no effective diffusion coefficient can be defined since the term in parentheses depends on the wave number as a parameter varied in the experiments. However, for small gradient pulse areas complying with the limit $k^2\tau_l p_v D_v \ll 1$, one may define $D_\mathrm{eff} = D_\mathrm{l} + p_\mathrm{v}D_\mathrm{v}$ as an effective diffusivity with some similarity to the fast exchange version described below. The initial part of echo attenuation curves can be thus fitted by the monoexponential decay function

$$\frac{A_\mathrm{STE}(k,\Delta)}{A_\mathrm{STE}(0,\Delta)} = \exp\left[-k^2(D_\mathrm{l} + p_\mathrm{v}D_\mathrm{v})\Delta\right] \quad \text{for } k^2\tau_\mathrm{l}p_\mathrm{v}D_\mathrm{v} \ll 1. \tag{10}$$

The general liquid/vapor exchange limit implies two more limits concerning the exchange rates relative to the experimental time scale (the interval Δ in the pulse sequences shown in Figure 1).

The Fast Liquid/Vapor Exchange Limit ($\tau_1 \ll \Delta$ and $\tau_\mathrm{v} \ll \Delta$)

This limit was treated in the literature many times [1–5] and corresponds to large diffusion paths during Δ. The amplitude of the stimulated echo is thus attenuated by diffusive displacements according to [6]

$$\frac{A_\mathrm{STE}(k,\Delta)}{A_\mathrm{STE}(0,\Delta)} = \exp\left[-k^2D_\mathrm{eff}\Delta\right] \tag{11}$$

In this case, the effective diffusivity, D_{eff}, that characterizes the decay, is the weighted average between the diffusion coefficients in the two phases, i.e.

$$D_{\mathrm{eff}} = p_{\mathrm{l}} D_{\mathrm{l}} + p_{\mathrm{v}} D_{\mathrm{v}}. \tag{12}$$

The coefficients D_{l} and D_{v} are given by Equations (1) and (2), respectively, and are reduced relative to the bulk values due to the pore space confinement.

The Slow Liquid/Vapor Exchange Limit ($\tau_1 \gg \Delta$ and $\tau_{\mathrm{v}} \gg \Delta$)

In the slow exchange limit when molecular exchange can be neglected on the time scale of the experiment, the attenuation of the amplitude of the stimulated echo by diffusion is characterized by a superposition of two exponentials corresponding to the two phases:

$$\frac{A_{\mathrm{STE}}(k, \Delta)}{A_{\mathrm{STE}}(0, \Delta)} = p_{\mathrm{l}} \exp(-k^2 D_{\mathrm{l}} \Delta) + p_{\mathrm{v}} \exp(-k^2 D_{\mathrm{v}} \Delta). \tag{13}$$

The diffusion coefficients D_{l} and D_{v} in the liquid and vapor phase, respectively, are reduced due to the pore space confinement [see Equations (1) and (2)]. Due to the fact that the number of spins in the vapor phase is usually much smaller than in the liquid phase, $p_{\mathrm{v}} \ll p_{\mathrm{l}}$, the only component that will contribute to the signal is the liquid component and no contribution from the vapor phase is expected to be perceptible in this limit.

Experimental

Samples and Instrumentation

Vycor porous glass VPQ #7930 was purchased from Corning Ltd. It consists of 96% SiO_2. The nominal mean pore size is $d = 4$ nm (± 0.6 nm). The porosity is specified by manufacturer as $\Phi_{\mathrm{t}} = 0.28$. VitraPor #5 porous silica glass was purchased from ROBU Glasfilter-Geräte GmbH, Germany. The nominal mean pore size is $d = 1$ μm (± 0.6 μm). The porosity was measured as $\Phi_{\mathrm{t}} = 0.43$.

The samples were pretreated as suggested by the manufacturer. This includes 30 min of boiling in 30% H_2O_2. The samples were then washed with distilled water and left in vacuum for 24 h at 95 °C. After that, the samples are considered to be dry with a nominal filling factor of $f = 0$. The solvents were then filled into the porous glass with the aid of the bulk-to-bulk method resulting in a filling factor 1 for the corresponding solvent.

The solvents examined in this study were cyclohexane (nonpolar; nonwetting) and demineralized water (polar; wetting). Partial evaporation was then used for the adjustment of the desired filling factor. This was performed in a glove bag in a dry nitrogen atmosphere (for VitraPor #5 sample) in order to avoid any undesired contamination by water from the air humidity. The solvent content reached by this procedure was determined by weighing. The samples were placed in a sealed container with practically no empty space that would allow for further evaporation. All experiments were done only after about 1 h permitting the fluid to equilibrate with respect to phase distributions. After this annealing period, no changes were perceptible any longer.

All diffusion experiments were performed with a Bruker DPX 400 NMR spectrometer equipped with a microscopy gradient unit. The data were recorded at room temperature and at a proton resonance frequency of 400 MHz using the standard pulsed field-gradient-stimulated echo technique in Figure 1A [12]. The gradient calibration was done with the aid of diffusion measurements in bulk water.

Due to differences in the susceptibility between porous matrix and filling fluids, internal gradients may appear in partially field porous media. These gradients may influence the decay curves of the stimulated echo. In the case of Vycor porous sample, test experiments have been done with the "rotary echo" [13] method given in Figure 1B, which is not affected by the internal gradients. In the case of VitraPor #5 sample, the susceptibility induced gradients were estimated with the method described in Ref. [14]. The conclusion is that any influence of such gradients on the measurements with the stimulated echo technique can be excluded regarding the experimental parameters used.

Results

Figure 2a shows typical echo attenuation curves recorded for two filling factors of VitraPor #5 (1 μm pores). The decay for the partial filled pores with water (squares) and cyclohexane (circles) obviously cannot be described by monoexponential functions. The decay curves can only be described on the basis of Equation (9) by assuming the "general liquid/vapor exchange" model given above. Fits of this formalism to the experimental data are represented by the solid lines. As optimal parameters for fitting we found: $\tau_{\mathrm{l}}^{\mathrm{water}} = 0.7\ s$; $\tau_{\mathrm{l}}^{\mathrm{cyclohexane}} = 0.05$ s; $m_{\mathrm{v,E}}^{\mathrm{cyclohexane}} = m_{\mathrm{v,E}}^{\mathrm{water}} = 1.4$; $m_{\mathrm{v,K}}^{\mathrm{cyclohexane}} = 2.2$ and $m_{\mathrm{v,K}}^{\mathrm{water}} = 3.2$; $m_{\mathrm{l}}^{\mathrm{cyclohexane}} = 0.5$; $m_{\mathrm{l}}^{\mathrm{water}} = 0.87$ or 0.95 for $f = 1$ and 0.15, respectively. Other parameters used in these evaluations were taken from the literature [2,15] and are indicated in Table 1. Based on Equation (10), effective diffusion coefficients can be extracted from the "initial" slope of the attenuation curve (dashed lines) corresponding to the low wavenumber limit, $k^2 \tau_{\mathrm{l}} p_{\mathrm{v}} D_{\mathrm{v}} \ll 1$. The data for the effective

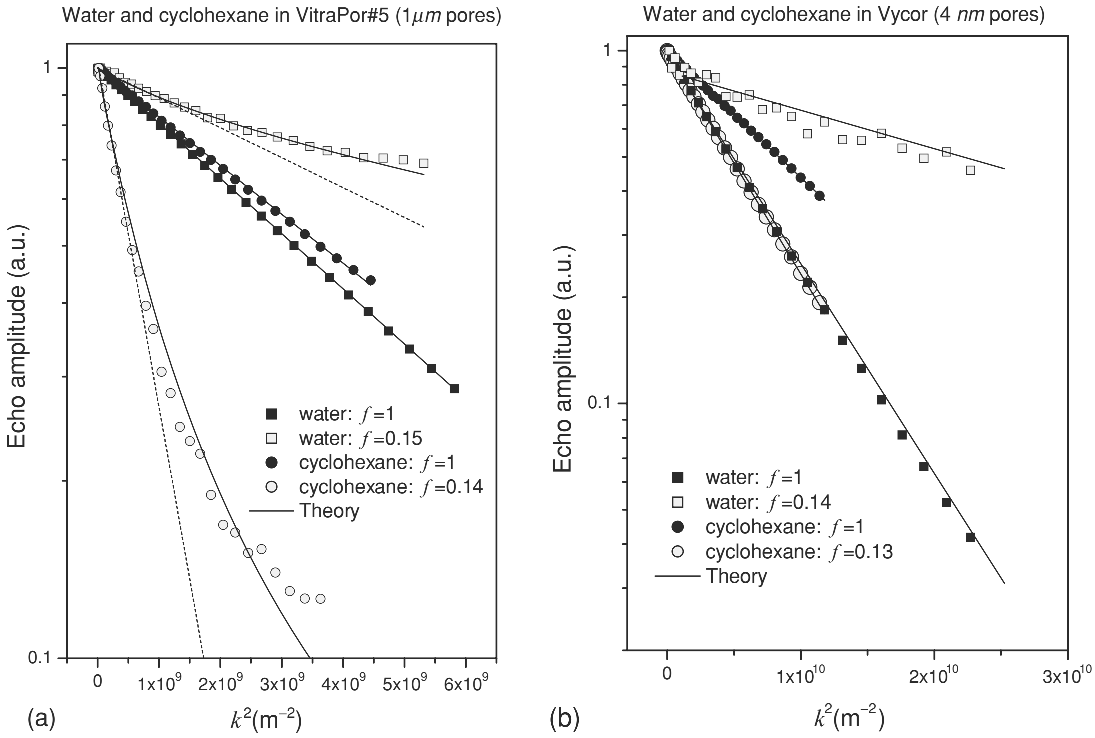

Fig. 2. (a) Echo attenuation curves for water (squares) and cyclohexane (circles) in VitraPor #5 for different filling degrees at room temperature. The experimental data are well reproduced by theoretical curves (solid lines) calculated on the basis of Equation (9) according to the "general liquid/vapor" exchange formalism. The fitting parameters (given in the text) were the mean residence time τ_l in the liquid phase and the exponents in Archie's law. All other parameters were preset by fixed literature values [2,15] as given in Table 1. (b) Echo attenuation curves for water (squares) and cyclohexane (circles) in Vycor for different filling degrees at room temperature. The theoretical curves (solid lines) are fits of Equation (11) to extract the effective diffusion coefficient corresponding to the "fast" exchange limit.

diffusion coefficients of water (squares) and cyclohexane (circles) are plotted in Figure 3 as a function of the filling factor. The theoretical curves are also indicated (solid lines). The different dependencies found for water and cyclohexane are attributed to the different vapor pressures [15] and the different surface interactions these two adsorbate species are subject to. The surface interaction is implied in the Knudsen term in Equation (2) which turned out to be important especially for water.

Table 1: The physical parameters of water and cyclohexane used in the fits of the theory to our experimental data [2,15]

	Water	Cyclohexane
ρ_v/ρ_l	2.5×10^{-5}	5.9×10^{-4}
$D_{l,0}$ (m^2/s)	2.3×10^{-9}	1.4×10^{-9}
$D_{v,0}$ (m^2/s)	2.4×10^{-5}	8.5×10^{-6}

The above results are in contrast with the measurements on Vycor (4 nm pores), where the echo decay (not shown) both for water and cyclohexane can be described by monoexponential functions (see Figure 2b). The conclusion is that "fast exchange" limit applies in this case and effective diffusion coefficients can be extracted as indicated in Figure 4. The fitting of the experimental results (solid lines) with an effective diffusion coefficient given by Equation (12) indicates different tortuosity effects on the Knudsen diffusion contribution in the case of water (squares) and cyclohexane (circles). The deviation of the theoretical curve, in the case of cyclohexane filled sample, from the experimental data can be due to residual water adsorbed from the air, which could not be removed by the procedure described above. Another possible

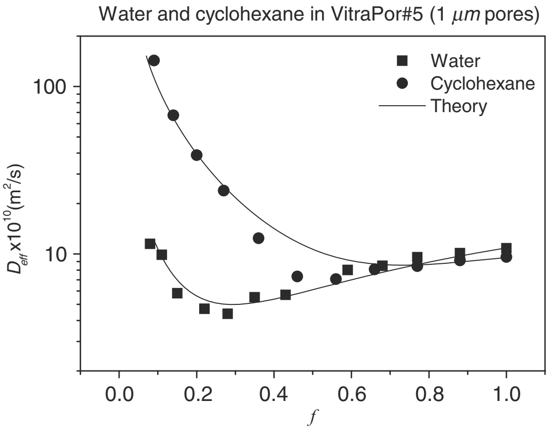

Fig. 3. Effective diffusion coefficients at room temperature for water (squares) and cyclohexane (circles) in VitraPor #5 as a function of the filling factor. The data have been extracted from the echo attenuation curves by fitting a monoexponential function [see Equation (10)] to the initial (low wave number) section. The solid lines represent fits of the effective diffusion coefficient $D_{\text{eff}} = D_l + p_{\text{v}} D_{\text{v}}$ to the data. The fitting parameters are: $m_{\text{v,E}}^{\text{cyclohexane}} = m_{\text{v,E}}^{\text{water}} = 1.4$; $m_{\text{v,K}}^{\text{cyclohexane}} = 2.2$; $m_{\text{v,K}}^{\text{water}} = 3.2$; $m_{\text{l}}^{\text{cyclohexane}} = 0.5$; $m_{\text{l}}^{\text{water}} = 0.87$.

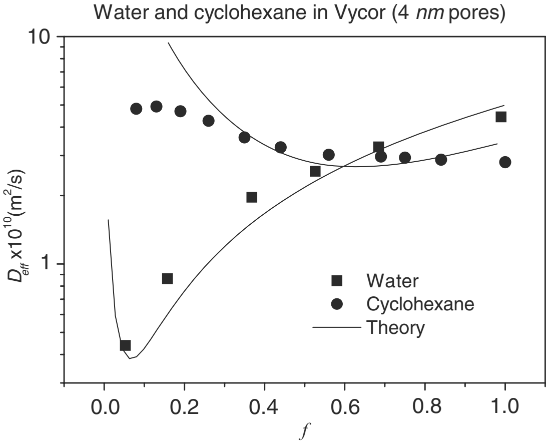

Fig. 4. Effective diffusion coefficients at room temperature for water (squares) and cyclohexane (circles) in Vycor as a function of the filling factor. The data have been extracted from the echo attenuation curves which were monoexponential functions corresponding to the "fast exchange" limit. The solid lines represent fits of the effective diffusion coefficient given by Equation (12) to the data. The fitting parameters are: $m_{\text{l}}^{\text{cyclohexane}} = m_{\text{v,E}}^{\text{cyclohexane}} = 1.1$; $m_{\text{v,K}}^{\text{cyclohexane}} = 0.01$; $m_{\text{l}}^{\text{water}} = m_{\text{v,E}}^{\text{water}} = 1.2$; $m_{\text{v,K}}^{\text{water}} = 2.0$.

explanation is the change of the vapor phase density introduced by the interactions with the surface for low filling factors [6].

Discussion and Conclusions

Translational diffusion of water and cyclohexane as polar and nonpolar solvent species was studied in porous silica glasses with nanometer (Vycor: mean pore diameter 4 nm) and micrometer pores (VitraPor #5: mean pore diameter 1 μm) using NMR diffusometry as a function of the filling factor. The general "two-phase exchange model" well describes all experimental features. The results can be further analyzed into "fast" and "slow" molecular exchange limits between the liquid and vapor phases.

In the case of Vycor (4 nm pores) a "fast exchange" between the liquid and vapor molecules is present both for water and cyclohexane filling fluids for a diffusion time of 300 ms. The data on VitraPor #5 sample (1 μm pores) can be interpreted in the frame of the "general liquid/vapor exchange" formalism, for an experimental time scale of 200 ms. One can conclude that the pore dimension plays an essential role for the applicable exchange limit. Extrapolating the pore size to larger and larger mean diameters, one can infer that this would finally lead to the slow exchange expected to be relevant for well separated liquid and vapor filled compartments independent of the filling fluid.

The vapor phase effect on diffusion as a function of the filling degree was clearly demonstrated in this way. Due to the molecular exchange, the values of the effective diffusion coefficient in the case of cyclohexane in VitraPor #5 sample (1 μm pores), exceed the bulk value by a factor of ten for low filling factors. Molecular exchange means that the solvent molecules are intermittently subject to diffusion features in either phase. Translational displacements in the vapor phase are much faster than in the liquid phase and contribute to the enhancement of the effective diffusion coefficient. For diffusion in the vapor phase, two mechanisms can be distinguished, namely ordinary ("Einstein") and Knudsen diffusion with, possible different, tortuosity effects from the sample structure. Finally, the mean residence time of the solvent molecules in the liquid phase can be evaluated from the fits of the theory to the experimental echo attenuation data.

Gas Adsorption on Carbon Nanotubes

Tanja Pietraß
Department of Chemistry, New Mexico Tech, Socorro, NM 87801, USA

Introduction

Since their discovery in 1991 [1], carbon nanotubes (CNTs) have attracted much attention due to their unique mechanical and electronic properties. Single-walled carbon nanotubes (SWNTs) can be envisioned as a single sheet of graphite rolled into a seamless tube. In multiwalled carbon nanotubes (MWNTs), several of these tubes are stacked inside each other in a concentric fashion. The length and direction of the roll-up vector determine the diameter and chirality of the tube. Statistically, one-third of tubes should be metallic, while the other two-thirds are semi-conducting [2]. Potential applications of CNTs range from field-emitting devices to gas sensors [3].

In 1997, CNTs were reported to store large amounts of hydrogen gas with uptake capacities in the range of 5–10% by weight (wt%) [4]. This result sparked intense research activity due to the potential to exceed the benchmark set by the Department of Energy of 6.5 wt% uptake capacity for an economically viable hydrogen storage medium [5]. The ensuing and continuing controversy about the uptake capacity and sorption mechanism has not yet been settled [10,11]. Results from experimental and theoretical studies indicate hydrogen storage capacities from less than 1 wt% to about 14 wt% [6–9]. A possible origin for these discrepancies may be due to the fact that a large number of production and purification methods are used, resulting in a wide variety of samples.

Experimental studies concerning gas adsorption on CNTs typically employ macroscopic techniques, such as temperature programmed desorption, thermal gravimetric analysis, or adsorption isotherms [6,9,12]. Spectroscopic tools, and in particular magnetic resonance techniques, have been rarely used for the study of gas adsorption. In this contribution, a summary of the literature will be provided together with a discussion of the data generated in our laboratory.

NMR Spectroscopy of CNTs

CNTs, and in particular SWNTs, are typically synthesized using a ferromagnetic catalyst, such as Fe, Co, or Ni. Residual catalyst particles in the sample often prohibit the application of NMR techniques. However, in these situations, ESR may still be able to provide useful information.

A review published in 2002 summarizes the application of ^{13}C NMR and ESR techniques to the structural investigation of CNTs which also includes a section on graphite and graphene [13]. In graphite, the susceptibility enhancement due to 3D stacking leads to strong shifts in the NMR spectra. The intrinsic isotropic shift of a single graphene sheet was deduced to be $\delta_{\mathrm{iso}} = +128$ ppm with an anisotropy of $\delta_{\mathrm{aniso}} = -163 \pm 5$ ppm [13].

A few attempts to record ^{13}C NMR data of CNTs have been undertaken. Maniwa *et al.* compared the ^{13}C NMR of different carbon forms, one of which is described as a bundle of nanotubes [14]. The ^{13}C NMR spectrum displays a line width on the order of 1000 ppm, which is attributed to the large diamagnetic susceptibility of the tubes, possibly in conjunction with the cylindrical structure [14]. A distribution of over 500 ppm centered at the graphene position is reported for MWNTs [13]. It has been suggested that such wide distributions could be due to residual catalyst particles, and the broadening could be reduced by annealing the samples at 1,600 K [15]. A subsequent theoretical study on perfect and isolated SWNTs indicates that high resolution ^{13}C NMR should be able to distinguish metallic and semiconducting tubes with a splitting of 11 ppm [16]. Experimental results have not yet confirmed this prediction, most likely due to a lack of a high-quality sample. Distributions on the order of 200 ppm were observed for SWNTs [13,17] that could be reduced upon MAS. It should be noted that ^{13}C spin-lattice relaxation time measurements indicated the existence of two components that were assigned to metallic and semiconducting CNTs, respectively [19].

We investigated nine different commercial MWNT and SWNT samples before and after subjecting them to an oxidative purification procedure [18]. Sample characteristics, as provided by the manufacturers, and metal contents from residual catalyst as determined by ICP-MS upon complete destruction of the carbon framework, are presented in Table 1 [19].

Recording ^{13}C NMR spectra proved difficult and only two of the samples (MRGC, NL1020) yielded analyzable data. A peak centered at 80 ppm and covering a range of about 160 ppm was obtained for unpurified NL1020, while MRGC displayed a broad peak around

100 ppm. On purification, a large peak at about 22 ppm emerged.

ESR Spectroscopy of CNTs

The high conductivity of graphitic materials results in asymmetric Dysonian line shapes [13,20]. For CNTs, theoretical work predicts fundamental differences in the ESR spectra of SWNTs and MWNTs. While MWNTs are expected to exhibit only a single, narrow peak, spin-charge separation should lead to a splitting for SWNTs [21], which has not yet been confirmed experimentally. Kosaka *et al*. performed ESR studies of CNTs before and after purification [22]. The temperature dependence of the *g*-factor allowed for distinction between conduction electrons and defect sites, introduced in the oxidative purification procedure [22]. The same authors later concluded that annealing removed some types of defects [23]. A similar observation was made by Ishii *et al*. [24]. In contrast, Beuneu *et al.* observed a decrease in line width with irradiation of MWNTs due to a decrease in the *g*-factor anisotropy and in increase in motional narrowing [25]. Byszewski and Nabialek [26] and Kotonosov and Shilo [27] observed Dysonian line shapes with the ESR signal disappearing upon purification which they ascribed to a spin-angular momentum interaction [26]. Temperature dependent studies on MWNTs carried out by Bandow [28] showed the existence of conduction electrons with a largely temperature independent *g*-value, while the intensity of the resonance changed with temperature. The temperature independence of the *g*-factor in MWNTs was confirmed by Lee *et al.* [29] Petit *et al.* [30], however, found Dysonian line shapes at all temperatures for SWNTs, indicating that the metallic character persisted even at the lowest temperatures. Only slight asymmetries in the line shape were observed in solutions and suspensions of unpurified, purified, and shortened SWNTs [31]. The distinction between graphitic particles and MWNTs in solutions of various organic polymer hosts was reported by Coleman *et al.* [32].

For the multi-walled samples listed in Table 1, ESR spectra could only be obtained for MRGC and MRMWC. While MRGC gave rise to a Dysonian line shape, a symmetric line was observed for MRMWC. Purification removed one of the resonances in MRGC, which was assigned to graphitic particles, as suggested by TEM [19].

The high metal content of the SWNT samples resulted in ferromagnetic resonances which disappeared upon purification. A narrow, weak resonance was observed for CNI and MRSW upon acid purification, which was assigned to defects [19].

Gas Adsorption on MWNTs

To the best of our knowledge, Shen *et al.*'s [19] work is to date the only source for ESR data on gas exposure

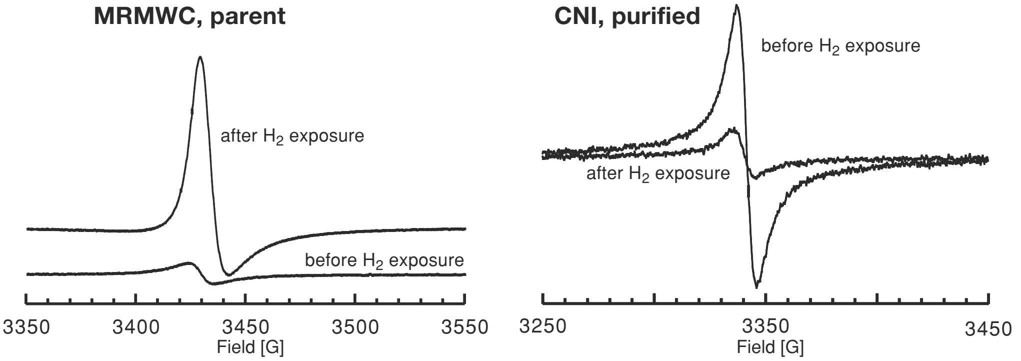

Fig. 1. ESR spectra of unpurified MRMWC and purified CNI before and after hydrogen adsorption. The data were collected at 4.2 K on a Bruker EMX spectrometer operating at a microwave frequency of 9.4 GHz. The samples were heated under vacuum before data acquisition, and exposed for 5 min at ambient temperature to a hydrogen (UHP grade, Matheson–Trigas) pressure of 136 kPa inside the sealed ESR tube.

of CNTs. Among the multi-walled samples described in Table 1, hydrogen exposure greatly increased the ESR signal intensity for MRMWC and MRGC. For the MRGC parent material, an increase of both signal components, assigned to graphitic particles and CNTs, was observed [19]. After purification, the line shape became Dysonian upon hydrogen exposure. It should be noted that MRGC was prepared without a metal catalyst, and the conduction electrons must therefore stem from metallic nanotubes or semiconducting tubes with a small band gap. A possible explanation for the observed increase is a decrease in band gap, such that semi-conducting tubes previously unobservable may become accessible to ESR [19]. Although this explanation is speculative, it is in agreement with theoretical work that shows that hydrogen adsorption on single-walled, radially deformed carbon nanotubes causes the energies of the valence band edge, and conduction band edge to change resulting in a decrease in band gap [33]. This effect is particularly pronounced for zigzag nano-tubes [34]. Hence, a similar increase in signal intensity is expected for other MWNTs, and in fact, was observed for MRMWC as shown in Figure 1.

NMR spectroscopy has been more widely used than ESR spectroscopy to analyze gas adsorption on carbon nanotubes. Early work discussed different carbon materials under a hydrogen pressure of 60 bar [35]. When compared to pure hydrogen gas, significant shifts and changes in line widths were observed for nanotubes, activated carbon, and nanofibers, due to the diamagnetic susceptibility of the carbon materials. Yu *et al.* [36] exposed unpurified MWNTs to hydrogen gas, and studied the ^{1}H NMR shifts and relaxation times as a function of pressure and temperature. At a hydrogen pressure of 300 kPa, the shift of the resonance was inversely proportional to temperature. At 250 K, the shift was about −5 ppm, and increased to about 60 ppm at 70 K. Spin–lattice and spin–spin relaxation times, T_1 and T_2, showed bi-exponential decay. One component was assigned to free hydrogen gas, while the longer T_1 component showed Korringa-type relaxation behavior, evidence of the metallic character of the tubes.

We used ^{1}H and ^{2}H NMR spectroscopy to study hydrogen and deuterium adsorption on the samples listed in Table 1, as a function of gas pressure. In our setup, the pressure could be varied without changing the sample position. After subjecting the samples to the highest gas pressure of 1,480 kPa, the samples were exposed to vacuum which led to the immediate and complete disappearance of the NMR signal. This is a clear indication of fast and reversible physisorption. None of our samples showed any sign of chemisorption.

^{1}H and ^{2}H NMR spectra for multi-walled (MRGC and MRMWC) and single-walled (MRSW and CNI) carbon nanotubes are presented in Figure 2. The ^{1}H NMR spectra for hydrogen exposed Nanolab samples gave rise to broad peaks that seemed to consist of a large number of components and were impossible to phase. These data will not be discussed.

The diminished signal intensity for both purified MWNT samples correlate with the smaller amount of sample weighed into the NMR tube. The ^{1}H NMR spectra of hydrogen exposed MRGC are composed of at least two components that shift downfield with increasing pressure. As shown in Figure 3, the component at −11 ppm (at 1,480 kPa) is dominant at lower pressures, indicating that the sites corresponding to this component are preferentially occupied. Considering that one ESR signal component disappeared upon purification, and that this component was identified as graphitic particles based on the TEM analysis [37], a similar conclusion can be drawn for the NMR data. The component at 2 ppm (at 1,480 kPa)

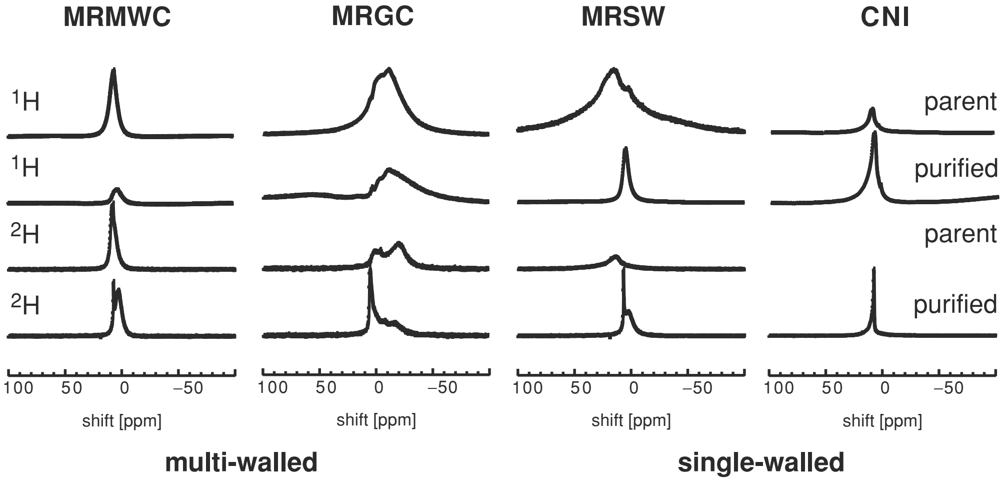

Fig. 2. ^{1}H and ^{2}H NMR spectra of parent and purified MWNTs and SWNTs after exposure to a hydrogen (UHP grade, Matheson–Trigas) or deuterium (D_2 99.6%, Cambridge Isotope Laboratories) pressure of 1,480 kPa. The narrow resonance discernible in the ^{2}H NMR spectra is due to free hydrogen gas. The data were recorded at ambient temperature on a Bruker MSL-400/Tecmag Apollo NMR spectrometer at a Larmor frequency of 400.13 and 61.42 MHz, respectively. Note that the signal component at 4 ppm, which is most obvious in the ^{1}H NMR spectra of purified MRGC, is due to probe background and also present when removing the sample.

is also diminished in intensity after purification, and is thus likely due to hydrogen adsorbed on graphitic particles. Therefore, the component at -11 ppm is tentatively assigned to hydrogen in contact with other carbon structures such as nano-onions or carbon nanotubes [37]. The line width of this peak component increases with pressure [38]. The large deviation from the typical chemical shift range for hydrogen is indicative of a Knight shift contribution due to interaction with metallic carbon nanotubes, and in agreement with the Dysonian line shapes observed with ESR [19].

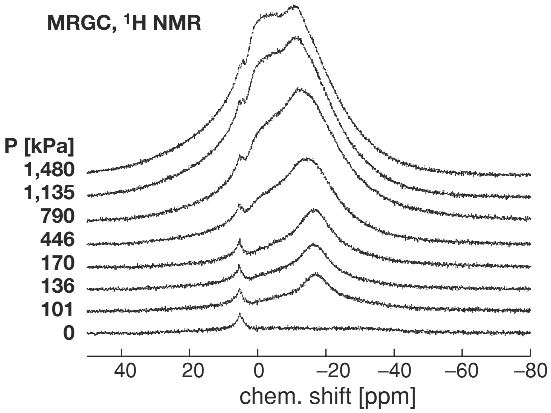

Fig. 3. ^{1}H NMR spectra of parent MRGC nanotubes after exposure to hydrogen (UHP grade, Matheson–Trigas) at a variety of pressures. Note that the signal observable at 0 kPa is due to probe background. The data were recorded at ambient temperature on a Bruker MSL-400/Tecmag Apollo NMR spectrometer at a Larmor frequency of 400.13 MHz.

^{2}H NMR data largely agree with the ^{1}H NMR results. The largest discrepancy lies in the different position of the -11 ppm resonance, which appears at -20 ppm in the ^{2}H NMR spectra. It remains to be resolved whether this effect can be attributed to differences in the two isotopes. When comparing the overall line width for the two isotopes, they scale with a factor of 6.5 which is remarkably close to the ratio of the gyromagnetic ratios, γ. Hence the most likely origin is susceptibility broadening. The narrower ^{2}H NMR line widths allow the resonances for free deuterium to be distinguished from adsorbed gas [38].

Both ^{1}H and ^{2}H NMR data for MRMWC reveal only a single resonance (Figure 2) due to adsorbed hydrogen. This is surprising given the fact that TEM data revealed the presence of nanofibers [37]. Moreover, the tube walls are severely damaged upon purification which is expected to cause the formation of defect sites as confirmed by ESR [19]. The much narrower NMR line widths and the line position suggests a much smaller contribution from conduction electrons, when compared to MRGC and a smaller number of sites accessible to hydrogen. These facts are in agreement with the hypothesis that MRMWC is predominantly made up of semiconducting nanotubes, and that nanofibers do not present preferred adsorption sites for hydrogen [38].

Gas Adsorption on SWNTs

Tang *et al.* [17] investigated electronic properties of CNTs under a variety of conditions using NMR spectroscopy. They found that oxygen exposure substantially affected the ^{13}C T_1, and suggested as the most probable mechanism the paramagnetic nature of the oxygen molecule. However, the authors indicated that changes in the electronic properties could contribute as well. Nevertheless, this observation underlines the necessity to carefully evacuate CNT samples before conducting any experiments. Schmid *et al.* [39] investigated hydrogen adsorption on fragmented SWNTs using ^{1}H NMR spectroscopy. The SWNTs were ball-milled at a hydrogen pressure of about 800 kPa, and then washed with hydrochloric acid. It was shown that both line width and spin-lattice relaxation were mainly affected by the paramagnetic impurities introduced via ball-milling. The authors quantitated the hydrogen uptake by comparison to an external reference of glycerine, and estimated an uptake of 5 wt%. Shiraishi *et al.* [40] observed a narrow resonance (less than 300 Hz) at 5.1 ppm. Due to the similarity of this shift to that of water, the authors exposed the sample to SO_2 gas. They observed no change in the resonance, concluding that it could not be due to water. The T_1 was measured at about 0.1–0.2 s, significantly longer than the ones we observed on our samples, which were all in the range of ms. In subsequent work, Schmid *et al.* [41] performed temperature dependent ^{1}H NMR studies on SWNTs synthesized with the non-magnetic catalysts rhodium and platinum, and subjected to a hydrogen pressure of about 2,300 kPa. They observed hydrogen desorption at about 150 K. The authors were not able to distinguish between different adsorption sites. Kleinhammes *et al.* [42] investigated the adsorption of ethane and methane on SWNTs using ^{1}H NMR spectroscopy. They concluded that the interior of the tubes became accessible to the gases upon cutting the tubes using an oxidative procedure. T_1 measurements revealed two components which were assigned to adsorbed and free gas. Co-exposure to oxygen gas did not affect the spectra which led the authors to conclude that oxygen did not enter the endohedral sites. Furthermore, the authors studied the effect of adsorbed gases on ^{13}C NMR relaxation times. These were strongly affected by oxygen due to its paramagnetism and, surprisingly, also by He. The authors argued that the small He can enter the interstitial sites and thus has access to the majority of the carbon atoms.

Unlike for MWNTs, we observed a reduction in ESR signal intensity when exposing SWNTs to hydrogen gas (Figure 1). The symmetric ESR line shapes indicate that the observed signal is due to isolated spins such as dangling bonds [19]. Hydrogen adsorbs preferentially on such defect sites as has been shown for mechanically prepared nanostructured graphite [43]. ^{1}H and ^{2}H NMR spectra are shown in Figure 2. The large metal content in CNI caused a low signal-to-noise ratio in the ^{1}H NMR spectra, so that no ^{2}H NMR was attempted. For the purified CNI sample, the ratio of the ^{1}H to ^{2}H line width is about 9, slightly larger than expected for pure susceptibility broadening. Additional contributions to the line width may arise from dipolar contributions.

TEM and ICP-MS showed that the MRSW sample was high quality despite the high metal content before purification (Table 1). Indeed, the ESR spectra revealed a ferromagnetic resonance as for CNI [19]. Correspondingly, the signal-to-noise ratio in the ^{1}H NMR spectra was low. After purification, only a single resonance was observed and the overall line width was reduced to 2.4 kHz from 16.1 kHz. ^{2}H NMR results mostly corroborated the ^{1}H NMR findings (Figure 2), although the line position for the main peak component changed. The ratio of the line widths for the two isotopes was about 20 at a pressure of 1,480 kPa, indicating significant contributions to the line width other than susceptibility broadening. Spectral hole burning and two-dimensional exchange experiments indicated that the line width is determined by a heterogeneity in adsorption sites. The same conclusion was drawn from ^{129}Xe and ^{131}Xe NMR spectroscopy [45]. Hole recovery experiments at different pressures suggest that exchange among these sites is diffusion limited [44].

Summary

Magnetic resonance spectroscopy as a tool to study gas adsorption in carbon nanotubes is an emerging field. The main difficulty encountered lies in the fact that CNTs are highly inhomogeneous. Careful characterization and possibly purification are necessary to minimize the interaction of adsorbates with impurities such as residual catalyst particles, other carbon nanostructures, graphitic, and amorphous carbon. The most pertinent questions, the nature of the adsorption and the gas storages capacities, have not yet been satisfactorily answered with magnetic resonance or any other technique.

However, all data seem to indicate that none of the samples investigated exhibited extraordinary gas sorption capacities in the pressure and temperature ranges investigated using magnetic resonance tools. We observed exclusively physisorption for our samples. The slopes of the ^{1}H NMR integrated signal intensities as a function of pressure for the samples listed in Table 1 were smaller by about a factor 2 than for pure hydrogen gas (Figure 4a). Even when taking into account that the available volume in the NMR pick-up coil was reduced due to the dead volume of the CNTs, we estimated an upper limit of the

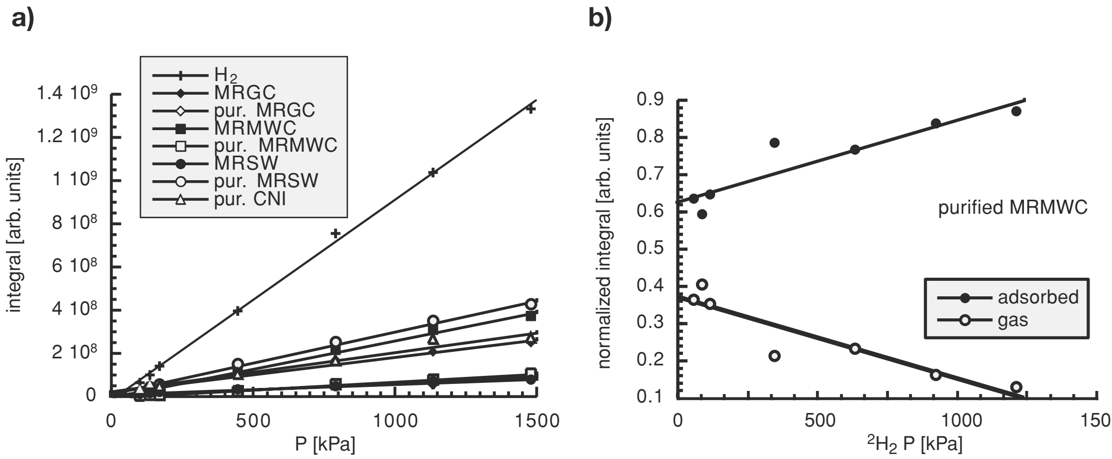

Fig. 4. (a) ^{1}H NMR integrated signal intensities as a function of pressure for different CNT samples. Pure hydrogen gas is included for comparison. (b) Integrated and normalized NMR signal intensities after decomposition into a gas and adsorbed component for purified MRMWC. Note that with increasing pressure, hydrogen is preferentially adsorbed on the CNTs.

uptake capacity of our samples to about 0.1% [38]. These findings were corroborated by ^{129}Xe and ^{131}Xe NMR experiments where adsorption (for unpurified MRMWC and MRSW) was observed only for temperatures below 200 K. Our data show that the distinction between free and adsorbed hydrogen is easier using ^{2}H due to decreased susceptibility broadening and dipolar interactions. In Figure 4b, the decomposed and normalized ^{2}H NMR signal intensities for purified MRMWC are plotted as a function of pressure. The difference in slopes clearly indicates that with increasing pressure, hydrogen preferentially enters the adsorbed phase. More data are needed to understand gas adsorption in these exciting materials, and magnetic resonance techniques are an ideal tool to study them.

Introduction

The long-established method of distinguishing between heterogeneous and homogeneous *line shapes* was introduced in the seminal paper by Bloembergen *et al.* [1]. The differentiation between the two types of spectral lines is based on whether one can alter the shape or just the amplitude of a line by an external perturbation. This concept has been applied many times particularly in optical hole burning spectroscopy where the distribution of transition frequencies can often be traced back to structural inhomogeneities in the material under study. It is well known that the frequency of an electronic transition, for example, sensitively depends on the local symmetry. This technique has been successfully applied to the structural elucidation of glasses [2].

In condensed matter where there is a well-defined structural heterogeneity it is natural to expect that there will also be spatially non-uniform dynamics. The study of the recovery of spectral holes burnt into an inhomogeneously broadened line provides but one means of testing for such a scenario. However, for systems devoid of an evident structural heterogeneity, such as supercooled liquids, questions regarding possible dynamic disorder have for a long time been most prominently discussed in the field of dielectric spectroscopy rather than NMR. In this context, we mention the important works of Kohlrausch [3], Curie [4], and von Schweidler [5] on the one hand and papers by Wagner [6] and Cole and Cole [7] on the other. The approaches used in these works merely *assumed* that either a distribution of correlation times is present or that the correlation function itself decays non-exponentially. More systematic attempts to distinguish between these two scenarios experimentally using optical [8, 9] and dielectric techniques [10, 11] were carried out in the 1970s by various groups. In retrospect it can be stated that a well-established consensus as to whether the dynamics of disordered systems should be considered homogeneous or heterogeneous was *not* reached at this stage. Prior to the breakthrough achieved in the early 1990s there was very little activity in this area employing NMR techniques [12]. In their pioneering 1991 work Schmidt-Rohr and Spiess [13] resolved the homogeneity vs. heterogeneity issue for the structural relaxation, the so-called α-relaxation, which accompanies the vitrification transition of an amorphous polymer. To this end they introduced a reduced four-dimensional (4D) NMR technique which later was further reduced to an echo experiment employing four equally long evolution times. The nature of the secondary or β-relaxation in small-molecule glass-formers had been clarified previously by the observation of a non-exponential recovery in a deuteron spin–lattice relaxation experiment [14]. This work uses the theoretical statement that spin–lattice relaxation must be exponential for isolated deuterons in high field [15].

These experiments not only set the stage for numerous other NMR investigations but also stimulated the development of related optical [16], dielectric and magnetic spectroscopic techniques [17–19]. Since both theoretical [20, 21] and experimental work [16,20,22,23] in the field of dynamical heterogeneity has previously been reviewed, in the present chapter, we will focus on recent developments using NMR techniques and on aspects not widely appreciated in the glass community.

In this article we first discuss the spatial and dynamical heterogeneity in disordered materials as monitored via the rotational (Sections "Rotational Dynamics Near the Vitrification Transition" and "Freezing in Glassy Crystals") and translational (Section "Heterogeneous Transport in Ionic Conductors") degrees of freedom. The study of secondary relaxations using NMR techniques is then given separate consideration in the Section "Probing Secondary Relaxations." The concluding Section "Single-Molecule Spectroscopy" deals with some results and prospects arising from single-molecule spectroscopy for the investigation of dynamic heterogeneity.

Rotational Dynamics Near the Vitrification Transition

In the following we will use our previous definition of the term dynamic heterogeneity [24]: "we will call a system dynamically heterogeneous if it is possible to select a dynamically distinguishable subensemble by experiment or computer simulation." Using the reduced four-dimensional technique of Schmidt-Rohr and Spiess it is possible to implement such a selection experimentally. The technique is based on a sequence of seven radio frequency pulses which yields a four-time correlation function of the form

$$E_4(t_p, t_{m1}, t_{m2}, t_{m3}) \propto \langle \exp[i\varphi(0)] \exp[-i\varphi(t_{m1})] \times \exp[i\varphi(t_{m2})] \exp[-i\varphi(t_{m3})] \rangle \qquad (1)$$

Here the t_{mi} with $i = 1,2,3$ denote three mixing times and the phase angles φ are those acquired during the corresponding evolution times t_p. With appropriate phase cycling the sine and cosine contributions to the general four-time stimulated-echo (4t-SE) function can be mapped out separately [25].

A few degrees above the calorimetric glass transition temperature supercooled glasses and polymers exhibit a non-exponential structural relaxation. The 4t-SE functions in many of these materials have been measured using ^{2}H- and ^{13}C-NMR. Two important findings have emerged (for a compilation see Ref. [22]). First, it was generally observed that slow subensembles can be selected thus demonstrating the existence of dynamical heterogeneity of the primary relaxation. This conclusion was confirmed later by several other techniques [16,17,22] and furthermore a measure of the degree of heterogeneity was defined [24]. Second, the echo variant of the reduced 4D experiment provided evidence for a short-lived dynamic heterogeneity. The life-time of the heterogeneity τ_{het} relative to that of the typical structural relaxation time τ_α was characterized by a rate memory parameter $Q = \tau_{\text{het}}/\tau_\alpha$ [26]. While in neat samples typical Q-parameters were found to be close to one [27], experimental methods employing impurity probes give Q-parameters as large as 1000 [16,22].

A third parameter that has been used to characterize dynamic heterogeneity is its length scale ξ. The original four-time experiments were *not* designed to probe length scales directly. However, length scale determinations became possible by augmenting the original seven-pulse experiments with cross-polarization steps to an abundant species such as ^{1}H thus facilitating pronounced spin-diffusion effects [28]. A possible spatial heterogeneity for which ξ is well defined is sketched in Figure 1a. In reality, the spatial structure of the slow domains may be more complex than that depicted in the diagram and the definition of a unique length scale is often far from being unambiguous [20]. Nevertheless, given the fact that prior to these experiments, length scales could only be *estimated* using more or less well-accepted model assumptions, they marked a major step forward in the field of glass science.

Some results on the viscous liquid sorbitol are reproduced in Figure 1b [29]. Comparison of the dynamic selection experiments with calculations based on the assumption of slow spherical domains reveals evidence for length scales $\xi_{\text{het,NMR}}$ of 2.7 ± 1.2 nm. Results from the four glass-formers that have been studied so far using this type of experiment, indicate that $\xi_{\text{het,NMR}}$ is in the range of 1–4 nm, not too different from previous estimates, see e.g. [30, 31]. The relative error in $\xi_{\text{het,NMR}}$ which is typically about 30–50% has so far precluded the establishment of correlations with other properties characterizing the highly viscous state such as, e.g. measured by its fragility index [29].

Freezing in Glassy Crystals

A glass transition solely due to the freezing of the orientational degrees of freedom is sometimes exhibited by so-called plastic or glassy crystals. Well-known representatives of this family of (quasi-) monoatomic substances that were recently studied using NMR are C_{60} [32], cyanoadamantane [33, 34], and *ortho*-carborane (OCA) [35].

Four-time correlation functions have so far been only measured for OCA. By performing a detailed analysis of the experimental results the relatively complex reorientational geometry in this material was unraveled. Of particular importance in the present context was the finding that the molecular motion involves a sequence of small-angle tilts about locally preferred axes as well as symmetry adapted threefold jumps [35]. The rates for the tilt and for the jump motions were shown to be somewhat different. This difference is the source of the intrinsic non-exponential response which characterized this crystal. In addition, evidence for dynamic heterogeneity was obtained by measuring the 4t-SE function described above. As has been emphasized in more detail elsewhere [22], the geometry of the molecular motion enters into the interpretation of such experiments if the evolution time t_p is finite. Since it is impractical to let $t_p \to \infty$, the case $t_p \to 0$ has been analyzed both experimentally and theoretically [36]. If one uses the sin–sin–sin–sin correlation function for very small t_p then this amounts to studying the particularly simple form $L_4 \propto \langle \omega_1 \omega_2 \omega_3 \omega_4 \rangle$. Here ω_i denotes the perturbed NMR frequency during the evolution interval i. It turns out that this function can be decomposed into several parts one of which is independent of the rotational motion but sensitive to dynamic exchange. In particular it was found that, in the absence of dynamic

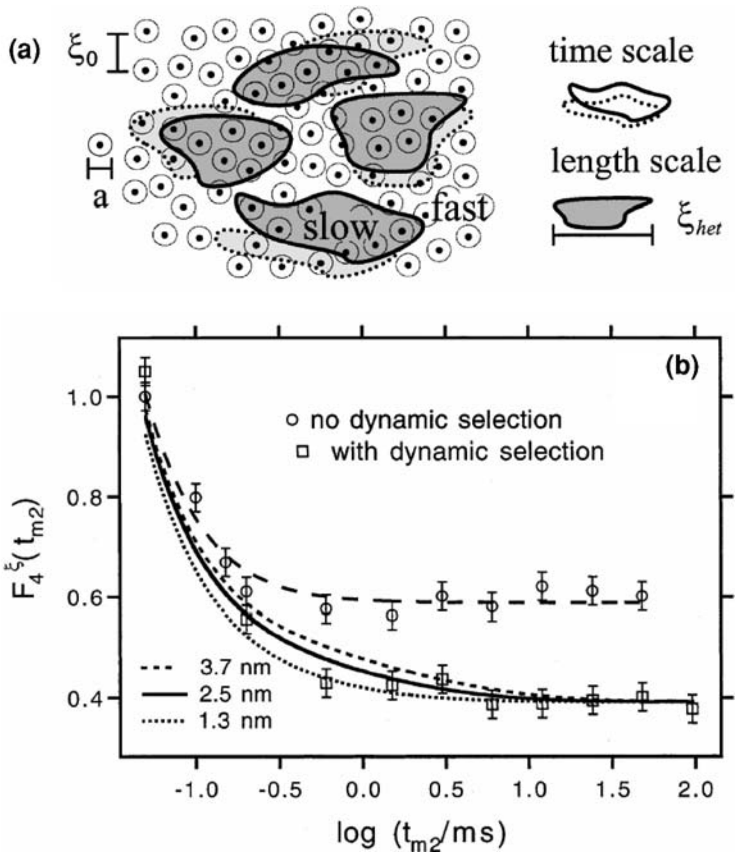

Fig. 1. (a) A sketch of the length scale of dynamic heterogeneities. The temporal "fluctuations" of the positions of the shaded areas are meant to indicate that the specified molecules or polymer segments switch between fast and slow states. Reproduced by permission from Ref. [28]. (b) Echo intensities for the 4D3CP experiment as a function of the mixing time t_{m2}. The data were recorded at 275 K on sorbitol with and without dynamic selection. The best fit to the data is obtained for $\xi_{\text{het}} = 2.5 \pm 1.2$ nm. Reproduced by permission from Ref. [29].

exchange, this part for isotropic motions does not become smaller than 7/15 of the initial value of L_4 [36,37]. This experiment seems well suited to the study of substances with a complex molecular motion geometry.

The experimental data, together with the results of calculations based on the anisotropic tilt and jump model recently obtained for L_4 in OCA [38] are shown in Figure 2. The effective evolution time used in the experiment is approximately given by the mean length of the radio frequency pulses; in this case about 3 µs. The calculations are therefore only shown for a small range of evolution times. It is seen that as $t_p \to 0$ the plateau value of 7/15 is not exactly met and for finite t_p a large variation in the plateau value is observed. The experimental data exhibit smaller values than the results from the theoretical computations and thus are compatible with the presence of dynamic exchange in harmony with earlier measurements for much longer evolution times [35].

In order to better approach the limit $t_p \to 0$, one could generate the transverse magnetization at the start of the four evolution intervals *not* by a single pulse but by a solid-echo sequence. This would add four more pulses to this multiple-pulse experiment. A similar replacement of a single $\pi/2$ pulse by a solid-echo sequence has been used in the context of multidimensional spectroscopy [39].

Heterogeneous Transport in Ionic Conductors

Dynamic heterogeneity has been intensively studied for organic glass-formers, but for inorganic materials such as ionic conductors the issue has been rarely addressed. One of the pioneering NMR works focused on the molten nitrate melt $2Ca(NO_3)_2 \cdot 3KNO_3$ [40] and exploited the non-exponential ^{15}N magnetization recovery to demonstrate that distinguishable subensembles can be selected. In a further study on the glassy state of this material dynamic heterogeneity was exhibited using non-resonant dielectric hole burning spectroscopy [41].

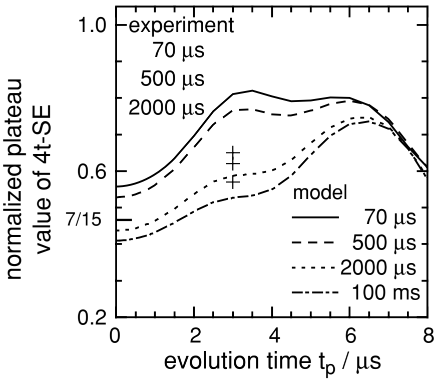

Fig. 2. The normalized plateau values ($t_{m2} \to \infty$) of the sin–sin–sin–sin correlation for OCA are shown as crosses for three different mixing times $t_{m1} = t_{m3}$. The corresponding two-time correlation function is characterized by a time constant of 720 µs. The assignment of the evolution time t_p takes the quadrupolar evolution during the pulses into account on an empirical level. The solid lines represent the computations of the evolution time dependence using the tilt and jump model [35] for the motion of the icosahedral molecules for several mixing times $t_{m1} = t_{m3}$. It seen that for the anisotropic tilt and jump model the isotropic limit of 7/15 is not met. Taken from Ref. [38].

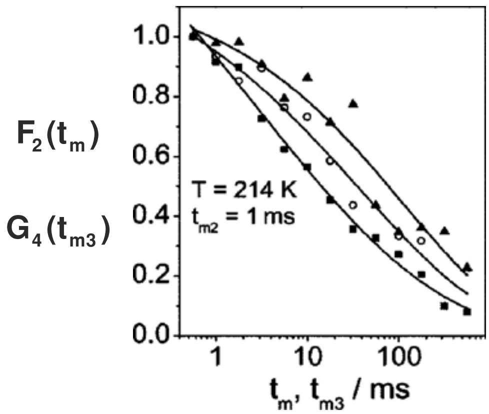

Fig. 3. The ^{109}Ag NMR data of a $(AgI)_{0.3}$–(1/3)$(2Ag_2O$–$P_2O_5)_{0.7}$ glass at T = 214 K shown here were normalized to the data points measured for the shortest mixing time. The two-time correlation function $F_2(t_\mathrm{m})$ (squares) is compared to the four-time correlation functions $G_4(t_\mathrm{m3})$. For the latter functions t_m2 was set to 1 ms and t_m1 was chosen as 1 ms (circles) or 7 ms (triangles). The solid lines represent fits using a stretched exponential function. For further details see Ref. [42] from which this figure was adapted.

The question whether dynamically distinguishable subensembles can be selected is of particular interest in the context of molten and solid electrolytes because it is not clear a priori how much the long-ranged ion–ion interactions homogenize the response of the mobile charge carriers. A question which has often been discussed in this context is whether there is an enhancement of forward-backward hops. In other words one wants to know whether a site memory effect exists. In order to address this question experimentally at least a three-time correlation function must be measured.

Measurements of higher-order correlation functions by stimulated-echo NMR techniques were recently carried out using the mobile ^{109}Ag species as the nuclear probe. Four-time correlation functions were first reported for silver phosphate glasses [42] and then also for related crystalline and amorphous silver ion conductors [43, 44]. As an example, in Figure 3 the two-time correlation function $F_2(t_{m2})$ [45] is compared with a low-pass filtered correlation function $G_4(t_{m3})$ of a $(AgI)_{0.3}$–(1/3)$(2Ag_2O$–$P_2O_5)_{0.7}$ glass. These are compared. These and related results [42–44] show that slow subensembles can be selected, demonstrating the dynamical heterogeneity of the translational degrees of freedom in these materials.

Light nuclear species such as ^{6}Li, ^{7}Li, and ^{9}Be or heavier spin ½ nuclei such as ^{77}Se or ^{125}Te would also seem to be suitable for such studies. For lithium in conducting glasses, the application of multiple-time correlation functions was considered from various perspectives [46, 47] but so far has not been exploited experimentally.

Probing Secondary Relaxations

The dynamics in a frozen structure that emerged from a dynamically heterogeneous melt are expected to be heterogeneous as well. In fact, in the previous paragraph we have discussed such a situation for the special case of ion conducting materials. The phenomenon is, however, more general and was, for instance, observed in two-dimensional "cross" spectra of mobile tracers in glassy hosts [48].

Several aspects of NMR studies concerning the secondary relaxation in glasses were reviewed earlier [49,22]. As mentioned above, one of the simplest methods to identify dynamic heterogeneity is to apply deuteron relaxometry and to check whether the longitudinal magnetization recovers in a non-exponential fashion [14,50,51]. If so, the difference between the mean relaxation rate, as measured via the initial slope of the magnetization recovery curve, and the mean relaxation time becomes very pronounced [52].

As demonstrated by Leisen *et al.* a dynamic low-pass filter can also be used to select subensembles out of a distribution of spin–lattice relaxation times [53]. It was found that by selecting the response of polystyrene segments with correlation times slower than about 10 ms, the subsequently measured magnetization recovery time, most sensitive to motions with rates near the Larmor frequency (of 45 MHz in that experiment) was slowed down somewhat. When investigating the dynamics of the methyl group of the supercooled liquid propylene carbonate it was found in a stimulated-echo experiment that the magnetization recovered faster than in the conventional T_1 experiment [54]. These and related effects were recently exploited and shed new light on the interplay between slow (i.e. primary) and fast (e.g. secondary) relaxation processes near and below the glass transition temperature [55].

Single-Molecule Spectroscopy

The concept of selecting particular subensembles is most uniquely implemented in single-molecule experiments. Mechanical and optical detection schemes with single-spin sensitivity have been developed. Most recently, a mechanical technique exploiting the sensitivity of the atomic force microscope was used to resolve the signal from a single unpaired electron spin in silicon dioxide [56]. Optical detection has also been achieved for a single electron as well as for single nuclear spins [57]. The cited experiments were all conducted at liquid helium temperatures. However, at room temperature single-spin detection has proven to be possible only in specific cases. For example Gruber *et al.* have studied a single paramagnetic nitrogen-vacancy (N-V) defect in diamond [58].

A particularly promising approach for the study of dynamic heterogeneity is the general capability of these techniques to record a time series for single molecules. Although *not* using single-*spin* detection but rather dielectric or optical single-molecule spectroscopy, such time series have been used, e.g. to characterize the spectral diffusion and switching of low-energy excitations in two-level systems [59]. As well, single-molecule techniques have been used to investigate dynamic heterogeneity in an amorphous polymer [19] and in the context of enzymology [60]. In the latter case, multiple-time correlation functions describing the chemical reaction kinetics were used to distinguish homogeneous from heterogeneous scenarios both of which could be implemented by changing the experimental conditions. In addition, polarization resolved recording of a single-molecule fluorescence time series [61] was used to probe dynamic heterogeneity in polymers [62] and simple organic glass-forming liquids [63].

Conclusion

The measurement of multiple-time correlation functions has emerged as an important tool for the elucidation of the nature of dynamical heterogeneities in disordered condensed matter. Relevant information comes from combining the results of various two-, three-, and particularly four-time NMR stimulated-echo experiments which are often used in conjunction with cross-polarization steps to a nuclear species characterized by spin-diffusion. The most important quantities observed in the context of the vitrification transition are the heterogeneity life-times and the associated length scales. A major limitation of these experiments arises because various relaxation times resulting from nuclear coupling constants, molecular correlation times, and spin-relaxation times impose severe restrictions on the time scales that can be investigated using these multiple-time correlation functions. Therefore, for a given material, measurements using these techniques can reasonably be obtained in a relatively narrow temperature range which typically is only a few degrees wide. As a result, other methods will certainly continue to play a major role in the selection of dynamically distinguishable subensembles. These include non-linear dielectric methods, nano-mechanical experiments using scanning microscopy and, probably most importantly, optical spectroscopies with sensitivities down to the single-molecule level.

Nuclear Magnetic Resonance in Ferromagnetic Multilayers and Nanocomposites: Investigations of Their Structural and Magnetic Properties

C. Mény and P. Panissod
Institut de Physique et Chimie des Matériaux de Strasbourg UMR 7504 ULP-CNRS, 67034 Strasbourg Cedex, France

Introduction

In the past, nuclear magnetic resonance (NMR) studies have proved useful for structural investigations of magnetic multilayers in the direct space and at the atomic scale, complementing standard structural investigations [1]. Actually NMR provides with an original insight into the structural and magnetic characterization of composite nanostructured materials. Indeed the yield of NMR experiments is twofold. On one hand, the NMR spectrum, usually acquired in zero external field, reflects the distribution of hyperfine fields in the sample, and thus gives information about the different chemical configurations and site symmetries in the sample, the different phases, their structure, and their defects. On the other hand, the evolution of the spectral shape against the external field strength and orientation or against the radio frequency field strength probes the magnetic anisotropy or the magnetic stiffness of the electronic moments around the nucleus site, thus providing an information comparable to that given by ferromagnetic resonance (FMR) measurements. Therefore, combining both yields makes it possible to correlate the inhomogeneous magnetic properties of a composite sample to its different structural components [2]. The structural aspects of NMR studies are summarized in the first part of the chapter. Most of the chapter is devoted, though, to the analysis of NMR data in terms of local magnetic properties.

NMR and Atomic Structure

NMR probes primarily the hyperfine field (HF), arising from ordered local magnetic moments around the observed nuclei. HF determines the NMR resonance frequency. Since the moments depend on the local structure and chemical environment, specific structural regions correspond to specific frequency ranges in the NMR spectrum. The relationship between the hyperfine field and the local structure is usually inferred from studies of structurally well-known standard alloys and compounds [3] but theoretical calculations (although difficult) can be undertaken as well [4]. The analysis of the NMR lines yields the fractions of atoms involved in the various atomic configurations or structural components in a sample. For example, in a perfect Co/X multilayer, the spectrum should exhibit two narrow lines only, one for the bulk part of the Co layers (close to the frequency of bulk ferromagnetic Co) and one for Co atoms at the interfaces. An example Co NMR spectrum observed in a Co/Cu multilayer is shown in Figure 1. The layered structure is obviously far from perfect here. The spectrum can be coarsely separated into three parts: a main line at 215 MHz corresponding to bulk Co with fcc structure, a set of shoulders at higher frequencies corresponding to Co in hcp-like environments (bulk hcp Co at 225–228 MHz, stacking faults at 220–225 MHz), and a set of lines below 200 MHz corresponding to Co atoms with at least 1 Cu among their 12 nearest neighbors (Co atoms at the Co/Cu interfaces). The main line frequency is slightly lower than that of pure fcc Co (217 MHz), which is due to the expansive strains resulting from the difference between Co and Cu lattice constants [5]. The extended tail observed in the low frequency range is typical of diffuse interfaces, but a small fraction of sharp interface areas is evidenced by the well-defined peak at 165 MHz, which corresponds to Co with three Cu nearest neighbors at perfect ⟨1 1 1⟩ interfaces [1]. In samples with interface spectra extending over a spectral range corresponding to a spread of nearest neighbor (NN) configurations A_nB_{Z-n} around the probed nuclei (say B), modeling the spectral shape does provide more quantitative information about intermixing at the interfaces (short-range admixture). Simulated spectra consist of a sum of $Z+1$ lines ($Z = 12$ NN in compact structures), arising from B nuclei surrounded by $(Z-n)$ B atoms and (n) A atoms. The different lines are, in most cases, equally spaced [3]. Considering a model (topological and chemical) of the interface structure, configuration probabilities (line intensities) can be calculated, which are used to reconstruct the spectrum. The refined parameters obtained from the fitting procedure give a direct insight on the short-range order at the interfaces. Figure 2 illustrates

(C_a, concentration of the alloy in the atomic plane and A_a, area fraction of the alloy in the plane are the parameters of the model.)

some models that have been successfully used to describe the interface spectra of Co/X multilayers [1]. Note that the expected spectral shapes are quite different between the different models, which shows that the different types of interface structure can be easily discriminated (see Figure 2 legend for more details about the model parameters). For example, the interface spectrum of the sample in Figure 1 can be fitted with model C mostly alloyed.

Local Magnetic Moments—Hyperfine Field and Magnetization Profiles

The direct yield of an NMR experiment in magnetic materials is the hyperfine field produced by the spontaneous electron spin polarization at the observed nuclei. As such the measurement provides a direct insight, element and site specific, onto the electronic moment values and, possibly, the magnetic structure. This rather standard aspect is not developed here. Let us only mention that, in multilayers where there are several mixed planes at interfaces, the analysis of the interface concentration profile yields also the average HF for each atomic plane, which reflects the magnetization profile at the interfaces [2].

Zero-Field NMR—Local Restoring Field and Magnetic Stiffness

In magnetic materials, a DC external field is not necessary because the spontaneous magnetic moment creates a large internal field, the HF, at the nuclei. In addition, the nuclei are not directly excited by the external radio frequency field H_1 but by the oscillation of HF following the electronic moment response to H_1. The radio frequency field experienced by the nuclei ($B_\perp$) is therefore strongly enhanced compared to the external one (H_1). This enhancement, related to the transverse susceptibility of the samples (and therefore sample dependant), is often characterized by the so-called enhancement factor $\eta = B_\perp / H_1 = HF/H_r$, where H_r is the effective field that restores the equilibrium position of the electronic moments. When the NMR signal is recovered, the reverse process occurs: the precessing transverse nuclear magnetization exerts a torque on the electronic magnetization,

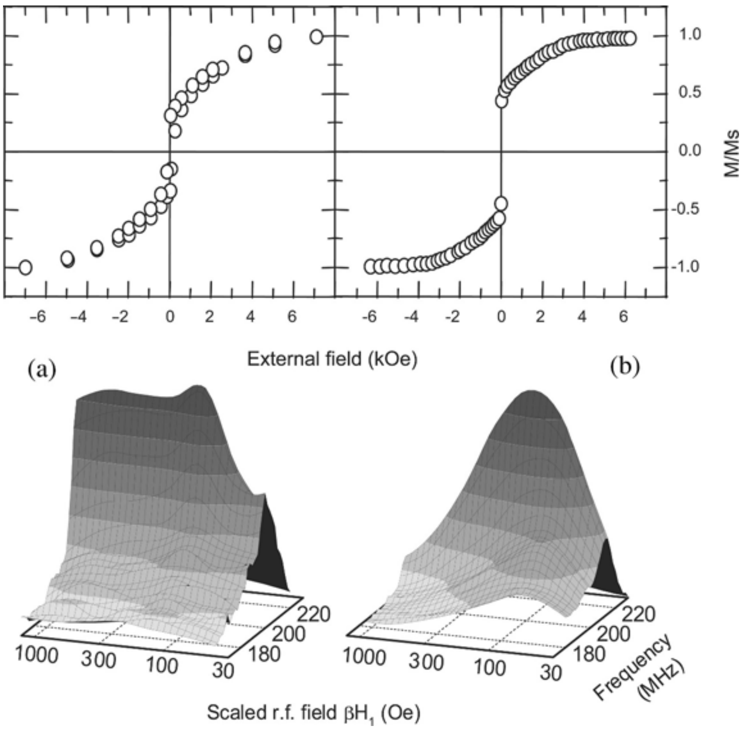

Fig. 3. Co/Cu multilayers with a large antiferromagnetic coupling showing similar magnetization loops (top panels) but very different degrees of coherence in their magnetization process (bottom panels). (a) Case of broad distribution of restoring field (inhomogeneous coupling). (b) Case of homogeneous magnetization process (homogeneous noncollinear coupling).

which is thus driven into rotation (or oscillation). Since the actual signal in the probe coil is mostly induced by the electronic magnetization, it is thus enhanced by the same factor η. Actually, there is a spread of enhancement factor values within a sample, which results from the distribution of magnetization orientation, demagnetizing field, etc. [6]. The resulting enhancement factor distribution is the convolution product of these distributions and tends to a lognormal distribution. Therefore, the spin-echo intensity in a single-phased magnetic material has a Gaussian dependence upon $\log(H_1)$ and can be expressed as a function of the external radio frequency field amplitude H_1 and frequency ω according to [7]:

$$S(H_1,\omega) \propto \langle\eta\rangle \exp[-\log^2(H_1/H_{\mathrm{opt}})/2\sigma^2]\omega^2 N(\omega)\gamma \times I(I+1)/T, \qquad (1)$$

where $\langle\eta\rangle$ is the average enhancement factor, $N(\omega)$ the nucleus density (the "true" NMR intensity), σ the width of the Gaussian distribution in $\log(H_1)$, and H_{opt} the radio frequency field value for which the signal is maximum. In a pulsed NMR experiment, the signal is maximum when the nuclear spins experience an effective radio frequency field strength such that, after the pulse sequence, the nuclear magnetization is perpendicular to HF: $\gamma\langle\eta\rangle H_{\mathrm{opt}}\tau = \pi/2$. Therefore, the radio frequency field strength for which the NMR signal is maximum measures directly the average sample enhancement factor. More recently, rather than using a dimensionless factor to characterize the sample stiffness, we have chosen to use the restoring field $H_{\mathrm{r}} = \mathrm{HF}/\langle\eta\rangle$. This restoring field is directly proportional to $H_{\mathrm{opt},}$ i.e. $H_{\mathrm{r}} = \beta H_{\mathrm{opt}}$ with β depending only on the probed nucleus (γ) and on the experimental setup. The restoring field has the advantage to be quantitatively comparable to macroscopic magnetic data (anisotropy field, coercive field, or exchange bias field) [2,8]; it is also the field that defines the resonance frequency in FMR experiments. In order to measure H_{r}, one has to record a set of spectra for several values of the radio frequency power. If the radio frequency field strength is scaled as βH_1, then H_{r} is directly read as the position of the maximum signal intensity on the βH_1 axis of the 2D NMR spectrum (Figure 3). Considering that each frequency range is associated with a specific region of a composite sample, such 3D plot images directly the structural inhomogeneities, along the frequency axis (NMR), and the magnetic inhomogeneities, along the radio frequency field axis. Therefore, the projection of the line of crest on the base plane yields the frequency, i.e. structural, dependence of the restoring field.

As an example, Figure 1 displays the 1D NMR spectrum $N(\omega)$ of a typical Co/Cu multilayer and the frequency dependence of the restoring field strength acting on Co moments. It can be observed that the interface moments (below 210 MHz) are magnetically softer than the bulk moments (210–230 MHz). This is a rather general observation in multilayers and shows that the magnetic moments rotate more easily in the interface planes than in bulk planes. This is a consequence of the lower number of magnetic neighbors and the reduction of the moment in the mixed interfaces. It is often observed that the coercive field of the layer corresponds to the value of H_r measured by NMR at the interfaces. As first noticed by Thomson *et al*. [8], this is a strong indication that the magnetization reversal is initiated at interfaces.

The restoring field of each frequency region can also be compared from sample to sample. For example, it is generally found in metallic multilayers that the coupling between the magnetic layers oscillates between ferromagnetic and antiferromagnetic as a function of the non-magnetic spacer thickness: this results from a Ruderman–Kittel–Kasuya–Yoshida (RKKY) like mechanism [9]. Such coupling strength oscillations are readily observed on the restoring field measured by NMR but, again, interface and bulk moments behave differently. For example, in Co/Ru multilayers, the oscillations of H_r resulting from the coupling have a larger amplitude at the interfaces than in the bulk [2]. The latter observation is readily explained by the fact that the antiferromagnetic coupling acts first between two interfaces through Ru. Therefore, its contribution to the restoring energy is expected to be larger at the interface planes than in the bulk of the Co layers.

The examples presented until now have pointed out the magnetic differences between different parts of the magnetic layers that are selected by their different NMR frequency range. Besides that the variation of the NMR signal with the RF field strength may evidence a more global magnetic inhomogeneity. Such inhomogeneity is revealed by the observation of very broad $S(H_1)$ curves with several peaks. The usefulness of the observation is illustrated by the example (Figure 3) of two Co/Cu multilayers. The magnetization loops of the two samples are similar (a rapid increase at low field followed by a slow saturation). Such curves can be interpreted as resulting from the inhomogeneity of the coupling strength, parts of layers being antiferromagnetically coupled and others being ferromagnetically coupled. Alternatively, one can interpret them in terms of homogeneous non-collinear coupling [10]. The NMR observation in the first multilayer shows a very broad distribution of restoring field in its 3D curve $S(\omega, H_1)$ that proves the inhomogeneous nature of the magnetization process (coupling inhomogeneities). On the contrary, the second multilayer exhibits a quite narrower distribution of H_r, which is consistent with a homogeneous magnetization process (non-collinear coupling).

Magnetic Phase Separation

If a material consists of several phases, more than one Gaussian distribution of $\log(\eta)$ is needed to describe the signal intensity as a function of the excitation field. In favorable cases, i.e. when the different phases in a sample have largely different structure and magnetic stiffness (by a factor of 3 at least), it is possible to separate the spectra arising from each of the phases and to determine their average restoring field and enhancement factor. The example shown in Figure 4 is that of a granular CoCu alloy [11]. Figure 4a shows the βH_1 dependence of the spin-echo intensity at two exemplary frequencies: 200 and 215 MHz. At both frequencies, two Gaussian distributions had to be used: a soft one: $H_r \sim 0.9$ kOe and a hard one: $H_r \sim 6.4$ kOe. Figure 4b displays the NMR spectrum recorded for $\beta H_1 = 2$ kOe as well as its hard and soft components that are deduced by fitting $S(H_1)$ with two η distributions at each frequency. The spectrum corresponding to the softer component is typical of a CoCu alloy (smooth and broad frequency spread of the NMR intensity), while

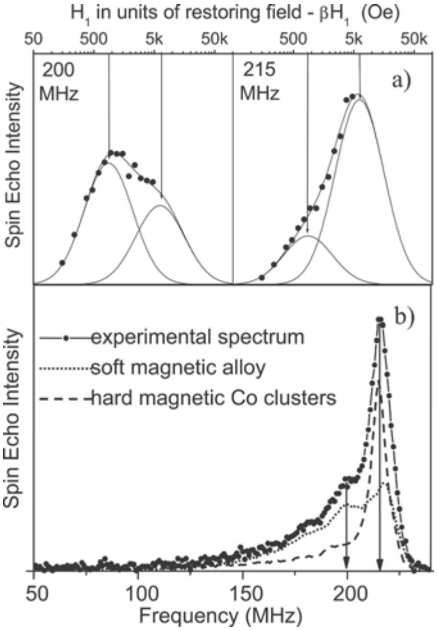

Fig. 4. CoCu melt spun granular alloy. (a) Spin-echo intensity vs. H_1 strength at two exemplary frequencies showing the existence of two magnetic phases (two restoring fields). (b) ^{59}Co spectrum and its decomposition into the spectra of the soft and hard phases.

the hard phase is dominated by a sharp pure fcc Co peak. The low frequency tail of this line is strikingly similar to the spectrum observed in Co/Cu multilayers with rough interfaces but limited interdiffusion. The interfacial intensity amounts to about 50% of the total intensity indicating that these Co clusters have a large surface to volume ratio, which can be understood if they are flat or needle like.

In Field NMR—Local Magnetic Anisotropy

Besides zero-field measurements, an external DC field is applied sometimes in order to saturate the magnetization. This is mostly used to remove domain walls or to perform standard, field swept, spectrum recording. In the experiments that are reported in this section, the external field dependence is used in a similar way as in standard magnetometric methods, i.e. in order to follow the magnetization process. However, all these measurements are, of course, analyzed at selected frequencies and, therefore, they probe the local magnetization process.

When the variation of the resonance frequency is studied vs. the external field orientation it allows the investigation of the anisotropic properties of the sample. This kind of in-field NMR experiment parallels closely torque magnetometry measurements. It must be performed on a single crystal, or at least, an oriented sample. Based on the fact that the resonance frequency is proportional to the vector sum of the external field and HF, the angles between HF, the moment, and the external field can be measured which yields quantitatively the magnetic anisotropy in frequency-selected components of the sample. The method has been employed by de Gronkel *et al.* [12] in order to determine the local magnetic anisotropy of the fcc and hcp components of mixed thin Co films.

When a small DC external field is applied to a multidomain ferromagnet, the resonance frequency does not shift immediately as expected. This is due to the compensation between the external field and the demagnetizing field that increases as the sample magnetizes. However, in small single domain particles the resonance line starts shifting from the smallest field values. The bimodal distribution of sizes of Co clusters embedded in silica has been demonstrated this way. As seen in Figure 5, the NMR spectrum observed in the samples consists in two main lines: at 217 MHz a standard line arising from large, multidomain, fcc Co clusters that does not shift with increasing field, and, at 223 MHz, another line that shifts exactly as $-\gamma_{\mathrm{Co}} H_{\mathrm{ext}}$ (a minus sign because in transition metals HF is antiparallel to the magnetization). Therefore, the 223 MHz line has to be attributed not to hcp Co but to small fcc Co spheres, the 6 MHz up shift being due to the 6 kOe demagnetizing field that adds to HF [13].

Finally, when the DC field strength is large enough to yield a single domain state, the restoring field is the vector sum of the external field H_{ext} and the anisotropy field H_{an}. Hence, when H_{ext} is applied along the easy magnetization axis, the enhancement factor is $\mathrm{HF}/(H_{\mathrm{ext}} + H_{\mathrm{an}})$ and the signal intensity varies as $1/(H_{\mathrm{ext}} + H_{\mathrm{an}})$ with the external field strength. Therefore, in a similar manner as through the measurement $S(\beta H_1)$, the local magnetic anisotropy can be measured through the variation of the signal intensity vs. the DC field strength. This has been applied by Thomson *et al.* [8] on Co/Cu Multilayers for bulk and interface Co atoms.

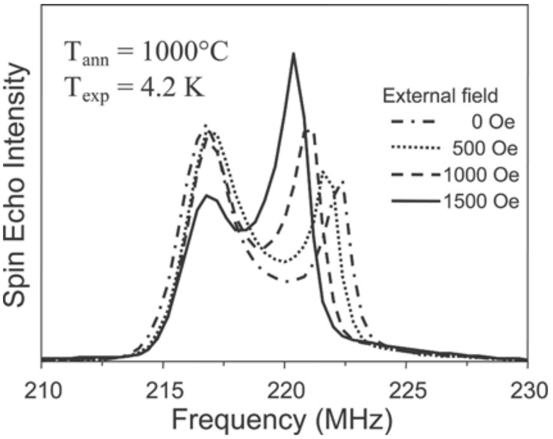

Fig. 5. ^{59}Co spectra of cobalt granules in silica showing two populations of sizes. At 217 MHz: large multidomain fcc Co clusters (do not shift under field). At 223 MHz: small single domain fcc Co clusters (shift under field). The spacing between the two lines in zero field is due to the demagnetizing field (6 kOe) in the single domain spheres.

Conclusions

In this paper, we have shown that NMR is a unique tool to correlate the nanostructure of composite magnetic materials and their magnetic properties. In summary, because they contribute to the NMR spectrum at different frequencies, different regions of the samples can be selected and their magnetic properties can be separately probed.

Besides the magnetic inhomogeneity that is expected from the composite design of the nanomaterials, such as the magnetization and magnetic stiffness profiles at multilayer interfaces, NMR can also image directly large inhomogeneities of interactions and/or anisotropy between the magnetic components. This may help to discriminate between various interpretations of the magnetization process of the composite structure.

Ultimately, such studies can help to identify the various magnetic phases that may be present in a composite sample, from both structural (topology and chemical nature) and magnetic (anisotropy and stiffness) viewpoints.

^{1}H Solid-State NMR of Supramolecular Systems

Ingo Schnell and Hans Wolfgang Spiess
Max Planck Institute for Polymer Research, Postfach 3148, 55021 Mainz, Germany

Introduction

Dipolar recoupling NMR experiments of protons and other spin-$\frac{1}{2}$ nuclei in solids, performed under fast magic-angle spinning (MAS), provide new and versatile spectroscopic tools, by use of which topics of general interest in materials science and bioscience can be addressed. For instance, in advanced synthetic as well as biological systems, self assembly of carefully chosen building blocks is of central importance [1–4]. Hydrogen bonding and aromatic π–π interactions are key features of supramolecular chemistry [5]. Despite being highly ordered on a local scale, such systems often do not crystallize. Therefore, their structures cannot be determined by conventional X-ray crystallography or neutron scattering. Hence, alternative characterisation methods are needed that provide information on molecular structure and dynamics, and preferably require only small amounts of as-synthesized samples without isotopic enrichment. Due to their high natural abundance of protons in organic solids, ^{1}H NMR spectroscopy meets these requirements [6–8] when fast MAS [9,10] ensures sufficient resolution of ^{1}H chemical shifts [11]. In case the selectivity provided by ^{1}H resonances is insufficient, a whole set of heteronuclear ^{1}H-X dipolar recoupling schemes (primarily with X = ^{13}C,^{15}N) has recently been developed [12–14], which combine information on ^{1}H chemical shifts or ^{1}H–X dipole–dipole couplings with the increased site resolution of X chemical shifts. These techniques take advantage of the significant simplification of the dipolar-coupled multispin network due to the decoupling performance of fast MAS [15].

Since MAS with spinning frequencies of 30 kHz and more became commercially available in 1998, the development of solid-state ^{1}H–^{1}H and ^{1}H–X dipolar recoupling methods has systematically been pursued by combining fast MAS and dipolar multiple-quantum (MQ) NMR spectroscopy [11,14], including in particular ^{1}H–^{1}H double-quantum (DQ) NMR spectroscopy. The latter method makes use of the homonuclear dipole–dipole coupling between the involved spins and thus inherently combines information on ^{1}H chemical shifts with the information on the mediating ^{1}H–^{1}H coupling. In studies of supramolecular systems, fast-MAS NMR methods have provided new insight into hydrogen-bonded structures in the solid state [16–20], columnar stacking and molecular dynamics of discotics [14,18,21,22], chain order and translational motion in polymer melts [23,24], and others. In this article, these new approaches for studying supramolecular organization will briefly be outlined, and their capabilties and advantages will be demonstrated on three examples.

High Resolution Solid-State NMR

Various aspects of solid-state NMR are subjects of other articles of this Handbook. For a full treatment of earlier work including multi-dimensional NMR techniques, please also refer to the extended monograph [25].

Magic Angle Spinning

A recent advance of particular importance to solid-state NMR is the availability of fast MAS with spinning frequencies of 25–60 kHz, as pioneered by Samoson [10]. For most organic solids, this means that the MAS frequency exceeds the strongest dipole–dipole couplings which are of the order of 20 kHz, e.g. in CH_2 groups with a proton–proton and proton–carbon distances of about 180 and 110 pm, respectively. Moreover, given such a strong coupling, the remaining spins are in most cases coupled over longer distances, so that the corresponding remote couplings are weaker and thus more efficiently averaged by MAS. In this way, MAS simplifies the complex behaviour of multispin coupled networks to a superposition of two-spin correlations which are dominated for each spin by its strongest coupling(s) to its closest-neighbour(s). This simple picture is indeed borne out in an elaborate theoretical treatment of multi-spin systems under fast MAS, combining Floquet theory and perturbation theory [15]. The higher-spin contributions are found to scale with increasing powers of the inverse rotor frequency and become less and less important at higher and higher MAS rates.

Thus, the dipolar decoupling effect of fast MAS has a two-fold implication for MAS-NMR experiments: Firstly, maximum spectral resolution is accomplished for densely coupled spins, such as ^{1}H, as soon as higher-spin correlations are efficiently suppressed, because the dominating two-spin correlations behave inhomogeneously under

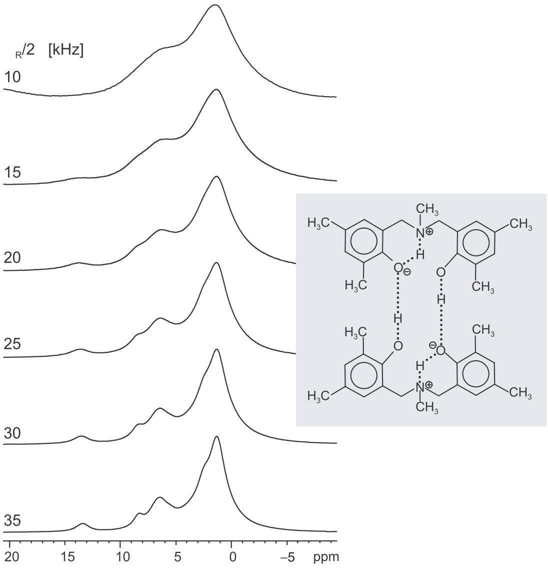

Fig. 1. Spectral resolution achievable at MAS frequencies between 10 and 35 kHz in the ^{1}H solid-state MAS spectrum of a crystalline hydrogen-bonded benzoxazine dimer, the chemical structure of which is depicted in the inset.

MAS, according to the terminology introduced by Maricq and Waugh [26], and therefore do not contribute to the width of the resonance line. Secondly, dipolar recoupling schemes will first re-introduce the dominating pair coupling and establish the respective pair correlation with relatively high selectivity before, at longer recoupling times, the whole multispin network forms again through multiple couplings. Consequently, the dominating coupling(s) can be measured by means of recoupling experiments with high accuracy.

Figure 1 shows ^{1}H NMR spectra recorded at different MAS frequencies on a crystalline benzoxazine dimer as an example [16] to illustrate the dipolar-decoupling and line-narrowing performance of MAS. It is obvious from Figure 1 that, for ^{1}H spectra of rigid solids, MAS needs to be applied at frequencies $\geq$ 25 kHz. At higher spinning frequencies, the resolution still increases very gradually, but the maximum resolution is not only determined by the technically available MAS frequencies, but also by the material itself. When the degree of crystallinity, i.e. the structural order, of a material is not perfect, the local distributions of electrons around the nuclei are affected by local disorder or variations of the packing structure. These phenomena give rise to dispersions of the chemical shifts and, thus, to an inherent line width, which cannot possibly be reduced by averaging techniques. Therefore, in amorphous samples, maximum ^{1}H resolution is often found to be achieved at MAS frequencies of about 30–35 kHz, and faster spinning would not further increase the spectral resolution.

Dipolar Recoupling Schemes

The fast-MAS NMR experiments considered in this article employ sequences of strong radio-frequency (RF) pulses separated by delays, during which the spin system evolves under the internal interactions. These pulse sequences are often referred to as “laboratory frame” sequences [27,28], because the quantisation axis is given by the static magnetic field B_0 along the laboratory z-axis. “Rotating frame” pulse sequences, in contrast, are characterised by a continuous application of RF fields, so that the spin system evolves no longer freely but in the presence of transverse RF fields. Levitt and coworkers have introduced a general and powerful concept by means of which the recoupling (and decoupling) properties and performances of pulse sequences can be analysed in terms of generalised symmetry properties [29]. Based on this concept, a number of pulse sequences have been proposed for various purposes, and a few of them are also applicable under fast MAS conditions, i.e. at spinning frequencies $\geq$25 kHz.

The principle of laboratory-frame recoupling pulse sequences is well established [27,28], and can easily be understood by considering the rotor modulations,which are introduced by the sample rotation. The spatial parts of the interaction Hamiltonians are modulated by the MAS frequency ω_R and twice the MAS frequency $2\omega_R$. For illustration, the respective oscillations are depicted in Figure 2b. By averaging—in other words: integrating—over a full rotor period, the modulated interactions vanish because positive and negative parts of the oscillations cancel each other. An obvious way to avoid this cancellation is to invert the sign of the spin part by a pulse sequence simultaneously to the sign changes imposed on the spatial part by MAS. Effectively, recoupling is accomplished by inducing a “counter-rotation” in spin space relative to MAS rotation in real space. As there are two modulation frequencies, ω_R and $2\omega_R$, the sign change in the spin part can be performed in intervals of either $\tau_R/2$ or $\tau_R/4$ [30].

The type of RF pulses required for this sign inversion depends on the nature of the spin part of the respective interaction. For interactions depending linearly on a spin (i.e. CSA and heteronuclear dipole–dipole couplings), the sign inversion is straightforwardly achieved by π pulses. The approach of utilizing π-pulse trains with pulse spacings of $\tau_R/2$ was first realised in the REDOR experiment, which was initially introduced by

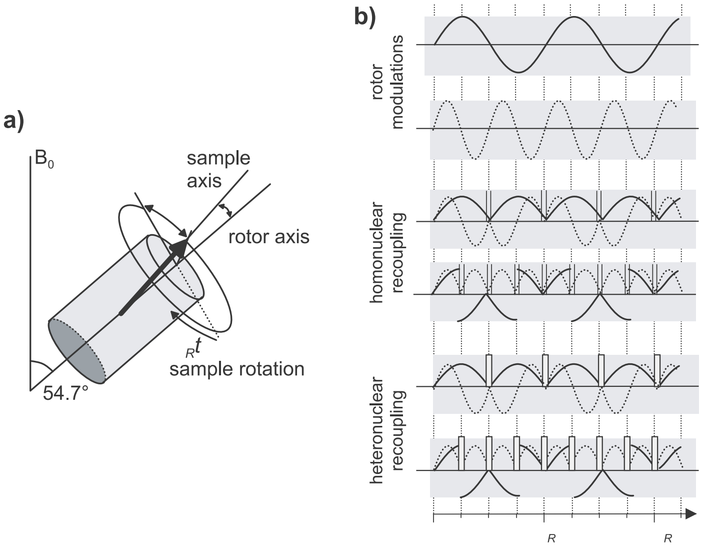

Fig. 2. (a) Geometric relations under MAS conditions, including the definition of the angles β and γ. They relate the main axis of a tensor representing a symmetric anisotropic interaction to the rotor and the magnetic field axes. (b) Modulations of an anisotropic interaction under MAS (top) and pulse sequences for recoupling interactions which depend on the nuclear spin in a bilinear (middle) or linear fashion (bottom). The pairs of $\pi/2$-pulses and the π-pulses (bottom) recouple homonuclear and heteronuclear dipole–dipole couplings, respectively.

Schaefer and Gullion [31,32] in order to recouple the heteronuclear dipole–dipole couplings between two kinds of low-γ nuclei. Interactions with a bilinear spin dependence (i.e. homonuclear dipole–dipole and quadrupole couplings) can be recoupled in an analogous fashion by the so-called Back-to-Back (BaBa) pulse sequence [11]. In this sequence, each π-pulse of REDOR-type recoupling is replaced by a pair of $\pi/2$-pulses with orthogonal phases. Effectively, these pairs of $\pi/2$-pulses invert the sign of the spin part of the homonuclear dipole–dipole and quadrupole coupling.

Rotor Encoding and Sideband Patterns

The ^{1}H–^{1}H DQ MAS experiments discussed in this article follow the principal scheme depicted in Figure 3a. While fast MAS is continuously applied, dipole–dipole couplings are recoupled by appropriate pulse sequences (BaBa) during two periods. These are separated by an indirect spectral dimension t_1, which is inserted to shift the phases of the two recoupling blocks relative to each other and/or to record a ^{1}H spectrum with DQ chemical-shift resolution. At the end of the pulse sequence, the ^{1}H signal is detected during the direct spectral dimension t_2. An efficient and sensitive way of measuring anisotropic interactions in general, and ^{1}H–^{1}H dipole–dipole couplings in particular, is the generation of spinning sideband patterns via rotor encoding (RE) of the recoupled interactions [11,33]. Such rotor encoding is accomplished by combining two recoupling blocks with different initial rotor phases, meaning that the second block is shifted with respect to the first by a time t_1, which is incremented in steps $\Delta t_1 < \tau_R$. The amplitude of the recoupled signal is then modulated according to [11]

$$S_{\sin}(t_1) \propto \sin(N_{\text{exc}}\Phi_{\omega_R}(0)) \cdot \sin(N_{\text{rec}}\Phi_{\omega_R}(t_1)) \qquad (1)$$

where the phase Φ_{ω_R} is determined by the dipole–dipole coupling constant D_{ij} and the orientation of the coupling vector relative to the rotor axis (angles β and γ):

$$\Phi_{\omega_R}(t) = \frac{3D_{ij}}{\omega_R} \cdot \sqrt{2}\sin 2\beta \cdot \sin(\omega_R t + \gamma) \qquad (2)$$

The time t_1 represents the delay between the two recoupling blocks, and N_{exc} and N_{rec} denote the numbers of rotor periods during which the first and second recoupling sequence is applied (referring to "excitation" and "reconversion", respectively). An example for sidebands arising from the recoupling of a ^{1}H–^{1}H dipole–dipole coupling is given in Figure 3b. The sideband patterns shown there correspond to the expression given in Equation 1.

^{1}H–^{1}H Double-Quantum Spectroscopy

Homonuclear DQ NMR spectroscopy is based on the generation of DQ coherences (DQCs) via homonuclear dipole–dipole couplings. Under MAS conditions, dipolar recoupling pulse sequences are applied to excite DQCs

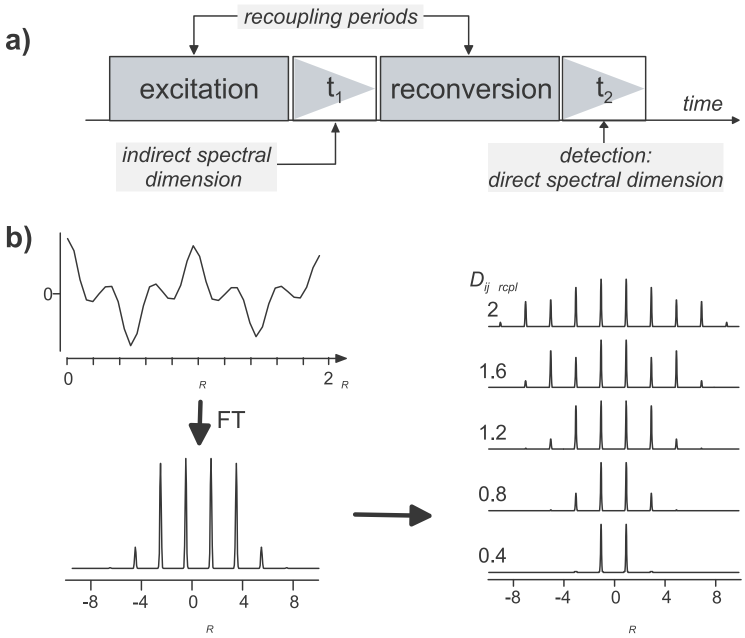

Fig. 3. (a) Schematic representation of the two-dimensional recoupling experiments described in this article. (b) Modulations of the t_1-signal arising from rotor-encoding in a dipolar ^{1}H–^{1}H DQ experiment performed under ω_R-recoupling conditions. The corresponding sideband patterns are shown below, together with the dependence of the sideband patterns on the product of the dipole–dipole coupling and the recoupling time (on the right).

and, subsequently, to reconvert them back into observable magnetisation. Accordingly, the overall recoupling time τ_{rcpl} can be split up into an excitation time τ_{exc} and a reconversion time τ_{rec}. The intensity of a DQ signal sensitively depends on the coupling D_{ij} between the respective pair of nuclei i and j. In the limit of short excitation/reconversion times, i.e. $D_{ij}\tau_{\text{exc/rec}} \ll 1$, the signal intensity is proportional to $D_{ij}^2\tau_{\text{exc}}\tau_{\text{rec}}$ [19]. Therefore, DQ signal intensities can be used as a qualitative and even semi-quantitative measure for internuclear distances [18] and molecular motions [23].

In most fast-MAS work on protons, the simple BaBa sequence is used for dipolar recoupling, as it proved to be extremely robust and easy to use. Two nested phase cycles consisting of four steps each are used to select the coherence transfer pathway $0 \rightarrow 2 \rightarrow 0 \rightarrow -1$ with an overall 16-step phase cycle. For ^{1}H–^{1}H DQ spectroscopy under fast MAS (30 kHz spinning with $\tau_{\text{exc}} = \tau_{\text{rec}} = \tau_R$), DQ signals are expected in a solid material for all proton pairs with a distance of less than approximately 0.4 nm [11,16]. In the DQ dimension, the chemical shift of the signals correspond to the sum of the chemical shifts of the two nuclei, A and B, involved in the DQC: $\omega_{AB} = \omega_A + \omega_B$. In the single-quantum (SQ) dimension, the signal splits up into the two single-spin resonances, ω_A and ω_B, so that for $\omega_A = \omega_B$ a single peak is found on the so-called DQ "diagonal", while for $\omega_A \neq \omega_B$ pairs of signals are located at either side of the DQ "diagonal".

Applications to Supramolecular Structures

Hydrogen Bonds in Bilirubin

Bilirubin is an unsymmetrically-substituted tetrapyrrole dicarboxylic acid, which is found in the body as a product of the metabolism of haemoglobin from red blood cells [18]. The involvement of the carboxylic acid groups in strong intramolecular hydrogen bonding renders bilirubin effectively insoluble in aqueous solution. In Figure 4a, the distances between the hydrogen-bonded protons as well as their geometrical arrangement are specified. Usually, the exact localisation of protons by X-ray scattering is very difficult. Indeed, in the first X-ray single-crystal study [34], the positions of the vital hydrogen-bonded protons were very poorly defined. Furthermore, although Le Bas *et al.* went to considerable trouble to obtain a single crystal of suitable quality to allow the location of the hydrogen-bonded protons, they were still forced to artificially calculate the position of one of the three hydrogen-bonded protons in each half of the bilirubin molecule [35]. Therefore, an alternative determination of the proton positions by solid-state NMR is of particular interest.

Figure 4b shows the region corresponding to the hydrogen-bonded protons of a rotor-synchronised ^{1}H–^{1}H DQ-MAS spectrum recorded on bilirubin at a MAS frequency of 30 kHz using one rotor period of BaBa recoupling to excite and reconvert the DQCs. Only the proton corresponding to the middle hydrogen-bonded peak at 10.8 ppm can then be seen to be in close proximity to both the other two hydrogen-bonded protons. By reference to the intramolecular hydrogen-bonded arrangement known from the single-crystal X-ray investigation, the peak at 10.8 ppm can be assigned to the lactam NH proton. From the DQ projection in Figure 4b, it is apparent that the pair of DQ peaks involving the SQ resonances at 10.8 and 9.1 ppm are significantly more intense than the other pair. Considering the intensities of the respective DQ peaks, the SQ resonances at 9.1 and 13.9 ppm can be assigned to the pyrrole NH and carboxylic acid OH protons, respectively.

The ^{1}H–^{1}H DQ MAS spinning-sideband pattern obtained for the lactam NH^1 resonance of bilirubin (at 10.8 ppm) is shown in Figure 4c, which was recorded at 30 kHz MAS using the BaBa sequence with $\tau_{\mathrm{exc/rec}} = 2\tau_R$. It is evident that the highest-order spinning sidebands are only observed for the NH^1–NH^2 pair. This immediately indicates, in agreement with the rotor-synchronised ^{1}H–^{1}H DQ MAS spectrum, that the dipolar coupling is the largest, and hence the proton–proton distance is the shortest, for NH^1–NH^2. Nevertheless, the longer recoupling time yields a meaningful sideband pattern also for the weaker OH–NH^1 coupling, so that both distances can be determined [18]. A sideband pattern, calculated assuming an isolated proton pair, is shown in Figure 4c as a dotted line with a slight displacement from the experimental peaks. A fitting procedure results in the coupling value and internuclear distance given in Figure 4c, which were also used for the calculated patterns. The determined proton–proton distance is accurate within an error margin of about ± 3 pm. From a detailed analysis of a set of spinning sideband patterns, the OH–NH^1 proton–proton distance as well as the H–H–H angle could also be determined as $r_{\mathrm{HH}} = 230$ pm and $122° \pm 4°$, respectively [18].

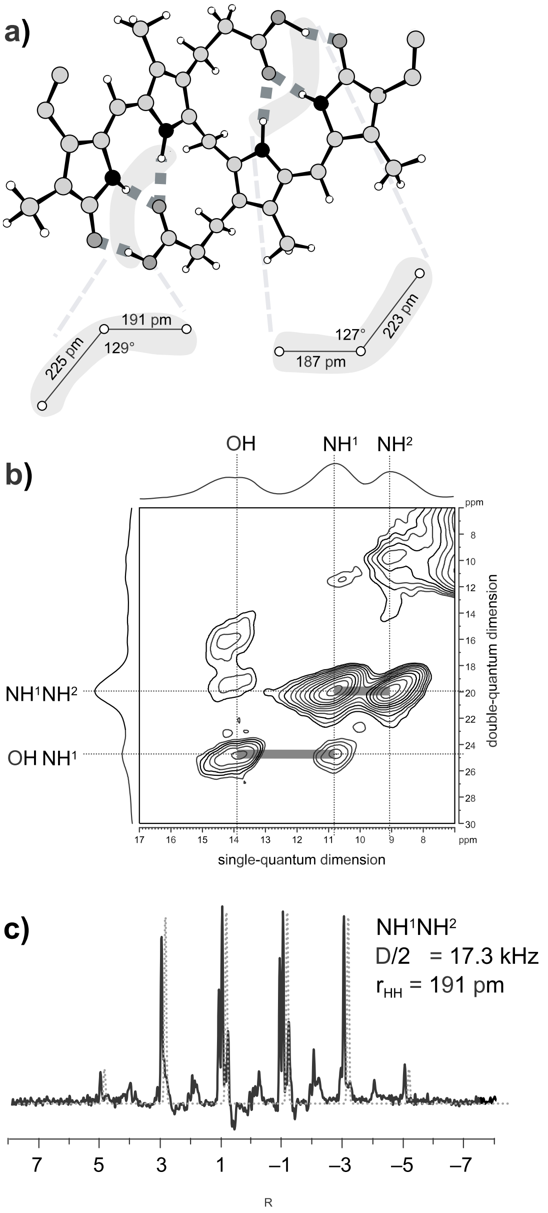

Fig. 4. (a) Chemical structure of bilirubin. The molecules form six intramolecular hydrogen bonds whose geometry is depeicted below. (b) Rotor-synchronised ^{1}H–^{1}H DQ MAS spectrum (700.1 MHz, 30 kHz MAS, BaBa recoupling, $\tau_{\mathrm{exc}} = \tau_R$) of bilirubin. The region of the hydrogen-bonded protons is shown, and the DQ peaks between hydrogen-bonded protons are highlighted. (c) ^{1}H–^{1}H DQ sideband pattern of the NH^1–NH^2 DQ signal (700.1 MHz, 30 kHz MAS, BaBa recoupling, $\tau_{\mathrm{exc}} = 2\tau_R$), indicating a proton–proton distance of 191 pm.

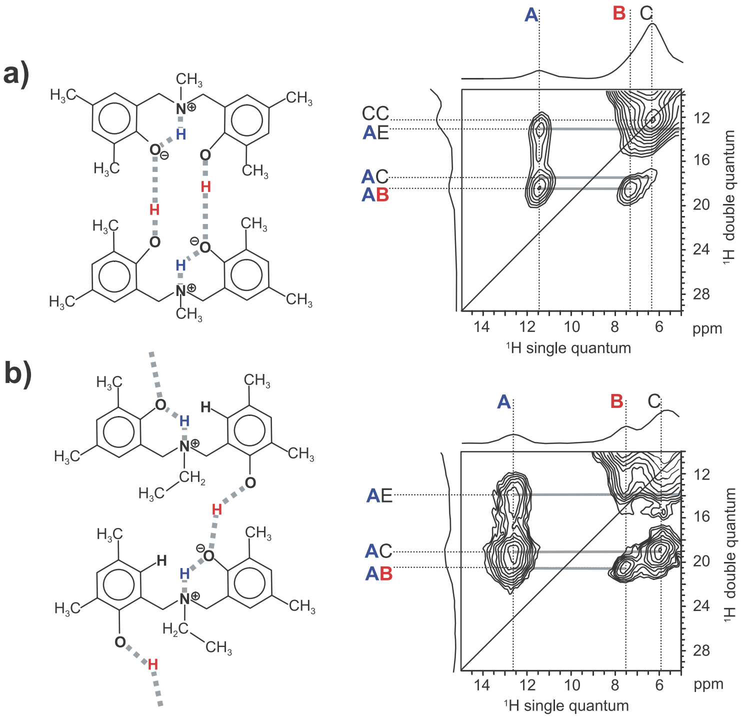
Packing Structures in Benzoxazines

Supramolecular structures influenced by self-assembly and hydrogen bonding are frequently observed in polymeric architectures, and polybenzoxazines are a classic example of such a structure [16]. They exhibit a number of unusual properties [36–39], which have been attributed to the unique intra- and intermolecular hydrogen bonding structure found in these materials, and therefore, this property has been the focus of recent investigation. In particular, extensive crystallographic, NMR and IR studies of the dimer precursors have provided much insight [40]. In particular, the *N*-alkyl subsituent was found to significantly influence the overall packing structure [16].

Consider first the ^{1}H–^{1}H DQ MAS spectrum of the methyl-substituted dimer in Figure 5. In the SQ dimension, the resonances of $\mathrm{N \cdots H \cdots O}$ (A), $\mathrm{O \cdots H \cdots O}$ (B) and aromatic protons (C) can be distinguished. The

Fig. 5. Hydrogen-bonded structures of *N*-methyl- (a) and *N*-ethyl-substituted (b) benzoxazine dimers and ^1H–^1H DQ spectra (700.1 MHz, 30 kHz MAS, BaBa recoupling, $\tau_{exc} = \tau_R$). The different DQCs formed by the hydrogen-bonded protons (A and B) provide evidence for the differences in the packing.



packing of the dimers in the solid-state structure is strongly influenced by the intra-molecular N···H···O and inter-molecular O···H···O hydrogen bonds which together form an extended N···H···O···H···O link. The two protons of these double hydrogen-bonds give rise to the intense AB cross peaks. In addition, there is some evidence of a weaker cross peak to the aromatic protons (AC), while there is no AA auto peak, which indicates that the nearest distance between two N···H···O protons is larger than about 0.4 nm. Moreover, the strong aromatic auto peak CC is due to the close proximity of two aromatic protons of two different hydrogen-bonded dimer pairs, and provides insight into the overall packing structure.

Although similar to that of the *N*-methyl dimer, the ^1H–^1H DQ MAS spectrum of the *N*-ethyl dimer exhibits some profound differences (Figure 5b). As for the methyl spectrum, clear AB cross peaks between the N···H···O and O···H···O protons can be identified, so providing evidence for the same type of extended N···H···O···H···O hydrogen-bonded link in both samples. The most striking differences between the methyl- and ethyl-dimer spectra are, while for the methyl dimer, there is a strong aromatic auto peak (CC) and only weak intensity corresponding to a DQC between a N···H···O and an aromatic proton (AC, see Figure 5a), the situation is reversed for the ethyl dimer (Figure 5b). These differences clearly indicate an alternative packing arrangement, which can be explained if one of the aromatic rings is flipped such that instead of pairs of hydrogen-bonded dimers there exist hydrogen-bonded chains as shown in Figure 5b. In addition, this arrangement gives rise to a close proximity of the O···H···O proton and the *N*-ethyl chain, and the resulting cross-peak between the O···H···O proton and the ethyl-chain CH_2 protons is, indeed, clearly seen in the ^1H–^1H DQ MAS spectrum of the ethyl dimer (see Ref. [16], not shown here). For the methyl dimer, where pairs of hydrogen-bonded dimers are believed to form, an analogous peak between the O···H···O proton and the *N*-methyl protons is neither predicted by the crystal structure nor apparent in the ^1H–^1H DQ spectrum.

Hence, the size of the *N*-alkyl substituent is responsible for the long-range packing of the benzoxazine dimers. For small methyl substituents, the dimers can form hydrogen-bonded pairs, while ethyl substituents (as well as larger alkyl substituents) force the molecules to twist about the central nitrogen and to arrange in an extended ladder-like hydrogen-bonded structure. Subsequent to the ^1H–^1H DQ NMR studies reviewed above, this finding could be confirmed by X-ray diffraction.

Columnar Stacking of Discotics

The solid phases and discotic mesophases of alkylated hexa-peri-hexabenzocoronenes (HBCs) represent striking examples of the wealth of information obtainable from fast-MAS ^{1}H–^{1}H DQ NMR experiments [14,17,21,22]. In the following, NMR findings about the packing of the HBC discs will briefly be discussed.

In the solid phases, HBC derivatives are found to adopt two different types of columnar stacking. In the "herringbone" arrangement, the aromatic cores are tilted relative to the columnar axis, while in the "planar" arrangement the disc planes are basically oriented perpendicular in the columns. The molecular tilt in the stacks is energetically preferred with respect to an optimised dense packing of the columns in the solid phase. The tilt can, however, be prevented by substituent effects on a molecular level, for example, by the steric requirements of phenylene (Ph) substituents, so that the HBC-Ph derivatives pack their columns in the material less densely. The two types of packing can readily be distinguished by means of ^{1}H NMR, because the ^{1}H resonance lines of the aromatic HBC protons are characteristically shifted due to ring-current effects which arise from the aromatic π-electron systems of adjacent HBC cores in the columns.

Considering a single molecule, the six-fold symmetry of a HBC core means that only one distinct aromatic ^{1}H resonance is expected, as is indeed found to be the case in the solution-state spectrum. However, as shown in Figure 6a, three aromatic resonances (A,B,C) are clearly identified in the solid-state ^{1}H spectrum of dodecyl-substituted HBC (HBC-C_{12}). This effect can be ascribed to the reduction of the six-fold molecular symmetry due to the packing arrangement in the crystal, as revealed by ^{1}H–^{1}H DQ spectra. In HBC-C_{12}, the six aromatic protons are grouped in pairs of "bay protons" with a proton–proton distance of approximately 200 pm, while the closest distance to another aromatic proton is >0.4 nm. Therefore, the aromatic region of the DQ MAS spectrum will be dominated, for short DQ excitation periods, by the dipole–dipole couplings within the three pairs. Strong CC auto and AB cross peaks are observed, which imply the presence of only two types of pairs of aromatic protons, H_A–H_B and H_C–H_C, in a ratio, as determined from the DQ peak intensities of ratio 2:1.

Assuming a "herringbone"-type of packing of the HBC cores [41], three different aromatic proton environments can be identified with respect to the degree to which the proton experiences the ring current of the adjacent layers. The least shielded resonance (highest ppm) belongs to protons which lie neither above nor below the π-orbitals of an adjacent layer. Protons situated close to an adjacent ring system are more shielded, and the highest shielding is found for protons which lie right above or below an adjacent aromatic core. Assigning these three differently

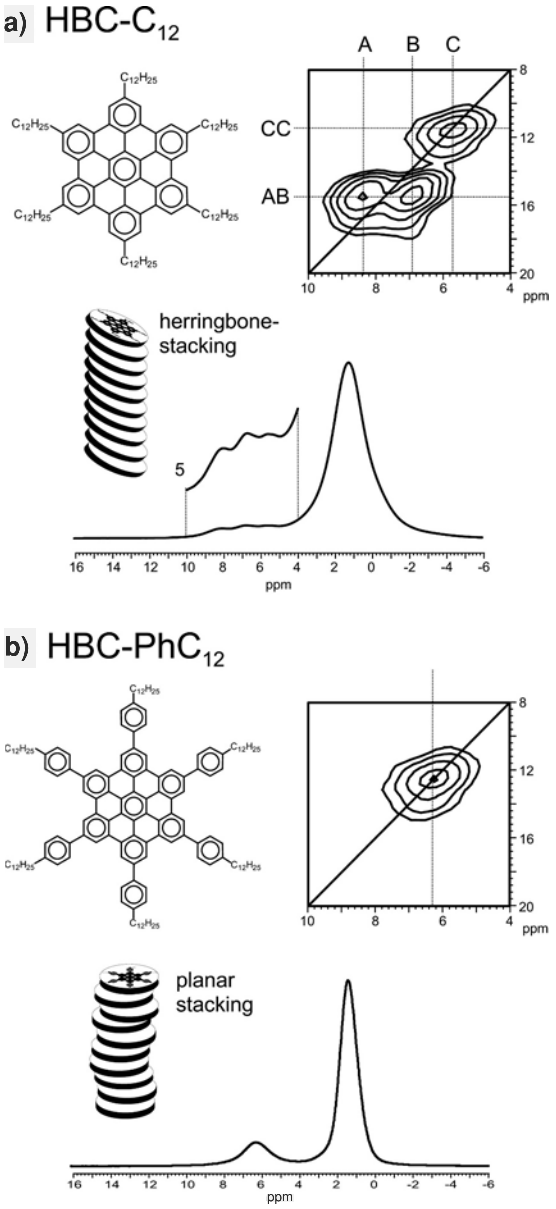


Fig. 6. Molecular structure, ^{1}H spectra (700.1 MHz, 30 kHz MAS) and ^{1}H–^{1}H DQ MAS spectra (700.1 MHz, 30 kHz MAS, BaBa recoupling, $\tau_{\mathrm{exc}} = \tau_R$) of two HBC derivatives: (a) HBC-C_{12} and (b) HBC-PhC_{12}. The ^{1}H NMR signals allow two types of molecular packing to be readily distinguished.

shielded types of aromatic protons to the A, B, and C resonances, respectively, the observed presence of only AB and CC pairs in the ratio 2:1, with the C resonance having the smallest chemical shift value (most shielded), can readily be explained. In this way, the characteristic ^{1}H–^{1}H DQ signal pattern provides a simple means of identifying the "herringbone" packing in the solid phases of HBC derivatives. This has also been confirmed in detail by quantum-chemical computations of the ^{1}H chemical shifts [42].

When instead a single aromatic ^{1}H resonance is observed in both, the ^{1}H fast-MAS spectrum and the ^{1}H–^{1}H DQ MAS spectrum (see Figure 6b), this serves as a strong indication for a planar stacking, i.e. with the HBC cores oriented perpendicular to the column axis [22]. In this case, the ring current effects caused by adjacent molecules are, on average, the same for all aromatic core protons, such that the aromatic ^{1}H line is shifted high-field, i.e. to lower ppm values, but no splitting is induced. The planar orientation is enforced in the solid phase of HBC-PhC$_{12}$ by the steric requirements of phenylene substituents at the aromatic core.

Quadrupolar NMR of Inorganic Materials: The Multiple-Quantum Magic Angle Spinning Experiment

Stephen Wimperis

Department of Chemistry and WestCHEM, University of Glasgow, Glasgow G12 8QQ, UK

Introduction

Over two-thirds of all NMR-accessible nuclides are quadrupolar with half-integer spin quantum numbers ($I = 3/2, 5/2, 7/2$, etc.). Far from being a minority interest, therefore, NMR of nuclei such as ^{7}Li, ^{11}B, ^{23}Na, ^{39}K, ^{71}Ga, ^{87}Rb ($I = 3/2$), ^{17}O, ^{25}Mg, ^{27}Al ($I = 5/2$), ^{45}Sc, ^{51}V, ^{59}Co ($I = 7/2$), and ^{93}Nb ($I = 9/2$) is central to the characterization and study of a wide range of minerals, glasses, novel oxide materials, and micro- and mesoporous solids, including zeolites. Although their quadrupolar coupling constants can be large (typically in the range 0–20 MHz), NMR of these nuclei is facilitated by the presence of a $|m_I = +1/2\rangle \leftrightarrow |-1/2\rangle$ "central transition" (CT) which, to a first-order approximation, is not broadened by the quadrupolar interaction. Figure 1a shows, however, that the ^{87}Rb central-transition NMR spectrum of polycrystalline RbNO$_3$, although relatively narrow, is still essentially a broad, almost featureless, "hump." The success of magic angle spinning (MAS) as a line-narrowing technique for spin $I = 1/2$ nuclei has encouraged its application to spectra of this type and yet, as the example in Figure 1b shows, despite achieving a significant narrowing of the ^{87}Rb lineshape, MAS still fails to resolve the three crystallographically distinct sites in RbNO$_3$.

The reason for the relative failure of MAS in this case is that the broadening of the CT spectrum in Figure 1a arises largely from a second-order quadrupolar interaction and this has second- and fourth-rank terms in its orientational dependence, with MAS capable of only fully averaging the former. In 1988, two methods were proposed for removing both the second- and fourth-rank quadrupolar broadening, and hence achieving truly high-resolution CT spectra. Both the double rotation (DOR) [1,2] and dynamic angle spinning (DAS) [2,3] experiments involve rapidly spinning the sample about two angles with respect to the magnetic field, either simultaneously in the case of DOR or sequentially in the case of DAS. Although these two techniques have been used with considerable success by a number of research groups, their use has neither become widespread nor commonplace, owing largely to the significant additional cost and mechanical complexity of the specialized NMR probe equipment that is required, but also to spinning rate limitations.

In this context, it is not surprising that the demonstration in 1995 by Frydman and Harwood of their novel multiple-quantum MAS (MQMAS) technique for removing the second-order quadrupolar broadening generated such instant and enormous interest [4,5]. Unlike DOR or DAS, this experiment is purely MAS based and can be performed on any NMR spectrometer that is equipped with a standard MAS probe. Figure 1c shows the success of the MQMAS technique in achieving a high-resolution ^{87}Rb NMR spectrum and resolving the three distinct Rb sites in RbNO$_3$.

The MQMAS experiment is now a well-established and popular method of obtaining high-resolution ^{17}O, ^{23}Na, or ^{27}Al NMR spectra of inorganic materials. The purpose of this article is to give a brief description of the technique as it is currently performed and to discuss how MQMAS NMR spectra of both crystalline and amorphous solids can be analyzed to yield chemical shift and quadrupolar parameters.

Multiple-Quantum MAS

For a spin $I = 3/2$ nucleus, the MAS-averaged ($\langle\ldots\rangle_{\text{MAS}}$) CT frequency can be written in a suitable rotating frame as

$$\langle\omega^{\text{CT}}\rangle_{\text{MAS}} = \delta_{\text{CS}}\omega_0 + \frac{2}{35}\frac{(\omega_Q^{\text{PAS}})^2}{\omega_0}\{-7 + 27 d^4_{0,0}(54.736^\circ) d^4_{0,0}(\beta)\}, \quad (1)$$

where δ_{CS} is the isotropic chemical shift, $\omega_0 = \gamma B_0$ the Larmor frequency, $\omega_Q^{\text{PAS}} = 3e^2qQ/(4I(2I-1)\hbar)$ a parameter describing the strength of the quadrupolar interaction, and $d^l_{m',m}(\theta)$ a reduced Wigner rotation matrix element. For simplicity, the quadrupolar axial asymmetry parameter, η, has been assumed to be zero. Thus, for a single crystallite spinning at the magic angle (54.736°) with respect to B_0, the CT has an isotropic frequency shift of $\delta_{\text{CS}}\omega_0 - 2(\omega_Q^{\text{PAS}})^2/5\omega_0$, as well as a rank $l = 4$ anisotropic shift that depends on the angle, β, between the sample

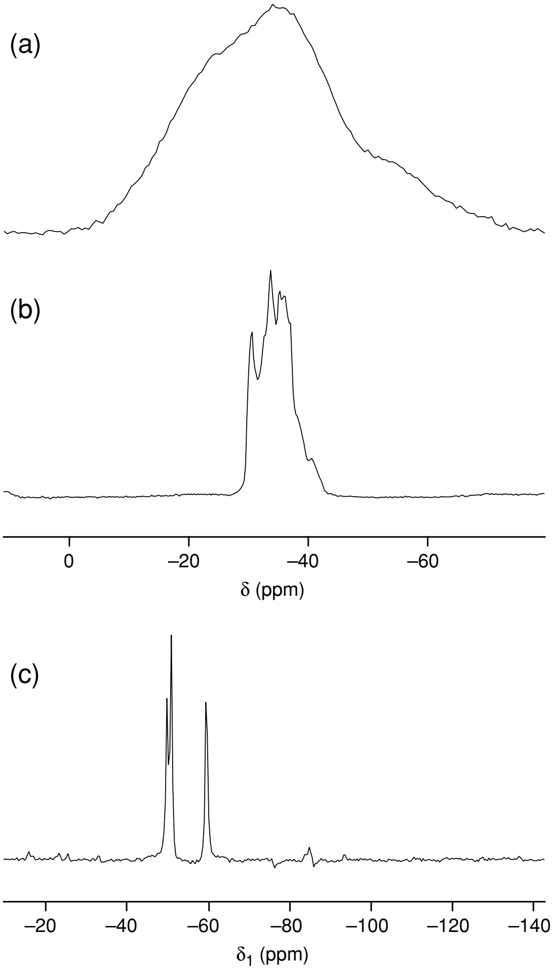

Fig. 1. ^{87}Rb ($\omega_0/2\pi = 130.9$ MHz) NMR spectra of $RbNO_3$. (a) Static; (b) MAS; and (c) isotropic triple-quantum MAS spectrum. The δ scales are referenced to the ^{87}Rb Larmor frequency and to 1 M $RbNO_3$ (aq). Adapted from J. McManus, Ph.D. thesis, University of Exeter, 2001.

rotation and quadrupole tensor axes. In a powdered solid, a spherical average over all orientations of the angle β must be considered and gives rise to the residual inhomogeneous second-order quadrupolar broadening observed in Figure 1b.

The key to the MQMAS experiment is that the residual fourth-rank quadrupolar broadening of the triple-quantum (TQ) transition ($|m_I = +3/2\rangle \leftrightarrow |-3/2\rangle$) under MAS conditions differs from that of the CT. For example, for a spin $I = 3/2$ nucleus:

$$\langle\omega^{\mathrm{TQ}}\rangle_{\mathrm{MAS}} = 3\delta_{\mathrm{CS}}\omega_0 + \frac{2}{35}\frac{(\omega_Q^{\mathrm{PAS}})^2}{\omega_0}\{21 - 21 d^4_{0,0}(54.736^\circ) d^4_{0,0}(\beta)\}, \tag{2}$$

Therefore, by performing a two-dimensional NMR experiment that correlates TQ coherences in the t_1 evolution period with CT coherences in the t_2 acquisition period, it is possible to refocus the residual fourth-rank quadrupolar broadening. If the time-domain signal, $s(t_1, t_2)$, in a two-dimensional triple-quantum MAS NMR experiment can be written as

$$s(t_1, t_2) = \exp\{-i\langle\omega^{\mathrm{TQ}}\rangle_{\mathrm{MAS}} t_1\}\exp\{-i\langle\omega^{\mathrm{CT}}\rangle_{\mathrm{MAS}} t_2\}, \tag{3}$$

then inspection of Equations (1) and (2) shows that the anisotropic fourth-rank terms cancel one another when $t_2 = (21/27)t_1 = (7/9)t_1$:

$$s(t_1, t_2 = (7/9)t_1) = \exp\{-i\omega^{\mathrm{MQMAS}} t_{1'}\}, \tag{4}$$

where $t_{1'} = (1 + (7/9))t_1 = (16/9)t_1$ and

$$\omega^{\mathrm{MQMAS}} = \frac{9}{16}\left(\left(3 + \frac{7}{9}\right)\delta_{\mathrm{CS}}\omega_0 + \frac{2}{35}\left(21 - 7\cdot\frac{7}{9}\right) \times \frac{(\omega_Q^{\mathrm{PAS}})^2}{\omega_0}\right) = \frac{17}{8}\delta_{\mathrm{CS}}\omega_0 + \frac{1}{2}\frac{(\omega_Q^{\mathrm{PAS}})^2}{\omega_0} \tag{5}$$

As expected, the frequency ω^{MQMAS} in Equation (5) consists of only isotropic terms and, hence, is identical for every crystallite orientation in the powder, regardless of the angle β. A spin $I = 3/2$ spectrum containing just the isotropic ω^{MQMAS} frequencies can be obtained by either Fourier transforming the cross-section through the time-domain signal defined by $t_2 = (7/9)t_1$ or, equivalently and more conveniently, projecting the full two-dimensional spectrum, $s(\omega_1, \omega_2)$, onto an axis with a gradient of 9/7, i.e. orthogonal to a gradient of $-21/27 = -7/9$.

Figure 2a shows the two-dimensional ^{87}Rb triple-quantum MAS spectrum of $RbNO_3$ recorded at $B_0 = 9.4$ T ($\omega_0/2\pi = 130.9$ MHz). The three “ridge” lineshapes (two are barely resolved) correspond to the three crystallographically distinct Rb sites in $RbNO_3$. The ratio of the fourth-rank broadening in the TQ dimension (δ_1) to that in the CT dimension (δ_2) is $-21{:}27 = -7{:}9$ (from Equations 1 and 2), and hence all three ridge lineshapes in Figure 2a lie on a gradient of $-7/9$. The isotropic spectrum shown in Figure 1c is obtained, as described above, by

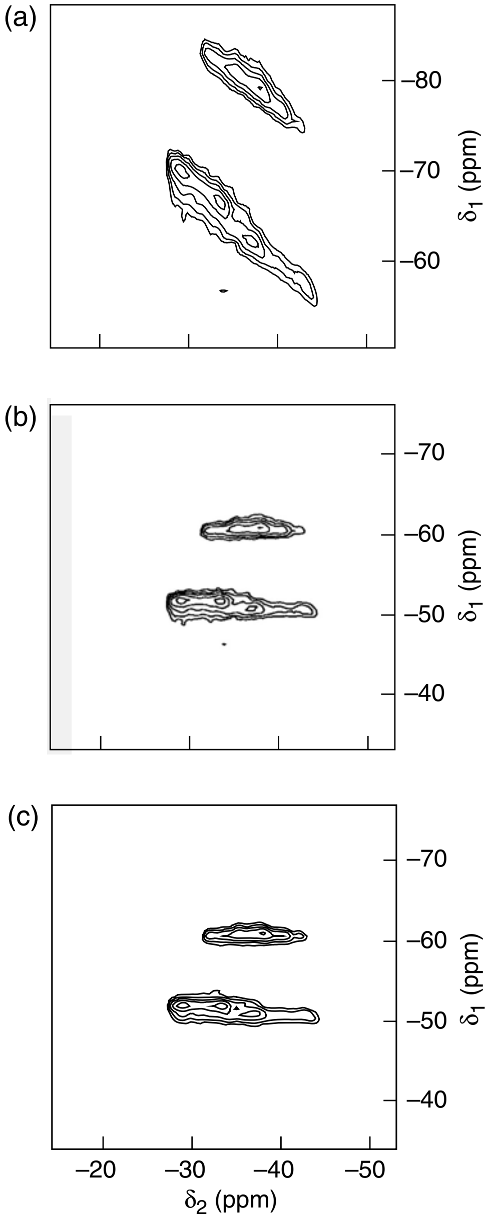

Fig. 2. Two-dimensional ^{87}Rb ($\omega_0/2\pi = 130.9$ MHz) triple-quantum MAS spectra of $RbNO_3$. (a) Nonsheared spectrum with ridge lineshapes at gradient of $-7/9$; (b) sheared version of (a) with ridge lineshapes parallel to δ_2; and (c) split-t_1 spectrum with ridge lineshapes parallel to δ_2. The δ scales are referenced to the ^{87}Rb Larmor frequency and to 1 M $RbNO_3$ (aq). Adapted from S. E. Ashbrook, D.Phil. thesis, University of Oxford, 2000.

projecting the two-dimensional spectrum onto an axis orthogonal to $-7/9$. This projection is most easily carried out by first "shearing" [6] the original two-dimensional spectrum, $s(\omega_1, \omega_2)$, to obtain the new spectrum $s(\omega_{1'}, \omega_2)$ where

$$\omega_{1'} = \frac{\omega_1 - \lambda\omega_2}{1 + |\lambda|}, \qquad (6)$$

and where λ is the gradient of the MQMAS ridge lineshapes, $-7/9$ in this case. As shown in Figure 2b, the ridge lineshapes in the sheared spectrum are parallel to the ω_2 axis and a purely isotropic spectrum is now easily obtained by projecting the sheared two-dimensional spectrum onto the $\omega_{1'}$ axis.

For half-integer nuclei with spin $I > 3/2$, triple-quantum MAS NMR spectra yield isotropic resolution of distinct crystallographic sites in a fashion similar to that shown for ^{87}Rb in Figure 2. The main difference is that the ridge gradient or "MQMAS ratio" is characteristic of each spin quantum number. For spin $I = 5/2$, for example, it is $+19/12$, while for spin $I = 7/2$ it is $+101/45$. For spin $I > 3/2$ nuclei, it is also possible to use MQ transitions of higher order than TQ to obtain high resolution, e.g. quintuple-quantum for spin $I = 5/2$ [7] and quintuple- and septuple-quantum for spin $I = 7/2$ [8], and these too will have their own characteristic MQMAS ratios, e.g. $-25/12$ for spin $I = 5/2$ quintuple-quantum. However, these higher order MQMAS experiments currently have very poor sensitivity compared with the TQ experiment and it seems unlikely that their use will ever become widespread.

Pulse Sequences for MQMAS

A typical MQMAS pulse sequence consists of the following steps: (i) excitation of MQ coherence, usually with a single radiofrequency pulse; (ii) time evolution of this coherence during the t_1 period of the two-dimensional experiment; (iii) application of a second pulse or group of pulses to convert the MQ coherence back into observable CT coherence; and (iv) detection of this coherence during the acquisition period, t_2.

Figure 3 shows probably the most popular pulse sequences for performing a TQ MAS experiment: the amplitude-modulated z-filter experiment [9] and two versions of the phase-modulated split-t_1 experiment [10,11]. The coherence pathway diagrams drawn below the pulse sequences are not merely decorative but specify the phase cycle that must be used with each experiment [12,13].

The phase cycle used in the z-filter experiment in Figure 3a retains coherences of order $p = +3$ and -3 during the t_1 period and these are combined to yield a signal

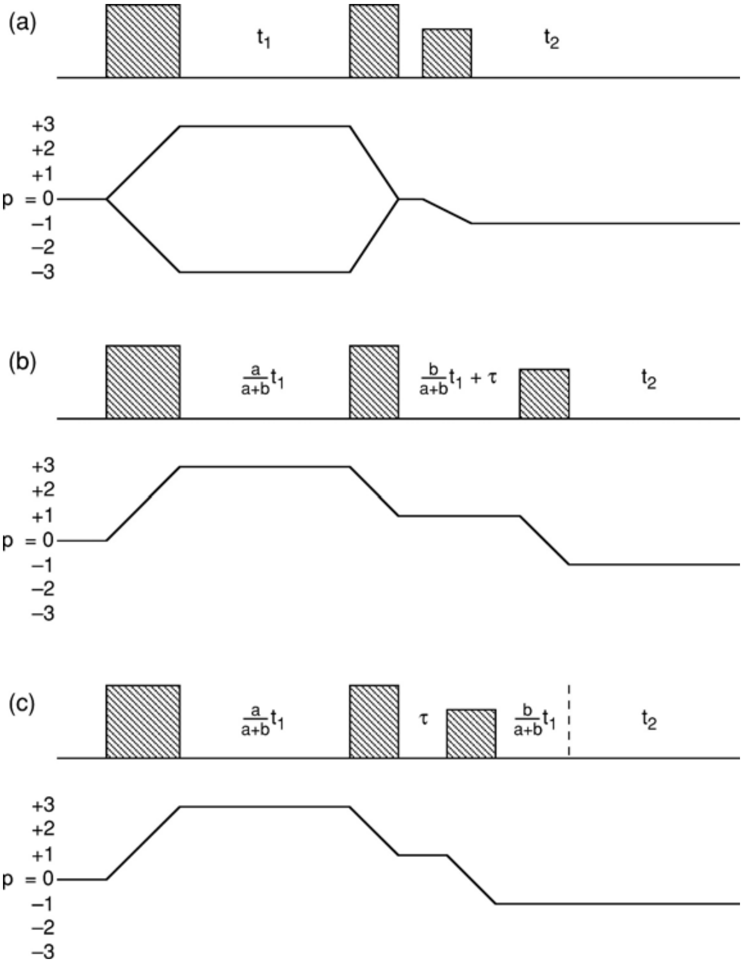

Fig. 3. Pulse sequences and coherence transfer pathway diagrams for three MQMAS experiments: (a) the amplitude-modulated *z*-filter experiment; (b) the phase-modulated split-t_1 experiment for negative MQMAS ratio (e.g. $-b/a = -7/9$ for spin $I = 3/2$ triple-quantum); and (c) the phase-modulated split-t_1 experiment for positive MQMAS ratio (e.g. $b/a = 19/12$ for spin $I = 5/2$ triple-quantum).

that is purely amplitude modulated in t_1 by first converting them into longitudinal (or z) magnetization (a state that has $p = 0$) before converting this into observable CT coherence (which has $p = -1$) with the final pulse. A two-dimensional NMR dataset that is amplitude modulated in t_1 should be Fourier transformed by the "hypercomplex" method if the desirable absorption-mode lineshape is to be obtained [6] and, in addition, either the States–Haberkorn–Ruben or TPPI method must be used when performing the experiment in order to determine the sense of coherence precession in t_1 [6].

In the experiments in Figure 3b and c, the t_1 period is split into two parts that mix TQ and CT evolution. This is done in such a way that the residual second-order quadrupolar broadening is refocused at the end of the t_1 period. Thus, these split-t_1 experiments yield spectra with ridge lineshapes already parallel to the ω_2 axis and that do not require shearing in order to extract an isotropic spectrum [10,11]. An example is shown in Figure 2c. The experiment in Figure 3b should be used where the MQMAS ratio is negative (e.g. $\lambda = -7/9 = -b/a$ for spin $I = 3/2$ triple-quantum), while that in Figure 3c is applicable where the MQMAS ratio is positive (e.g. $\lambda = +19/12 = b/a$ for spin $I = 5/2$ triple-quantum). The phase cycle retains only coherences of order $p = +3$ during the first part of the t_1 period and, hence, these experiments yield datasets that are phase modulated in t_1. Absorption-mode lineshapes are obtained in these experiments by virtue of using the final pulse to form a time-

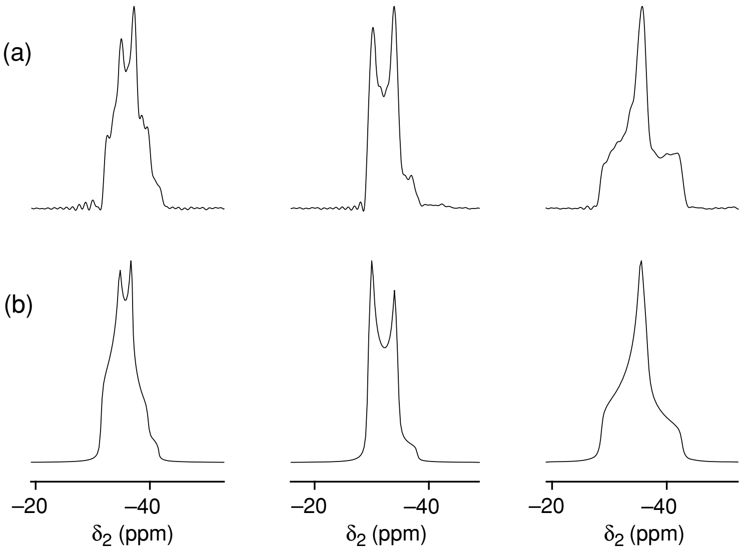

Fig. 4. (a) Cross-sections parallel to the ω_2 (or δ_2) axis through the three second-order broadened ridge lineshapes in the ^{87}Rb triple-quantum MAS spectrum in Fig. 2c. (b) The corresponding computer-fitted lineshapes, yielding values of δ_{CS}, C_Q, and η for each Rb site. Adapted from S. E. Ashbrook, D.Phil. thesis, University of Oxford, 2000.

symmetric spin-echo signal in the acquisition period t_2 [10,11,14,15]. After a suitable phase correction, the Fourier transform of a time-symmetric signal has no imaginary component and the basic two-dimensional complex (as opposed to hypercomplex) Fourier transform should be used. As the sense of coherence precession is already determined in a phase-modulated experiment, it would be quite wrong to apply either the States–Haberkorn–Ruben or TPPI method.

Both the *z*-filter and split-t_1 experiments are excellent methods of recording MQMAS spectra. The former is robust, requires little optimization, and has the virtue of familiarity in that it is similar to many other two-dimensional NMR experiments used for solids and liquids. The latter generally yield significantly higher sensitivity than the *z*-filter as $p = +3$ to $+1$ transfer is more efficient than $p = +3$ to 0 transfer [11], but require selection of a spin-echo interval τ that, inevitably, involves a degree of compromise when both broad and narrow lineshapes occur in the ω_2 dimension. With some experience, however, split-t_1 experiments become very easy to use and have the additional practical advantage that the signal does not shift in t_2 as the t_1 period is incremented, making application of weighting functions particularly straightforward [11].

Many alternatives to and variants of the pulse sequences in Figure 3 have been suggested. One class of experimental variants seeks to achieve greater isotropic resolution by utilizing higher order MQ coherences but, as mentioned above, currently it appears that the sensitivity of these is too poor to make them generally useful [7,8]. A second group seeks to improve the sensitivity of the triple-quantum MAS experiment by increasing the efficiency of the coherence transfer steps by substituting sophisticated pulse trains for the simple pulses in Figure 3 (e.g. the RIACT [16], FAM [17], SPAM [18], and, perhaps most interesting of all, DFS [19] sequences). However, although some impressive results have been shown on model systems, many of these results appear to have been achieved through extensive experimental optimization on spectra that already had high signal-to-noise ratios. It remains to be seen, therefore, whether such methods will have much use in real experimental practice on systems where the "ideal" forms of the spectra are not already known in advance.

Spectral Analysis

A full analysis of a peak in a two-dimensional MQMAS spectrum can yield the value of the isotropic chemical shift δ_{CS}, the quadrupolar coupling constant $C_Q = e^2qQ/h$ and asymmetry η, and, independently of the latter pair, a composite quadrupolar parameter $P_Q = C_Q(1 + \eta^2/3)^{1/2}$. All this information can be obtained from a single two-dimensional spectrum, without recourse to measurement at a second static magnetic field strength B_0, and it is this, just as much as the high resolution obtained in the isotropic dimension, that makes MQMAS such a useful spectroscopic tool [15,20,21]. Indeed, even in disordered or amorphous solids, where the increase in resolution over a conventional spectrum can be disappointing, this high information content still means that MQMAS spectra are worth recording.

The three parameters δ_{CS}, C_Q, and η can be obtained by fitting ω_2 cross-sections through the ridge lineshapes in a sheared or split-t_1 spectrum [15]. Figure 4 shows the three such cross-sections from the ^{87}Rb MQMAS spectrum in Figure 2c and the corresponding lineshape fittings. The values obtained for δ_{CS} are -31, -27, and -28 ppm, for C_Q are 1.7, 1.7, and 1.9 MHz, and for η are 0.6, 0.1, and 1.0, in order of increasing δ_1. Where applicable, this is the best method of extracting chemical shift and quadrupolar parameters. However, for it to be used, the signal-to-noise ratio must be good and a radiofrequency field strength, $\omega_1 = \gamma B_1$, that is reasonably strong compared with ω_Q^{PAS} must have been used in order to obtain undistorted lineshapes. Furthermore, this method may not be appropriate to disordered or amorphous solids (see below).

Alternatively, the two parameters δ_{CS} and P_Q can be obtained by measuring either the ω_1 and ω_2 or (in ppm, relative to the Larmor frequency and a reference peak) the δ_1 and δ_2 coordinates of the "center-of-mass" (c.o.m.) of a ridge lineshape [15,20,21]. For example, a straightforward generalization of Equation (1) to $\eta \neq 0$ shows that the shift of the center-of-mass of a ridge lineshape in the ω_2 dimension of a spin $I = 3/2$ triple-quantum MAS spectrum is given by

$$\delta_2^{\mathrm{c.o.m.}} = \delta_{\mathrm{CS}} - 7 \cdot \frac{2}{35}\frac{(\omega_Q^{\mathrm{PAS}})^2}{\omega_0^2}\left(1 + \frac{\eta^2}{3}\right). \qquad (7)$$

Similarly, Equation (2) indicates that the shift in the ω_1 dimension of a nonsheared spin $I = 3/2$ triple-quantum MAS spectrum is given by

$$\delta_1^{\mathrm{c.o.m.}} = 3\delta_{\mathrm{CS}} + 21 \cdot \frac{2}{35}\frac{(\omega_Q^{\mathrm{PAS}})^2}{\omega_0^2}\left(1 + \frac{\eta^2}{3}\right), \qquad (8)$$

while Equation (5) indicates that in a sheared or split-t_1 spectrum it is

$$\delta_{1'}^{\mathrm{c.o.m.}} = \frac{17}{8}\delta_{\mathrm{CS}} + \frac{1}{2}\frac{(\omega_Q^{\mathrm{PAS}})^2}{\omega_0^2}\left(1 + \frac{\eta^2}{3}\right). \qquad (9)$$

Thus, measurement of the two independent variables $\delta_1^{\mathrm{c.o.m.}}$ and $\delta_2^{\mathrm{c.o.m.}}$ allows determination of the parameters δ_{CS} and $(\omega_Q^{\mathrm{PAS}})^2[1 + (\eta^2/3)]$ (or, equivalently, δ_{CS} and P_Q). For the ^{87}Rb MQMAS spectrum in Figure 2c, the values obtained for δ_{CS} are -31, -27, and -29 ppm, and for P_Q are 1.9,1.7, and 2.3 MHz, in order of increasing δ_1. This method has the advantage of being easy to apply even when the signal-to-noise ratio is poor or the ridge lineshapes distorted but, as it relies upon determination of the center-of-mass of such a ridge lineshape, the limitations on its accuracy should be noted. It can also be applied to disordered or amorphous solids (see below).

Application to Disordered and Amorphous Solids

An MQMAS NMR spectrum of a disordered or amorphous solid does not usually yield discrete, well-defined ridge lineshapes such as those in Figure 2, which are typical of an ordered crystalline solid. Instead, rather featureless two-dimensional peaks tend to be observed that are significantly broadened in both frequency dimensions. These broad peaks arise as a result of a distribution of isotropic chemical shifts and quadrupolar parameters that reflect the underlying heterogeneity of the nuclear spin environments.

These distributions of NMR parameters correspond to broadening along characteristic gradients in the two-dimensional MQMAS spectrum. For example, in a nonsheared spin $I = 3/2$ triple-quantum MAS spectrum a distribution of δ_{CS} values corresponds, according to Equations (1) and (2), to a broadening along a gradient of 3 $\delta_{\mathrm{CS}}/\delta_{\mathrm{CS}} = +3$, while, from Equation (5), in the sheared or split-t_1 spectrum, it will be along $+17/8$. Similarly, Equations (1), (2), and (5) triple-quantum of P_Q values in a spin $I = 3/2$ triple-quantum MAS spectrum produces a broadening along a gradient of $+21/{-7} = -3$ in a nonsheared spectrum and $(1/2)/(-14/35) = -1/5$ in a sheared or split-t_1 spectrum. If present, these broadenings will, of course, be in addition to the basic anisotropic second-order quadrupolar broadening along the MQMAS gradient.

The effects of these distributions are shown for a spin $I = 5/2$ nucleus in the simulated nonsheared triple-quantum MAS spectra in Figure 5 [22]. Figure 5a shows the spectrum for a single crystallographic site with distinct δ_{CS} and P_Q values, as would be found in a crystalline solid. There is a well-defined ridge lineshape with a gradient equal to the spin $I = 5/2$ triple-quantum MQMAS ratio of $+19/12$. Figure 5b shows the same spectrum but with the addition of a distribution of δ_{CS} values leading to a broadening of the ridge lineshape along a $+3$ gradient. If, instead, a range of quadrupolar parameters were present the additional broadening would lie (for spin $I = 5/2$ triple-quantum MAS) along a gradient of $+3/4$, as shown in the simulated spectrum in Figure 5c. This lineshape looks quite different from that in Figure 5c because a change in P_Q not only shifts a ridge lineshape in the (in this case) $+3/4$ direction but also alters its width along $+19/12$.

Occasionally, as found in some studies of glasses, for example, the δ_{CS} distribution appears to be fully correlated with the distribution of quadrupolar parameters, C_Q and η, and ω_2 cross-sections through a broadened peak in a sheared or split-t_1 MQMAS spectrum still yield lineshapes, such as those in Figure 4, with the features characteristic of second-order quadrupolar broadening [23,24]. The analysis of such a spectrum, by fitting these cross-sections and extracting δ_{CS}, C_Q, and η, is highly

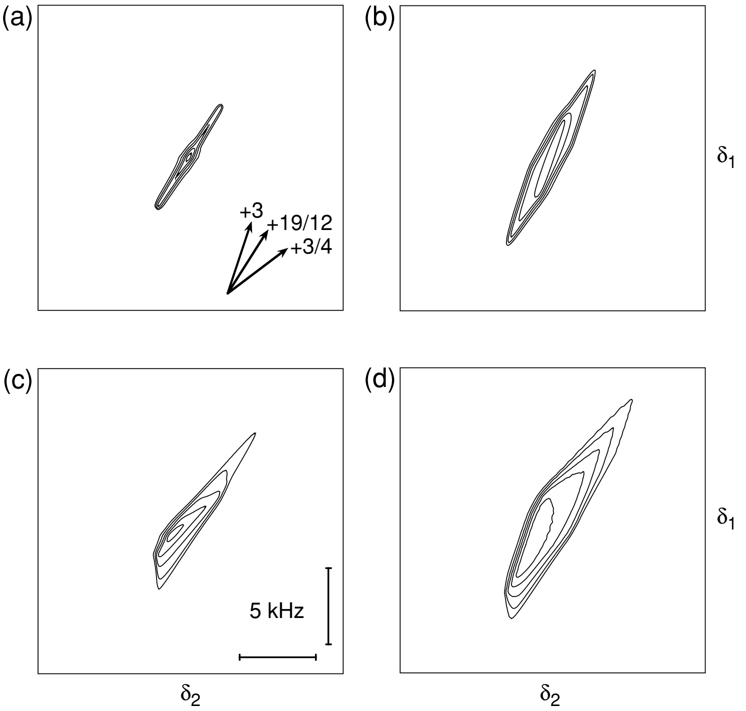

Fig. 5. Computer-simulated spin $I = 5/2$ lineshapes in nonsheared two-dimensional triple-quantum MAS spectra: (a) single ridge lineshape with $C_Q = 5$ MHz and $\eta = 1$; (b) same as (a) but includes a "boxcar" distribution of δ_{CS} of width 16 ppm; (c) same as (a) but includes a boxcar distribution of C_Q from 3 to 7 MHz; and (d) same as (a) but includes uncorrelated boxcar distributions of both δ_{CS} (of width 16 ppm) and C_Q (from 3 to 7 MHz). Simulations are for $\omega_0/2\pi = 104.3$ MHz and assume uniform excitation and conversion of triple-quantum coherences. Adapted from Ref. [22].

informative and has yielded valuable insight into the correlation of NMR parameters with the underlying structural ones, such as bond angles [23]. More commonly in amorphous solids, however, no apparent correlation can be observed between the distributions of chemical shift and quadrupolar parameters and cross-sections through the two-dimensional lineshape appear featureless. Such a case is simulated in Figure 5d, where uncorrelated distributions of both δ_{CS} and P_Q have been added to a spin $I = 5/2$ triple-quantum MAS lineshape [22]. In this case, it is still possible to use the center-of-mass of the two-dimensional lineshape to extract the mean values of the NMR parameters, $\langle\delta_{\mathrm{CS}}\rangle$ and $\langle P_Q\rangle$, while, if the shape of the distribution function is assumed, the widths of the distributions in δ_{CS} and P_Q can be estimated by fitting selected projections of the two-dimensional lineshape [22].

Figure 6a shows a peak from a ^{27}Al triple-quantum MAS spectrum of γ-Al$_2$O$_3$, recorded at $B_0 = 9.4$ T

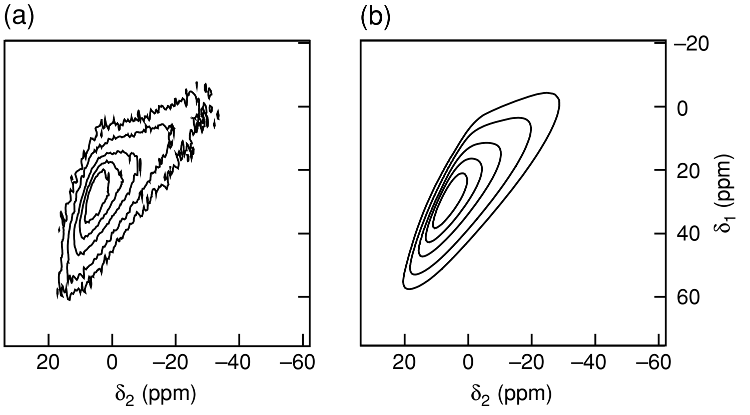

Fig. 6. (a) Peak (corresponding to the six-coordinate Al site) from nonsheared ^{27}Al ($\omega_0/2\pi = 104.3$ MHz) triple-quantum MAS spectrum of γ-Al$_2$O$_3$. (b) Computer-simulated lineshape with uncorrelated Gaussian distributions of δ_{CS} and P_Q (derived from fitting projections of lineshape in (a)). ($\omega_0/2\pi = 104.3$ MHz). This peak corresponds to the octahedrally coordinated Al site and exhibits features similar to the simulated lineshape in Figure 5d, characteristic of uncorrelated distributions of δ_{CS} and P_Q. The spectrum in Figure 6b was simulated using parameters derived from fitting projections of the lineshape in Figure 6a: $\langle\delta_{\mathrm{CS}}\rangle = 12$ ppm, $\Delta_{1/2}\delta_{\mathrm{CS}} = 5$ ppm (the half-width at half-height of a Gaussian distribution of δ_{CS} values), $\langle P_Q\rangle = 4.4$ MHz and $\Delta_{1/2}P_Q = 1.7$ ppm. The only fair agreement between the experiment and simulation is in part a consequence of the many assumptions made in the fitting and simulations, including uniform excitation and conversion of TQ coherences, $\eta = 1$, a complete absence of correlation between δ_{CS} and P_Q, and the Gaussian form of the distributions [22].

Summary

The MQMAS technique is one of the most powerful NMR methods for studying quadrupolar nuclei such as ^{17}O, ^{23}Na, and ^{27}Al in inorganic materials. This article has given a brief description of the experiment and outlined how MQMAS spectra can be analyzed to yield chemical shift and quadrupolar parameters. However, the reader is directed to the original literature, in particular Refs. [11,15], for more complete details on how to perform amplitude- and phase-modulated MQMAS experiments and on how to analyze spectra of nuclei of any spin quantum number.

Acknowledgments

I am grateful to the Royal Society for the award of a Leverhulme Trust Senior Research Fellowship, to EPSRC for funding our work on MQMAS from 1998 to 2003 (grants GR/M12209 and GR/N07622), and to Drs. Sharon E. Ashbrook and Jamie McManus for providing the spectra and simulations shown here.

Rheo-NMR Spectroscopy

Claudia Schmidt
Department Chemie, Universität Paderborn, Warburger Str. 100, D-33098 Paderborn, Germany

Introduction

Rheology, the science of deformation and flow, is of practical importance for the preparation, processing or application of different materials such as plastics, paints, detergents, oil or food [1]. Besides this practical importance, there is a fundamental interest in understanding rheological phenomena, in particular, those of complex fluids [2]. Different types of complex fluids, for instance, polymer melts and solutions, micellar systems, and solutions of colloidal particles share the common feature of having a mesoscopic length, given by the size of macromolecules, aggregates, particles or superstructures, which is intermediate between the molecular and macroscopic scale [3]. Connected with this mesoscopic length scale is a characteristic relaxation time that is long enough to be important on the time scale of rheological experiments, defined, for example, by the shear rate. For a simple liquid of small molecules, which tumble on the time scale of 10^{-12} s, the application of shear at a rate of several hundreds or even thousands of s^{-1} is a slow disturbance not affecting the molecules, the fluid is made of. In this case Newtonian flow is observed. In complex fluids, however, the longest relaxation times can be several seconds and longer so that a shear rate of lower than 10 s^{-1} brings the experimental time scale and the intrinsic time scale of the system to match. In this case the rheology often becomes nonlinear [4].

In order to understand the rheology of complex fluids, it is important to investigate *in situ* how the structure of the fluid is affected by the flow. Many experimental techniques that provide structural information, for example, microscopy, birefringence measurements, and scattering of light, x-rays or neutrons, have been applied to flowing samples [2,5,6]. Among the newer ones of these “rheophysical” methods are magnetic resonance experiments. The term “rheo-NMR”, now widely used, was introduced by Nakatani *et al.* for their *in situ* NMR studies of sheared polymer melts [7]. Some earlier applications of NMR to sheared systems include the investigations by Vera and Grutzner [8,9] and by Lacelle [10].

There are two different approaches in rheo-NMR. The first one aims at the spatial mapping of the flow field, also known as velocity imaging. Besides the velocity other parameters such as particle concentration or diffusion constants can be mapped. This field of magnetic resonance is also known as dynamic imaging or, when high resolution is obtained, as dynamic NMR microscopy [11]. The imaging aspects of rheo-NMR have been reviewed frequently [12–17] and will not be considered here. The second approach in rheo-NMR uses simple spectroscopy, mostly without spatial resolution, to obtain information about a sample under flow. This article focusses on this spectroscopic approach of rheo-NMR. Only applications to flowing systems will be considered; the extensive work on solid-like systems, elastomers in particular, is not covered.

In liquid crystal research, rheological information, namely viscosity parameters and elastic constants of nematic phases, is often obtained through NMR spectroscopy by observing either the relaxation of the director from an out-of-equilibrium orientation back towards the magnetic field or the director orientation under continuous rotation [18–32]. For such experiments the term rheo-NMR has been applied as well.

Experimental Aspects

The most simple form of shear flow is planar Couette flow between two parallel plates as shown in Figure 1a [1]. With one plate at rest, the force per unit area that moves the other plate defines the shear stress, σ. The shear, $\gamma = dx/dy$, describes the deformation, and the shear rate, $\dot{\gamma} = d\gamma/dt$, equals the velocity gradient, dv/dy, where v is the velocity. The viscosity, η, defined by

$$\sigma = \eta\dot{\gamma} \qquad (1)$$

is constant for a Newtonian fluid. Complex fluids often show non-Newtonian flow, for example, shear thickening or shear thinning, that is, an increase or decrease of the viscosity, respectively, with increasing shear rate.

For practical reasons, such as limited amounts of sample material, rotational shear cells are used. The most common ones are the cylindrical Couette and the cone-and-plate geometry, shown in Figures 1b and c. In a cylindrical Couette system, the sample is contained in the annulus between two concentric cylinders and the shear is applied by rotating the inner or outer cylinder. If the inner cylinder is

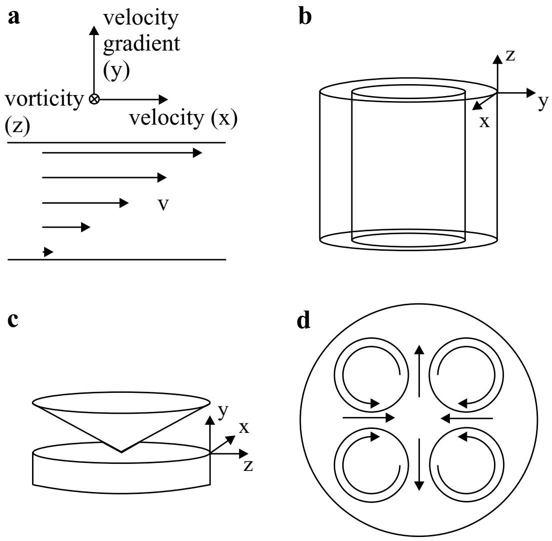

Fig. 1. Some flow geometries used in rheo-NMR experiments. (a) Planar Couette flow, the most simple type of shear flow, not used in experiments because of practical limitations. (b) Cylindrical Couette geometry. (c) Cone-and-plate geometry. (d) Four-roll-mill for extensional flow.

rotated inertia effects may cause a transition from laminar flow to Taylor vortex flow at high shear rates. Rheo-NMR experiments on Taylor vortices have been carried out, e.g., [9,33]. Compared to Couette systems, cone-and-plate devices have more uniform stress, provided the gap angle is small.

Shear occurs also in pipe or capillary flow. The stress varies across the radius and a parabolic velocity profile is observed for Newtonian liquids (Poisseuille flow). Rheo-NMR imaging of flow in cylindrical pipes or capillaries [34] and in more complex geometries with contractions and expansions [35] has revealed many interesting details.

Not only shear but also extensional flow has been studied by NMR. Callaghan and coworkers used a four-roll mill [36], shown in Figure 1d, where purely extensional flow occurs at the stagnation point in the center.

Since spin interactions are anisotropic, the orientation of the shear cell in the magnetic field is important. By aligning the symmetry axis of the shear device along the magnetic field direction spectral complexity due to different orientations of different parts of the sample is avoided. However, measurement at only one orientation with a single shear device does not provide complete information about the sample orientation in the locally biaxial shear field. Therefore, a cylindrical Couette system tilted at 90° to the magnetic field has been used, in combination with spatially selective excitation [36]. Nakatani *et al.* developed a motor-driven cone-and-plate insert for a sample tube that was used in the horizontal field of an electromagnet [7,37]. The cone-and-plate axis was perpendicular to the tube so that it could be oriented at arbitrary angles to the magnetic field. Alternatively, results obtained in axially aligned Couette and cone-and-plate systems can be combined [38].

The rotating part of the shear device can be driven by air, often using the spinner of a high-resolution NMR system [8–10,39], or by a mechanical motor [40–43]. In the latter case, samples of higher viscosity can be sheared. The motor drive can be mounted on top, which is the case in most laboratories, or below the superconducting magnet [42].

A rheo-NMR probe with a stress sensor was used by Grabowski and Schmidt [42,44]. Their cone-and-plate system consisted of a rotating plate, connected to a motor drive below the magnet, and a static cone fixed by a flexible spring. The steady-state position of the cone was measured optically. Calibration of the device with a fluid of known viscosity allowed for the determination of viscosities from the cone position.

The nuclei most commonly observed in flow experiments are ^{1}H [7,39,46–48] and ^{2}H [37,38,40,42,44–46,49–62] but also ^{13}C resonance has been used [63]. Despite the low sensitivity and the need for isotopic labeling ^{2}H has been used in the majority of experiments with spectral resolution because the single-site quadrupole interaction yields spectra that are easy to interpret. A few relaxation experiments have been carried out for protons with spectral resolution [39,47,48].

In the following, the application of ^{2}H rheo-NMR spectroscopy to liquid crystal polymers (LCPs) and surfactant solutions will be presented. Experiments were carried out with a Bruker MSL 300 spectrometer using a rotational shear device connected to a motor below the superconducting magnet with replacable tools of either cone-and-plate or cylindrical Couette geometry.

Nematic Liquid Crystals

The flow of nematic liquid crystals is described by the Leslie–Ericksen theory using six viscosity coefficients, α_i, five of which are independent [2]. Depending on the value of the flow-alignment parameter

$$\lambda = -\frac{\alpha_3 + \alpha_2}{\alpha_3 - \alpha_2} \tag{2}$$

two types of flow behavior can be distinguished. Flow-aligning nematics, characterized by $|\lambda| \geq 1$, show a stable director orientation in shear flow, whereas tumbling materials ($|\lambda| < 1$), exhibit a continuous rotation of the director. Below a critical shear rate, tumbling can be suppressed by a magnetic field.

The coupling between director and magnetic field in competition with the viscous torque is the basis for the measurement of viscosity parameters by a rheo-NMR-spectroscopic experiment [42]. In a cone-and-plate cell aligned parallel to the magnetic field, B_0, the angle between the nematic director and B_0, θ, is determined by the balance of the viscous and magnetic torques, yielding

$$\tan\theta = \mp\frac{\chi_a B_0^2}{2\mu_0|\alpha_3|\dot{\gamma}} \pm \sqrt{\left(\frac{\chi_a B_0^2}{2\mu_0\alpha_3\dot{\gamma}}\right)^2 \pm \left|\frac{\alpha_2}{\alpha_3}\right|}, \qquad (3)$$

where μ_0 is the magnetic susceptibility of the vacuum and χ_a is the anisotropy of the diamagnetic susceptibility. The upper and lower signs refer to flow-aligning materials and to tumbling systems below the critical shear rate, respectively. The critical shear rate is given by

$$\dot{\gamma}_c = \frac{\chi_a B_0^2}{2\mu_0\sqrt{-\alpha_2\alpha_3}}. \qquad (4)$$

For materials of sufficiently high viscosity such that moderate shear rates cause a substantial realignment of the director, a measurement of the director orientation θ as a function of $\dot{\gamma}$ yields α_2/χ_a and α_3/χ_a, according to equation 3 [42], and hence the flow-alignment parameter λ. The orientation angle θ is obtained from the quadrupole splitting of ^{2}H NMR spectra using

$$\Delta\nu = \frac{3}{4}\delta(3\cos^2\theta - 1). \qquad (5)$$

The motionally averaged quadrupole coupling constant, $\delta = e^2qQ/h$, is measured from the splitting at rest when $\theta = 0$. When the detection of the NMR spectra is combined with a simultaneous measurement of the viscosity, two additional viscosity parameters are obtained [42,44].

This rheo-NMR method has been applied to side-chain LCPs in bulk [42,45,49,50] and in solution [44]. Both flow-aligning and tumbling materials were identified. The onset of tumbling can be recognized qualitatively from line shapes that contain contributions from more than one angle θ.

In Figure 2, some results obtained for nematic polysiloxanes with different side chains are illustrated [45,50]. Homopolymers with only one type of side chain as well as random copolymers containing two different side chains, as shown on the top of Figure 2, were investigated. In the center of Figure 2, representative graphs of director orientation versus shear rate are depicted for the flow-aligning (PSi4) and the tumbling case (PSi6). Fitting equation 3 to the data yields the flow-alignment parameter λ. At the bottom of Figure 2, the λ values for three

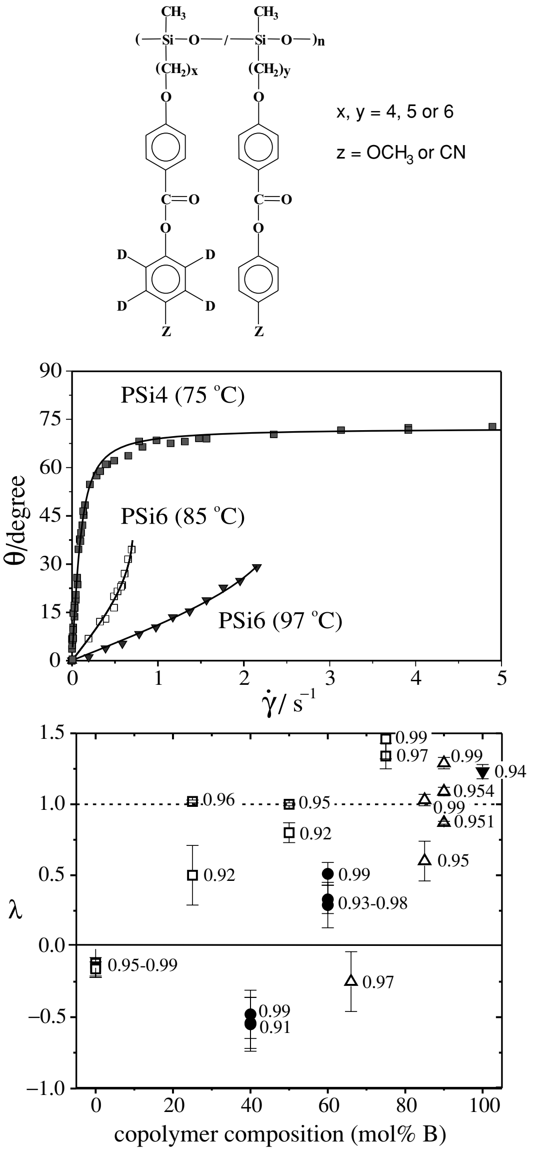

Fig. 2. Director alignment of LCPs in shear flow. Top: Chemical structure of the random copolymers ($n \approx 90$) studied by ^{2}H NMR spectroscopy in a cone-and-plate device. Center: Director orientation obtained from ^{2}H NMR spectra as a function of shear rate for the homopolymers with $z = \mathrm{OCH_3}$ and $x = 4$ (PSi4) or $x = 6$ (PSi6). Bottom: Flow-alignment parameters for different polymers (B: structural unit with $z = \mathrm{OCH_3}$ and $x = 4$, ▼: PSi4, □: $z = \mathrm{OCH_3}$, $x = 4$, $y = 6$, •: $z = \mathrm{OCH_3}$, $x = 4$, $y = 5$, △: $x = y = 4$, $z = \mathrm{OCH_3}$ or CN). The numbers next to the symbols represent the reduced temperatures T/T_{ni} (T_{ni}: clearing temperature). (From ref. [45]).

series of binary copolymers are compiled. The increase of λ with changing polymer composition can be correlated with a change of the phase structure from smectogenic to purely nematic [45,50]. In this respect, the investigated side-chain LCPs are similar to low-molar-mass nematics, for which flow tumbling is related to the existence of smectic clusters in the nematic phase.

Further investigations of nematic systems in shear flow by ^{2}H rheo-NMR spectroscopy include studies on a dimeric thermotropic material, for which the unusual observation of positive values for both α_2 and α_3 was made [51], and experiments on the calamitic and the discotic nematic phases of the surfactant system sodium dodecyl sulfate/decanol/D_2O, which were both found to be flow aligning and showed the different director orientations expected for rodlike and disklike aggregates [56]. Martins and coworkers studied the complex shear-induced reorientation behavior of lyotropic nematic solutions of polybenzylglutamate [64] and hydroxypropyl cellulose [43], which are both known tumbling LCPs.

In a recent publication, Cormier *et al.* reported on the extensional flow of the flow-aligning polymer PSi4 in a four-roll-mill [52]. By spatially selective excitation of the stagnation point the ^{2}H spectra of a protonated polymer sample containing a small amount of deuterated solvent were collected. Measurements at different strain rates show the expected flip from magnetic alignment to flow alignment along the axis of extension.

Hexagonal and Lamellar Lyomesophases

The shear-induced reorientation of the hexagonal mesophases of several nonionic surfactants was investigated by ^{2}H NMR spectroscopy [38,65–67]. Combined results from experiments in cone-and-plate and Couette geometry prove that the director aligns along the velocity axis. Log-rolling, an orientation along the vorticity axis, which was discussed initially on the basis of light scattering results, does not occur. Experiments at small shear rates below 10^{-2} s^{-1} starting from either disordered polycrystalline or magnetically aligned (by annealing at the isotropic-hexagonal phase transition) samples show that the reorientation is controlled by the strain and is independent of the shear rate. A simple model for the strain-controlled process of reorientation is shown on the top of Figure 3. The experimental data obtained for two solutions of $C_{12}E_5$ in D_2O (Figure 3, center) follow the predicted relationship between strain and orientation, $\gamma = \tan\theta$ [38].

The quadrupole doublets of both magnetically aligned and slightly sheared hexagonal samples exhibit a substantial linewidth, as shown in Figure 3 (bottom left). The detailed analysis of such line shapes using Tikhonov regularization [38,68] yielded a distribution of director orientations, which result from an undulation of the director. The undulation also causes the characteristic striated textures observed by polarizing microscopy [38,66] (cf. Figure 3 (bottom right)). However, when a sample is subjected to large shear at a small rate a substantial reduction of the linewidth is observed, indicating perfect alignment without undulations.

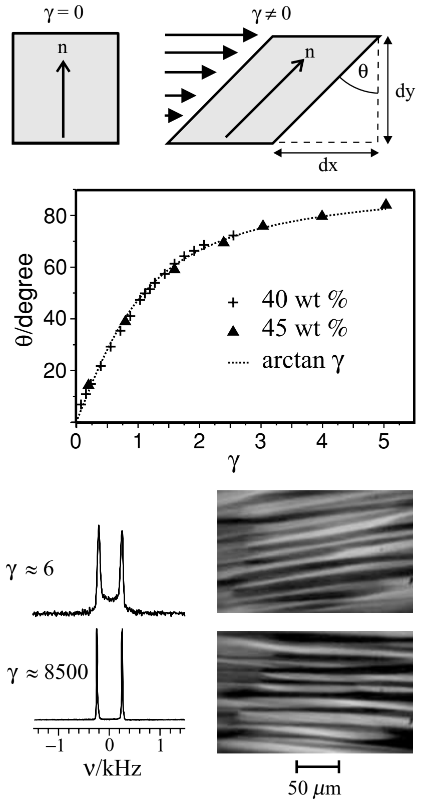

Fig. 3. Shear-induced alignment of the hexagonal phase of $C_{12}E_5/D_2O$. Top: Model of the realignment starting from an orientation of the director (**n**) along the velocity gradient axis. Center: Orientation angles in cone-and-plate geometry determined by ^{2}H NMR spectroscopy in dependence of the shear strain γ. Bottom: ^{2}H spectra at low and high strain (left) and micro-images of a sample sheared by a few strain units between crossed polarizers (right). The inversion of contrast upon inverting the angle between flow direction and polarizer axis indicates a director undulation (From Ref. [38]). (See also Plate 120 on page XVI in the Color Plate Section.)

First rheo-NMR experiments on lamellar phases were carried out on the nonionic surfactant system $C_{12}E_6/D_2O$ [53], confirming the shear-induced onion state, previously

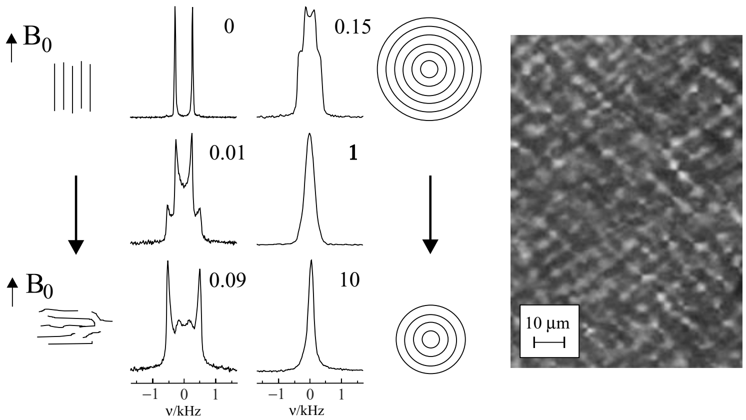

Fig. 4. Shear-induced formation of multilamellar vesicles (onions) in the lamellar phase of $C_{12}E_4/D_2O$ (35% w/w). Left: ^2H NMR spectra obtained in cone-and-plate geometry at increasing shear rates given in s^{-1} for each spectrum. At the beginning, the normal vectors of the layers (directors) are magnetically aligned in the velocity–vorticity plane. Shear at low rates leads to imperfect director alignment parallel to the velocity gradient. Increasing the shear rate induces the onion state. The vesicles get smaller upon increasing shear rate. Right: Microscopical image of the shear-induced onion texture between crossed polarizers (From Ref. [54]).

discovered [69]. This state of orientation is a metastable defect structure consisting of monodisperse, close-packed, multilamellar vesicles. Subsequently, the system $C_{12}E_4/D_2O$ was investigated by rheo-NMR as well as by conventional viscometry, rheo-light scattering and polarizing microscopy [54]. Like many other lamellar systems upon increasing shear rate, $C_{12}E_4/D_2O$ first shows an alignment of the layers in the velocity–vorticity plane accompanied by shear thinning. Further increase of the shear rate leads to shear thickening, indicating the formation of the onion structure. *In situ* NMR measurements, depicted in Figure 4, prove that the transition from aligned layers to onions is a gradual process that does not occur via a "two-phase" region. The decreasing linewidth is due to the decrease of the onion diameter from several micrometers down to about half a micrometer. Figure 4 (right) shows the characteristic onion texture as observed between crossed polarizers.

Rheo-NMR spectroscopy on other lamellar systems under shear has revealed further interesting details. Depending on the system, its components, concentration, and temperature, additional states of orientation may occur (cf. Figure 5). Besides the already mentioned alignment of layers in the velocity–vorticity plane (parallel orientation) and the onion state an alignment of layers in the velocity–velocity gradient plane (perpendicular orientation) is often found. The quadrupole splittings of one of the polymers, as shown in Figure 5, suggest such a perpendicular orientation at high shear rates [55], where the splitting is approximately the same as at rest.

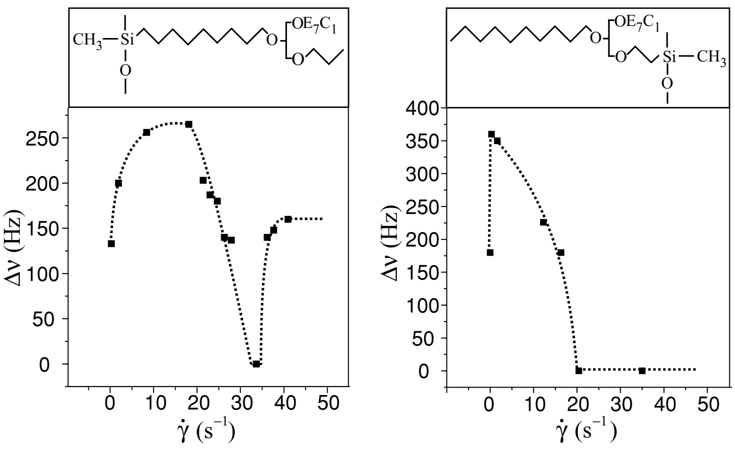

Fig. 5. Quadrupole splittings obtained for the lamellar phases of two different amphiphilic polymers in cone-and-plate geometry showing different states of shear orientation (From Ref. [55]).

Shear-Induced Phase Transitions

The sensitivity of NMR spectra to phase transitions was used for the investigation of the relaxation of shear-induced nematic order in an isotropic worm-like micellar system consisting of lecithin, D_2O, and cyclohexane [57]. When shear is stopped the nematic order disappears on the time scale of minutes. Time-resolved ^{2}H NMR spectra shows that the relaxation process is characterized by a continuous decrease of the measured quadrupolar splitting proportional to the nematic order parameter.

Conclusions

Rheo-NMR spectroscopy is a valuable addition to the stable of rheo-physical methods, yielding information complementary to other techniques. It is noninvasive and can be applied to opaque samples. Its future applications in material science will certainly provide more insight into the rheological phenomena of complex fluids.

Advances in Single-Sided NMR

J. Perlo, F. Casanova, and B. Blümich
Institut für Technische und Makromolekulare Chemie, RWTH Aachen D-52056, Germany

Introduction

Nuclear magnetic resonance (NMR) is an established powerful analytical tool widely used for structural and conformational analysis in chemistry, biology, medicine, and material science [1,2]. Material characterization is mainly carried out by measuring NMR parameters like the chemical shift, the nuclear spin relaxation times, the dipolar coupling, and the self-diffusion coefficient. Furthermore, NMR is employed to produce images contrasted by these parameters, and to characterize diffusive and coherent molecular motion in a non-invasive fashion. NMR methods have been initially developed to work in the homogeneous fields of strong magnets, but the limited working volume of these devices restricts the applications of NMR, in particular for *in situ* studies of large objects. But in addition to conventional NMR, where the sample is adapted to fit into the probe, there is inside-out NMR, which uses open magnet geometries specially adapted to the object under study. Such open magnets can be inexpensive and portable. They provide excellent versatility in accessing a large number of applications by NMR, which are inaccessible to closed magnet geometries. Historically the inside-out concept was developed for examining geological formations by lowering a full NMR spectrometer into a borehole to record signals from different formations [3]. Different tool geometries have been designed for well-logging [3,4] and water reservoir studies [5]. Later on the concept of single-sided NMR was extended to moisture detection in composites [6], medical diagnostics [7,8], and material analysis and quality control [9,10]

The price paid for non-invasiveness and access to arbitrarily large objects is the lack of high and homogeneous magnetic fields. This in turn limits the available experimental techniques, excluding for example high-resolution NMR spectroscopy methods, leaving for sample characterization mainly the measurement of signal amplitude, relaxation times T_1 and T_2, and the self-diffusion coefficient. Nevertheless, during the last years, the number of new methods especially developed to work in the inhomogeneous fields of single-sided sensors has considerably grown, so that, for example, multiple-quantum coherences [11], diffusion-relaxation correlation maps [12], images [13], and flow distributions can be measured [14]. Even the first steps to recover spectroscopic information in the presence of inhomogeneous fields have successfully been taken [15]. In the next sections, the state of the art in single-sided NMR is reported.

Material Characterization via Relaxometry by the NMR-MOUSE

A hand held single-sided NMR sensor that has extensively been used for non-destructive material testing is the so-called NMR-MOUSE® (mobile universal surface explorer) [9]. Its original magnet geometry combines two permanent magnets with opposite polarization placed on an iron yoke to form a U-shaped magnet. The open magnet defines a sensitive spot above its surface, from where the NMR signal is measured. Different regions of the object can be studied by simply repositioning the sensor. The main characterization procedure requires that a correlation between the relaxation times measured with the NMR-MOUSE and the material property of interest exists. An important example is the linear relationship between T_2 and the cross-link density of elastomers, which is explored to determine the homogeneity and the degree of vulcanization of intermediate and final products in the rubber manufacturing business [16].

The open geometry and mobility of the NMR-MOUSE are essential when investigating samples that cannot be moved, for example, specimens of Cultural Heritage, where the non-invasive and the non-destructive character are strict requirements for the safeguard of these objects. Examples of such applications are the analysis of historical building materials [17], and the degradation of antique paper, where, although only a small amount of paper (10–20 mg) is required, conventional NMR is destructive to the object under study [18].

As an example for single-sided NMR relaxometry, the use of the NMR-MOUSE is reported to study the water and oil absorption in polyethylene samples. This material is widely used in the construction of tanks and pipes used to store and transport different fluids. By simple molecular diffusion, the liquids penetrate the walls and sooner or later evaporate. Although the problem is well known, there are few experimental techniques to measure the degree of penetration *in situ*. The situation is even worse when

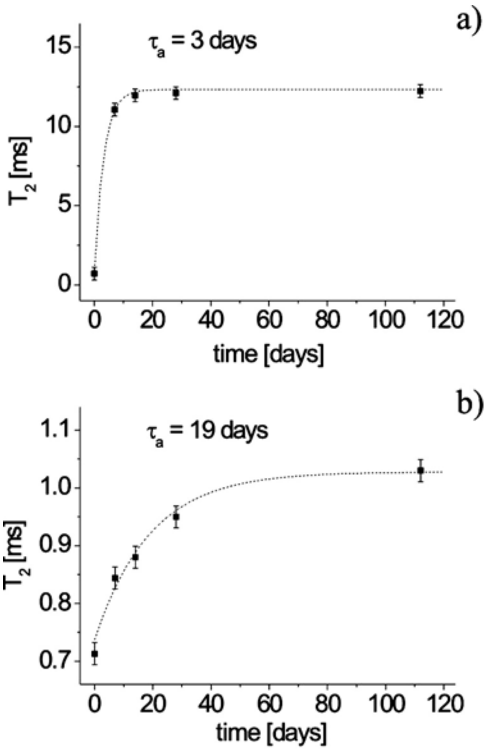

Fig. 1. Oil (a) and water (b) absorption in polyethylene. Samples with different contamination times were measured by applying a CMPG sequence. The decay of the echo envelope was fitted with a stretched exponential function to obtain T_2. The error bar corresponds to variations observed in a set of samples with the same contamination condition.

toxic substances are stored and already small evaporated quantities may give rise to relevant environmental damage.

A dedicated NMR-MOUSE sensor was set at the surface of polyethylene samples, and the presence of different contaminants was determined by measuring T_2 with a CMPG sequence. To study the characteristic absorption time of oil and water in polyethylene, different specimens were immersed in these solvents for 0, 7, 14, 28, and 112 days. Figure 1 shows the T_2 behavior as a function of the exposure time for both contaminants. The effect of the oil absorption is much larger than the one produced by the water, indicating that the oil strongly affects the material structure. Simply by correlating the dependence of T_2 with the weight of the sample as a function of the absorption, T_2 can be directly used to determine the amount of solvents inside polyethylene with good precision.

3D Imaging with a Single-Sided Sensor

Single-sided sensors are mainly used to characterize large size objects by measuring relaxation times and self-diffusion coefficients inside a spot near the surface. The complete object can be scanned by repositioning the sensor and an image with a typical resolution of about 1 cm can be obtained [19]. To obtain better spatial resolution, Fourier imaging techniques have been implemented with pulsed field gradients. In the presence of a strong static magnetic field gradient, only pure-phase encoding methods can be used to encode position across the selected sensitive volume [20]. Although long experimental times were initially required to produce 1D images, different methods have been proposed to improve the image quality and reduce the experimental time [21,22]. A milestone in the development of imaging methods for inhomogeneous fields was the design of a multi-echo acquisition scheme that reduces the experimental time up to two orders of magnitude [13]. The method has been implemented on a dedicated single-sided sensor, and different imaging experiments have been performed on objects with simple geometries to quantify the sensitivity enhancement and to test the performance of a 3D imaging multi-slice procedure. The multi-echo acquisition scheme has been also used to measure T_2 maps in heterogeneous objects, like samples from rubber with different cross-linking density across the object. The image contrast can be adjusted to relaxation time and diffusion weighting of the spin density.

In the following, applications of the open tomograph in medicine and in quality control of rubber products are demonstrated by two selected samples. A promising application of a mobile and low-cost single-sided tomograph is the diagnosis of arthritis, which produces deformation of the bones and joints. The multi-echo imaging sequence was implemented to produce cross-sections through a human finger at the positions marked in Figure 2A. Figure 2B shows two images of each slice reconstructed from the same experiment, but considering different parts of the acquired echo train. The first one possesses a low T_2 weight, while in the second one the T_2 contrast is increased to enhance the tissues with long T_2. The dimensions and shape of the bone and the bone marrow can be identified as well as the positions of vessels, arteries, and the tendon.

An application of the open tomograph to the quality control of rubber products is depicted in Figure 3 by example of slice-selective images of an air spring bellows from a shock absorber of a passenger car. The material is reinforced by two layers of textile fibers with perpendicular orientations. Figure 3b shows two 2D slice images, one for each fiber layer. The signal of the fibers is negligible compared to that of the rubber matrix, so that the fibers appear dark in the images. By projecting the 2D image

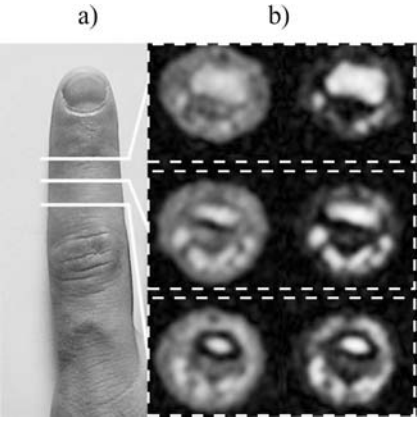

Fig. 2. (a) Human finger showing the position of the slices selected to be imaged. (b) Images obtained at three different positions along the fingertip. The image on the left shows the proton density while the one on the right possesses a strong T_2 contrast. For a slice thickness of 1 mm and lateral resolution of 1 mm^2, the imaging time was 9 min per slice.

along the fiber direction a 1D projection is obtained (Figure 3c). From the minima in the profile the position of the fibers can be determined with good precision, so that defects in the fiber layers can be identified.

Flow Characterization with a Single-Sided Sensor

Displacement or flow encoding is achieved by pulsed field-gradient techniques with pares of alternating gradients field pulses. Powerful sequences like the so-called 13-interval sequence have been designed to reduce distortions introduced by background gradients for displacement encoding in inhomogeneous fields [23], but they do not work in the highly inhomogeneous fields of single-sided sensors. The large off-resonance excitation in the static gradient field and the spatially inhomogeneous radio frequency field keep the radio frequency pulses from achieving uniform plane rotations for all the spins. The radio frequency pulses generate a large number of coherence pathways most of them being unfavorably encoded by the gradient pulses. Therefore, a new sequence to remotely measure the velocity distributions with a single-sided sensor was developed [14]. It consists of a 13-interval sequence and a suitable phase cycle to account for the signal from non-uniform rotations followed by a multi-echo acquisition scheme to overcome the sensitivity problem inherent to single-sided sensors. Moreover, the selective slice was moved along the depth direction, to spatially resolve the velocity distribution along the depth direction [24]. This method was used to measure the velocity profile of laminar flow through a rectangular pipe whose width is much larger than its height. For such an aspect ratio, the velocity

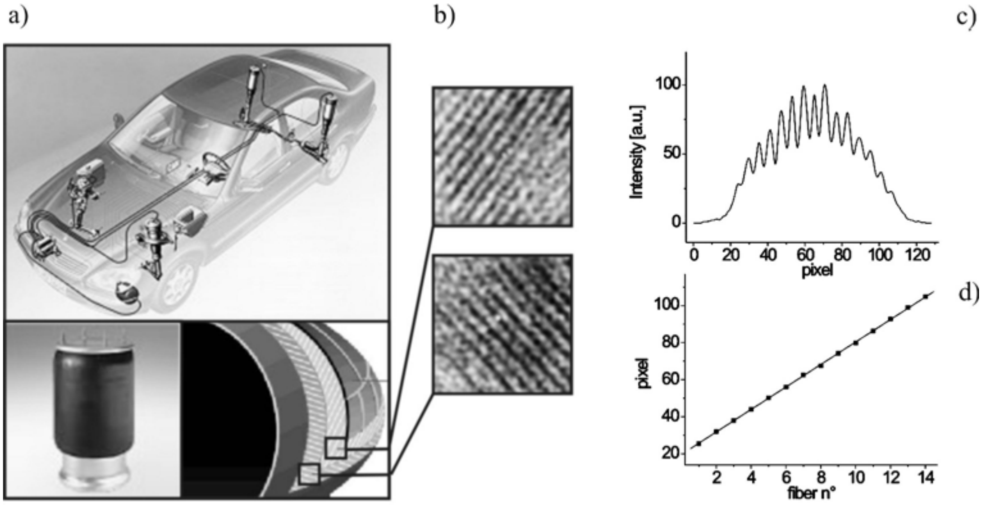

Fig. 3. (a) Airs springs are used in intelligent suspension systems that control the hardness of the shock absorber by adjusting the air pressure in the rubber bellows. The rubber matrix of the air spring bellows is reinforced by crossed layers of textile fibers. (b) Slice-selective 2D images of each fiber layer. The spatial resolution is about 200 μm, and the acquisition time of each image was 2 h. (c) Projection of one 2D image along the fiber direction. (d) Positions of the fibers determined from the 1D profile.

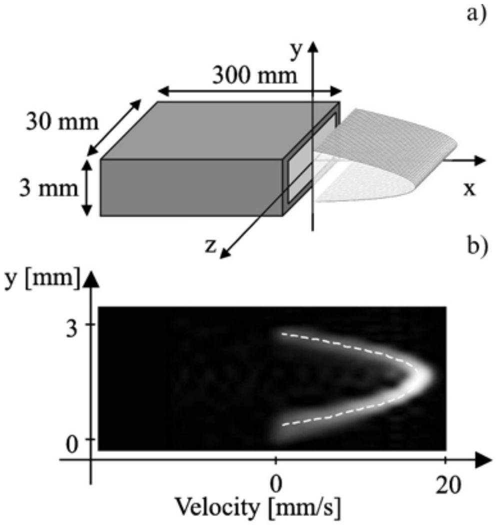

Fig. 4. (a) Laminar flow in a rectangular pipe. The velocity distribution is parabolic along the depth direction. (b) 1D velocity profile spatially resolved along the *y*-axis. The complete tube section was scanned in 10 slices, 0.3 mm thick. The measuring time was 5 min to obtain the velocity distribution in each slice with a resolution of 1 mm/s and a field of flow of 30 mm/s. The sensor used for these experiments is described in Ref. [13].

can be assumed to be constant along the long side, while it changes as a parabolic function along the short dimension (Figure 4a) [25]. Figure 4b shows the measured velocity distribution, which is in very good agreement with the predicted profile.

Conclusions and Remarks

Important advances in the development of dedicated single-sided sensors as well as pulse sequences suitable for their use have been reported during the last years. The conventional relaxation analysis has been combined with fast imaging methods to achieve a more detailed characterization of heterogeneous objects, and new sequences were developed to encode displacement, so that, for example, blood flow in vessels and arteries, and flow distributions in injectors and mixer can be analyzed non-destructively. The whole power of conventional NMR seems to become available to single-sided sensors, which are continuously finding new applications. The extreme versatility of such sensors to access immobile samples, in addition to the non-invasive character of the measurement identify this method as a unique tool to detect the presence of failures and defects in final products or at different stages during the production.

Site-specific Characterization of Structure and Dynamics of Complex Materials by EPR Spin Probes

Dariush Hinderberger and Gunnar Jeschke
Max-Planck-Institut für Polymerforschung, Postfach 3148, 55021 Mainz, Germany

Introduction

With the notable exceptions of magnetic materials and some transition metal catalysts most materials are diamagnetic and thus do not exhibit strong EPR signals. Occasionally, weak signals due to impurities and defects may be of significant interest, as for instance in semiconductors and optical materials, where such irregularities of the structure strongly influence those properties that have to be optimized for typical applications. The majority of materials, however, can be considered as EPR silent. This lack of background signals from the bulk of the sample provides the opportunity to apply EPR spectroscopy as a probe technique. Sites of interest in complex materials can thus be addressed with high specificity and a sensitivity corresponding to bulk concentrations of electron spins between 10 μM and 1 mM. Development of such approaches is strongly aided by similar work on biological systems [1]. Starting from the past decade several groups have focused on direct covalent attachment of stable free nitroxide radicals to interfacial sites in complex materials (spin-labeling) [2–5]. In an alternative concept, the electrostatic and hydrophobic interactions that govern self-assembly of supramolecular systems are utilized to direct spin probes with appropriate functionality to the site of interest [5–7]. Basic considerations about the choice of spin probes and the attachment of labels are discussed in Section "Addressing Specific Sites by Spin Probes and Spin Labels". Dynamics of such spin probes and labels on time scales between 10 ps and 1 μs can be characterized by the basic, fast and sensitive continuous-wave (CW) EPR experiment and is a rich source of information on both dynamics and structure of the materials themselves [6,8–10]. The most important approaches for analyzing such dynamics are discussed in Section "Detecting Supramolecular Interactions by Changes in Probe Dynamics".

Many materials of current interest exhibit structural features on length scales between 1 and 10 nm. Detailed structural information on this length scale is difficult to obtain by established characterization techniques unless the materials exhibit long-range order. Distance measurements between spin probes or spin labels [5,11–14] do not depend on such long-range order and can provide useful information even for conformational ensembles [14–17]. Measurements in the range between 1 and 2 nm are best performed with CW EPR measurements and have been reviewed in some detail before [5]. Therefore, Section "Characterization of Broad Distance Distributions" focuses on newer developments in the measurement of distance distributions in the range between 1.75 and 5 nm by pulse EPR techniques, while Section "Concatenated Macrocycles in Frozen Solution" demonstrates how such an approach can be used to characterize the coconformational ensemble of two concatenated macrocycles. Finally, Section "Polyelectrolytes: Probing Polyion-counterion . . . " illustrates application of a multitude of EPR techniques to a dianionic spin probe that interacts electrostatically with a cationic polyelectrolyte.

Addressing Specific Sites by Spin Probes and Spin Labels

Spin Probes as Tracers in Supramolecular Structures

Complex supramolecular structures are built from a number of different molecular constituents. Accordingly, characterization of their structure and dynamics is simplified if the constituents can be studied one by one. Such an approach requires spin probes that closely mimic certain constituents or have a strong preference for a certain domain in the material. In polymer films formed from collodial dispersions and the polymer dispersions themselves, we could selectively address polar and nonpolar sites and the head-group and tail-end regions of surfactant layers or surfactant aggregates [6,18]. Slightly polar probes in dispersions exhibited a stronger preference for the spherical polymer particles compared to the aqueous serum. For polymers above their glass transition temperature, they were found to diffuse from the serum into the particles on a timescale of several hours. By analyzing the diffusion kinetics of paramagnetic additive molecules, we could determine very small diffusion coefficients of less than $10^{-15}\,\mathrm{cm}^2\,\mathrm{s}^{-1}$ [8]. In general, spin probes can be selected or constructed that are

Graham A. Webb (ed.), Modern Magnetic Resonance, 1529–1537.
© 2008 *Springer.*

good tracers for constituent molecules whose size significantly exceeds 1 nm. The limit is given by the diameter of the nearly spherical nitroxide moiety that can be introduced as a five- or six-membered heterocycle (e.g., 2,2,5,5-tetramethyl-pyrrolidine-1-oxyl or 2,2,6,6-tetramethyl-piperidine-1-oxyl).

Principles of Spin Labeling

Nitroxide moieties are attached to macromolecules or surfaces via a linker group that has to be sufficiently long and flexible to avoid an influence of the label on the structure of the macromolecule [19]. On the other hand, the linker should be short enough to bring the label close to the intended site and rigid enough to couple it to the dynamics of the probed structure. As far as distance measurements on conjugated systems are concerned, the linker should break the conjugation pathway to avoid errors due to significant exchange coupling between the two spins [20]. Typically, the center of the nitroxide bond is thus separated by 0.6 to 1 nm from the point of attachment.

Detecting Supramolecular Interactions by Changes in Probe Dynamics

Continuous-wave EPR spectra of nitroxides are sensitive to rotational correlation times on time scales between 10 ps and 1 μs. In the range from 100 ps to 50 ns, the line shapes are a rich source of information on the specifics of the molecular reorientation process, e.g. on anisotropy of rotational dynamics or potentials that restrict reorientation. Rotational dynamics of spin labels attached to macromolecules is influenced by restricted sidegroup motion, local backbone fluctuations at the point of attachment, and global tumbling of the macromolecule. Successful line-shape simulations for such complex motion could be achieved in the context of site-specifically spin-labeled proteins by deriving a reorientation potential from molecular dynamics simulation and computing the EPR response from trajectories for Brownian rotational diffusion [22] in this potential [23]. A more abstract approach assumes that restricted sidegroup motion can be modeled by reorientation of the spin label in a cone and the combined effect of backbone fluctuations and global tumbling can be modeled by an axially symmetrical rotational diffusion tensor (slowly relaxing local structure model) [24]. At sufficiently high EPR frequencies, the latter slow processes do not significantly influence the line shape, as was demonstrated by a combined 250 and 9 GHz EPR study on membrane vesicles containing a chain and labeled phospholipid [25]. Detailed line-shape simulations based on a model of restricted rotational diffusion (microscopic order/macroscopic disorder) [26] were also successful for spin-labeled surfactant molecules in polymer dispersions [6].

In many cases, however, such detailed simulations are not feasible for material applications, either because the parameters for a complex reorientation process are distributed or the timescale of restricted motions in the temperature range of interest is too fast or too slow to resolve the details. Useful general information on the reorientation process can often be obtained nevertheless by *approximate* fits to a simple model of Brownian diffusion with an axially symmetric rotational diffusion tensor with principal values $R_{||}$ (unique axis) and $R_{\perp}$ (perpendicular to the unique axis) [6,10,18]. The sensitivity of CW EPR line shapes to the orientation of the unique axis in the molecular frame and to the rotational correlation time

$$\tau_r = \frac{1}{6\sqrt[3]{R_{\perp}^2 R_{||}}}. \tag{1}$$

is illustrated in Figure 1. Differences between isotropic rotational diffusion ($R_{||} = R_{\perp}$, left column) and preferential rotation about the z axis ($R_{||} = 10R_{\perp}$, second column from left) are best visible with high-frequency EPR (W-band, 94 GHz, bottom panel) as the difference is related to the g tensor, while preferential orientation about any other axis is easily recognized at X-band frequencies of 9.6 GHz, as it leads to significantly different averaging of the hyperfine tensor. The direction of the unique axis can provide information on the specifics of electrostatic attachment for ionic spin probes [6,10] (see also Section "Polyelectrolytes: Probing (Polyion-Counterion Interaction in Fluid and Frozen Solution") as well as on changes in the local environment of the spin probe due to changes in macromolecular structure or solvent conditions [27].

Characterization of Broad Distance Distributions

Many construction materials and most prospective functional materials derive their properties from a balance between flexibility and rigidity. This implies intermediate order on length scales beyond a few bond lengths (0.5 nm). In principle, such intermediate order can be detected by scattering techniques, but limited contrast, selectivity, and sensitivity restrict the complexity of the structures that can be characterized in detail. Distance measurements between site-specific spin probes or spin labels can overcome all these limitations and cover the distance range between 1 and 10 nm that is typical for such intermediate order. Moreover, distance measurements based on pulse EPR approaches [28] can provide not only just a single number for the average distance but also an estimate for the whole distance distribution [15]. Conversion of dipolar evolution functions to distance distributions is

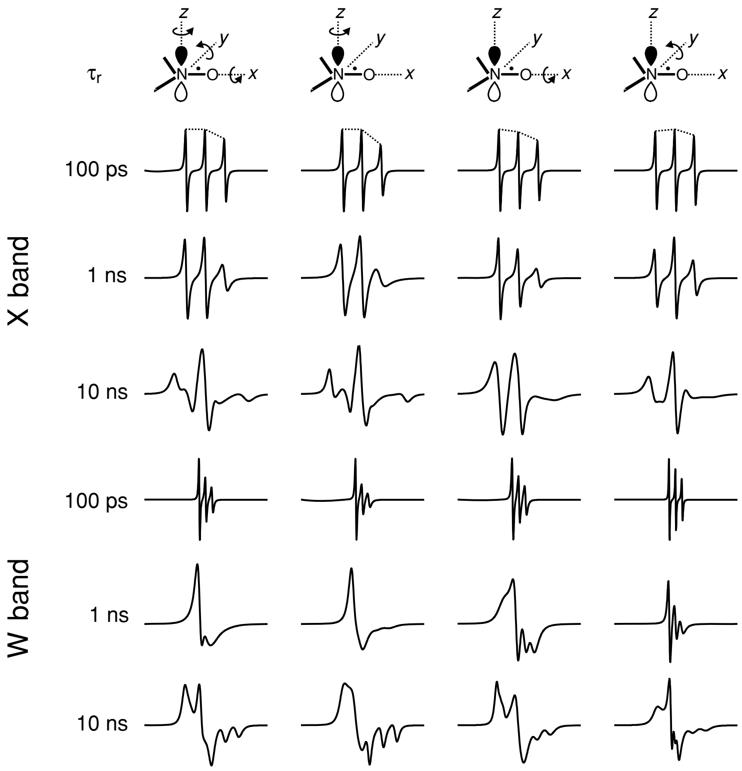

Fig. 1. Dependency of nitroxide spin probe spectra on rotational correlation time, preferential rotation axis, and EPR frequency. Panels from left to right correspond to isotropic rotational diffusion, and preferential rotation about the *z*, *x*, and *y* axis, respectively. Rotational diffusion about the preferred axis is assumed to be ten times faster than about other axes. X-band spectra are centered at 334.8 mT and are 10 mT wide, W-band spectra are centered at 3355 mT and are 30 mT wide. Simulations were performed with the Schneider/Freed suite of programs [21].

a (moderately) ill-posed problem, hence, some caution is advisable in the choice of data analysis procedures and in the interpretation of the results [17].

The main limitations of the method are illustrated in Figure 2. As the excitation bandwidth must cover the dipolar doublet (Pake doublet) of the two coupled spins, available microwave power and resonator bandwidth restrict the measurement to distances larger than 1.5–1.75 nm (blind volume around the observer spin, Figure 2A). The maximum observation time of the order of a few microseconds limits resolution in dipolar frequency domain and thus the maximum distances that can be measured. In most materials, distances up to 5 nm can be resolved quite nicely, while extension to distances up to 8 nm is possible in materials that are free of mobile protonated groups or are deuterated [17]. Spins at larger distances contribute a background signal with the general shape of a stretched exponential decay that must be removed by fitting the long-time decay and subtracting it (Figure 2B). The remaining dipolar evolution function is due to spins in the distance range of interest and can be converted to a distance distribution by an approximate Pake transformation [15], Tikhonov regularization, or fitting. A generalized and stable fitting procedure is obtained by defining the distribution by the amplitudes at sampling points and interpolating between the sampling points by Hermite polynomials [17]. The problem thus boils down to selecting a realistic resolution of the distance distribution, i.e. an appropriate number of sampling points. The broad asymmetric model distribution in Figure 2 cannot be approximated very well by only nine sampling points (C) so that a significant residual between experimental and fitted dipolar evolution function is found (arrows in D). A good fit is obtained with 17 sampling points (E and F). A further increase to 33 sampling points does not lead to a significant improvement of the fit residual (H) but introduces noise-induced features in the distance distribution (G). Generally, the minimum number of sampling points for which the residual is white noise provides the most realistic distance distribution. Distortions in this distribution increase more strongly than linear with an increase in noise amplitude.

Concatenated Macrocycles in Frozen Solution

In many cases, it is possible to construct a relatively simple approximate geometric model for the system under consideration. This considerably reduces the number of

fit parameters and may circumvent the problem of ill-posedness of the conversion of dipolar evolution functions to distance distributions. For a nanosized [2] catenane (Figure 3A) consisting of two macrocycles with both rigid and flexible sections, we could thus answer the question whether the distribution of co-conformations is uniform, i.e. whether all possible relative orientations and inter-center distances of the macrocycles occur with the same probability [16]. Approximation of the macrocycles by circular rings and of the linker and spin label by a straight line (Figure 3B) results in a model with only one free parameter, namely, the effective radius r_{eff} of the rings. Moreover, a prediction of this parameter can be derived by equating the circumference of the ring with the contour length of the backbone of the macrocycle. For the medium-sized macrocycle discussed here, this approach predicts $r_{eff} = 1.75$ nm. For a glassy frozen solution of this [2] catenane in *o*-terphenyl, we find poor agreement of the shape of the distance distribution for this geometric model with the experimental distribution and a poor fit of the experimental dipolar evolution function (Figure 3C and D). In contrast, data for a frozen solution of the same [2] catenane in chloroform can be fitted rather nicely and provide an experimental value $r_{eff} = 1.50$ nm that is in reasonable agreement with theoretical predictions (Figure 3E and F). Similar results were obtained for a larger [2] catenane with nominal $r_{eff} = 2.99$ nm (experimental value $r_{eff} = 2.60$ nm). These results indicate that the flexible alkyl sections of the macrocycles are expanded in the good solvent chloroform but partially collapsed in the poor solvent *o*-terphenyl. In the former case, the simple geometric model provides a surprisingly good description of the distance distribution, suggesting that the distribution of co-conformations is indeed uniform.

Polyelectrolytes: Probing Polyion-Counterion Interaction in Fluid and Frozen Solution

Polyelectrolytes are a class of macromolecular substances that are mainly governed by electrostatic interactions. In water and other polar solvents they dissolve into charged polymer chains, called polyions, and many small ions of opposite charge, called counterions. Despite their obvious importance in molecular biology (e.g. DNA) and materials science, these complex many-particle systems belong to the least-understood classes of macromolecules.

Polyelectrolytes are often studied either using methods that probe macroscopic properties (such as conductivity) or scattering techniques (light-, X-ray and neutron scattering), which can only probe residual long-range order in solution [29]. Using these widely-employed methods it is therefore hardly possible to understand local polyion–counterion interactions and to obtain information on the distribution of counterions around polyion chains. The latter point is of particular importance in the theoretical description of these systems [29,30]. It is possible to obtain information on electrostatic interactions between polyions and counterions by use of charged spin probes [9,10,31] and the techniques described in Sections "Addressing Specific Sites by Spin Probes and Spin Labels", "Detecting Supramolecular Interactions by Changes in Probe Dynamics" and "Characterization of Broad Distance Distributions". The scope of this approach was explored in studies on cationic poly(diallyldimethylammonium chloride), (PDADMAC) to which small amounts of the dianionic nitroxide spin probe Fremy's salt, nitrosodisulfonate FS were added (see Figure 5 for structures). In these studies the concentration of the used spin probe was kept constant at $c = 0.5$ mM and the polyelectrolyte repeat unit concentration was varied between 4 and 140 mM. The data are presented as a function of the ratio of the concentrations $R = [\text{FS}]/[\text{PDADMAC}]$. In addition, solvent composition and the amount of added salt were varied and the effect on the EPR parameters was analyzed.

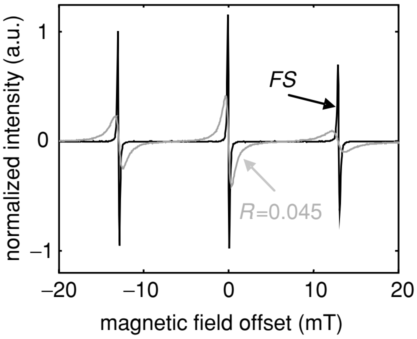

Fig. 4. X-band (9.79 GHz) EPR spectra in 66 wt.% glycerol/34 wt.% water at two different spin probe/PDADMAC ratios *R*. Black line: no polyelectrolyte, only FS; Gray line: $R = 0.045$. Spectra were normalized to equal double integral.

Figure 4 shows two CW EPR spectra (X-band) of FS in glycerol/water at room temperature with (gray line) and without (black line) added PDADMAC. On closer inspection of the line-shape it becomes apparent that the spectral changes are made up of two contributions: alterations of the relative amplitudes of the three individual hyperfine lines and non-Lorentzian broadening that affects all lines in the same way. Although the first contribution is indicative of a change in the rotational diffusion of the employed spin probes (see Figure 1), the deviation of the line shape from a derivative Lorentzian line could be assigned to spin-exchange broadening [32] due to enhanced intermolecular collisions of counterions situated close to the polyelectrolyte chain. Quantitative analysis requires a separation of both effects.

Using simulation programs by Schneider and Freed (see Figure 1; [21]), it was possible to reproduce the relative amplitudes of the three lines based on a model of Brownian rotational diffusion with an axially symmetric rotational diffusion tensor. However, even when spin–exchange interaction due to collisions with a *single* well-defined frequency was included in the Hamiltonian, the additional broadening and line shape changes could not be reproduced. Good fits were obtained by multiplying time-domain data $V_{\text{sim}}(t)$ corresponding to the simulated spectra with a stretched exponential decay function,

$$V(t) = V_{\text{sim}}(t)\exp(-(kt)^x), \qquad (2)$$

that accounts for heterogeneous exchange broadening in an empirical fashion (Figure 5A). Here, k is the characteristic decay constant and x is the stretch factor. The empirical broadening function accounts for a distribution

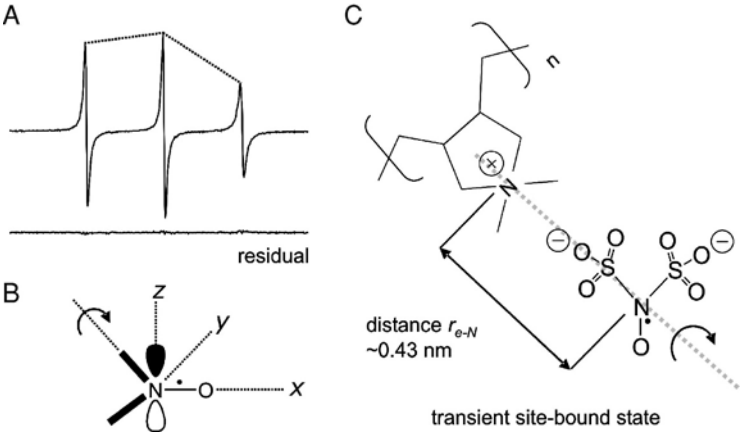

Fig. 5. Analysis of CW EPR (X-band, 9.79 GHz) spectra of FS ions in fluid solutions of PDADMAC. (A) CW EPR spectrum of FS at $R = 0.067$ in 50% ethanol/50% water and the residual after subtraction of a simulation according to Equation 2 with $k = 1.8 \times 10^{13}\ \mathrm{s}^{-1}$ and $x = 0.1$. (B) The rotational diffusion tensor used for this simulation. Rotation takes place preferentially along one of the nitrogen–sulfur bonds in FS, although both bonds are equivalent. The rotational rates are $R_{||} = 3.7 \times 10^9\ \mathrm{s}^{-1}$ and $R_\perp = 5.5 \times 10^7\ \mathrm{s}^{-1}$. (C) Illustration of the geometry and dynamics of the transient site-bound state derived from the analysis. The distance r_{e-N} was derived from ratio analysis of ESEEM data as explained in the text.

of spin–exchange frequencies which in turn is related to a distribution of local concentrations of spin probes close to the oppositely charged polyelectrolyte [9,10]. The detailed line-shape can also be reproduced in a more physically motivated picture by assuming that the radial counterion distribution around an individual polyion scales with the inverse square of the distance from the polyion [33]. Such scaling is suggested by a recent theoretical analysis of the charged cell model for polyelectrolyte chains and their counterions [34].

Irrespective of the solvent used, the CW EPR spectra could be fitted nicely by assuming an axially symmetric rotational diffusion tensor with the unique axis pointing along one of the sulfonate groups of the spin probe (Figure 5B and C). Rotation about the preferred axis was 15 (in water) to 100 (66 wt.% glycerol/34 wt.% water) times faster than rotation perpendicular to this axis [33]. Hence, the Coulombic interaction between the dianionic spin probes and the quaternary ammonium groups of the PDADMAC repeat units results in an attachment of FS that is transient and involves only one of the sulfonate groups at a time. During attachment, rotation about the axes perpendicular to the preferred axis requires reorientation of at least local segments of the polyion chain that causes the significant reduction of the rotational diffusion about these axes. Electrostatically, *site-bound* FS probes are in equilibrium with *territorially bound* probes, which are not directly attached but are located in the vicinity of the respective polyion chains and still interact with the electrostatic potential of larger segments of these chains. The lifetime of the site-bound state can safely be assumed to be shorter than 1 ns, since otherwise significant spectral components reflecting the slower motion would be expected (see Figure 1). This attachment–detachment process was termed as *dynamic electrostatic attachment* to stress its transient nature.

The site-bound state was further characterized by performing three-pulse electron spin echo envelope modulation (ESEEM) experiments [28] on glassy frozen solutions of the PDADMAC/FS samples. Ratio analysis of the decay provided a lower limit of the distance between electron spin and ^{14}N nuclear spin of the charge-bearing ammonium group of ≈ 0.43 nm for 20% of the spin probes (Figure 5C, [10,35]). This distance was found to be in excellent agreement with the distance in PDADMAC/FS contact ion pairs computed by a molecular force-field. The remaining 80% of the spin probes are presumably territorially bound.

Further details of the heterogeneous spin probe distribution were studied by applying the four-pulse version of the DEER experiment [36] to shock-frozen solutions of PDADMAC/FS in glycerol/water. The time trace of FS ions in PDADMAC ($R = 0.022$) obviously deviates from the exponential decay that would be expected for a homogeneous distribution of spin probes in three dimensions (Figure 6A). Variation of the concentration of PDADMAC reveals that the deviation increases with increasing R-values, i.e. with decreasing polyelectrolyte concentration. Due to the blind volume of the DEER experiment (see Section "Characterization of Broad Distance Distributions" and Figure 2) this heterogeneity cannot be attributed to the radial distribution that is observable with CW EPR, but must be related to the axial distribution along the chains. Indeed, the complete series of data can be analyzed using a two state model for the distribution of FS ions: FS ions are either distributed homogeneously in three dimensions (concentration c_{hom}) or along a one-dimensional linear object (linear spin density c_{lin}). The corresponding pair correlation function $G(r)$ for this model is given by:

$$G(r) = c_{\text{hom}} N_A + c_{\text{lin}}/r^2. \tag{3}$$

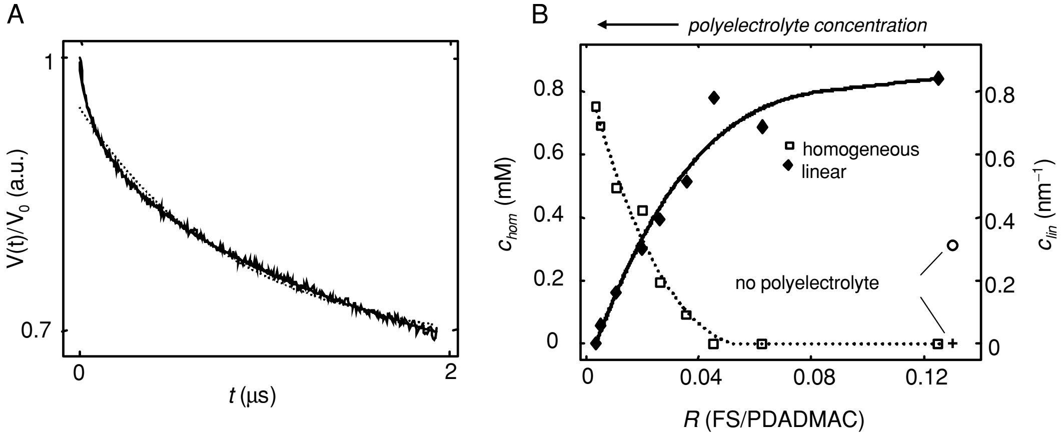

Fig. 6. Analysis of DEER time traces of FS in frozen solutions of PDADMAC in 66 wt.% glycerol/34 wt.% water. (A) Time trace at $R = 0.022$ (solid black line) with a single exponential decay (dotted black line) and a simulation according to Equation. 3 (solid gray line) overlaid. The extracted parameters for the latter simulation were $c_{hom} \approx 0.4$ mM and $c_{lin} \approx 0.3$ nm^{-1}. (B) Summary of the extracted parameters c_{hom} (open squares) and c_{lin} (filled diamonds) in the complete R-range investigated. The solid and dotted black lines are meant as guides to the eye.

where N_A is Avogadro's constant. Figure 6A shows that a simulation using $c_{\text{hom}} \approx 0.4$ mM and $c_{\text{lin}} \approx 0.3$ nm^{-1} (overlaid in gray) excellently reproduces the measured time trace. The two parameters are summarized for the complete series of measurements in Figure 6B. The homogeneously distributed component decreases with increasing R and is effectively zero for values larger than 0.05, whereas the component that is presumably distributed along one dimension follows an opposite trend and increases with R reaching a plateau value of $c_{\text{lin}} \approx 0.8$ nm^{-1} for $R > 0.05$. This behavior can be interpreted as a transition from a network of overlapping polyelectrolyte chains at high PDADMAC concentrations to a regime of isolated and locally extended polyelectrolyte chains at low polymer concentration. In the former regime, FS spin probes are distributed throughout the whole three-dimensional polyelectrolyte network, while with decreasing PDADMAC concentration, the single chain character increases and c_{lin} becomes larger. The plateau value of 0.8 nm^{-1} for c_{lin} is explained by the lower detection limit for electron spin distances of roughly 1.5 nm (see Section "Characterization of Broad Distance Distributions", [28]). As the DEER data are consistent with a picture of FS ions that are attached to a linear object one may indirectly conclude that the PDADMAC chains are in a locally elongated conformation with a persistence length of at least 5 nm, which is the range probed by a dipolar evolution function that is measured up to $t = 2\mu$s.

In conclusion, we find that for the complex structures formed by electrostatic self-assembly of polyelectrolytes and their counterions in solution, EPR spectroscopy on charged spin probes provide insights that are not accessible with other characterization methods. Similarly, the broad co-conformational ensemble of [2]catenanes, which is governed by the topological constraint that the two macrocycles must remain concatenated, would be difficult to elucidate with any other technique. These examples demonstrate that EPR spectroscopy is particularly well suited for characterizing the structure and dynamics of the materials that exhibit an intermediate degree of order on length scales between 0.5 and 10 nm.

Introduction

Organic semiconductors are conjugated molecules that act as charge carriers and are photo-active. Mainly due to their ease of processing, they offer great promise in replacing conventional semiconductors in optoelectronic devices, such as light-emitting diodes and photovoltaic cells [1]. In particular, organic light emitting diode (OLED) devices [2] have received considerable attention over the last 15 years. Their improved electro-optical properties, such as low operational voltage, high brightness, and luminescence efficiency combined with the ease of fabrication have made them very good candidates for flat panel displays.

The molecular structure and dynamics of organic semiconductors profoundly influence the transport of charge carriers and hence affect the performance of the devices in which they are used. As a group of materials, they offer an interesting blend of properties which are yet to be completely understood. Quantitative determination of the molecular structure and dynamics of the organic layer in OLEDs and other devices is a prerequisite to understand the properties of the devices and to optimize the processing parameters for maximum performance. This is complicated due the fact that the organic layers in OLEDs are generally amorphous, which greatly limits conventional diffraction-based techniques for structural investigation such as X-ray diffraction. NMR spectroscopy offers great potential in this regard, since it provides short-range structural information and does not depend on long-range structural coherence.

Several applications of solid-state and liquid-state NMR have been reported in the literature to study the structure and dynamics of organic semiconductors and the conducting polymers. The following list is not intended to be exhaustive, but illustrates the various possibilities of using NMR as an effective tool to study the organic semiconductors. For example, Yannoni and Clarke have conducted a structural study of polyacety-lene using solid-state nutation NMR spectroscopy [3]. There has been extensive use of NMR, as a tool, for studying the spin diffusion and electron conductivity in organic semiconductors [4]. ^{13}C and ^{2}H solid-state NMR has been used to study the structure and dynamics of polyanilines[5]. Also, the molecular geometry [6] and proton exchange [7] aspects of polyaniline have been probed by using NMR. The thermally-induced metal-semiconductor transition in organic salts has been studied using ^{13}C NMR. [8] The morphology and dynamics of lithium salt-based polyelectrolytes have been probed using ^{13}C and ^{6}Li NMR [9]. ^{2}H NMR has been used to characterize the phenylene ring flip motion in poly (*p*-phenylene vinylene) (PPV) films [10]. The structural aspects of nonconjugated polymers have been probed by ^{13}C NMR [11]. ^{129}Xe NMR has been used to study the microporous structure of polyacenic semiconductor [12].

In the present contribution, we focus on aluminum tris (8-hydroxyquinoline) (Alq$_3$), which is widely used as an electron transport and electron-hole recombination layer in OLED devices [2,13,14], A significant effort has been made to understand the properties, structure and dynamics of Alq$_3$, both in solution and in the solid state. In particular, fundamental studies directed towards the properties of the Alq$_3$ molecule, such as its electronic structure [15,16], dynamics [17–19], and crystal polymorphs [20–22], have been reported.

Alq$_3$ is an organometallic complex with the aluminum ion surrounded by three identical quinolinolate anions. In principle, both meridianal isomer, with the oxygen atoms forming meridian of the distorted coordination octahedron, and a facial isomer, with the oxygens forming a face of the octahedron, could exist. In the facial isomer, the three ligands are equivalent by symmetry, whereas in the meridianal isomer, they are distinct. As is well-known from earlier NMR studies [23], the meridianal isomer is the stable form in a solution at room temperature.

While the meridianal isomer of Alq$_3$ has so far been observed exclusively both in solvent-containing [23] crystals and in the pure α, β, and γ polymorphs [20] as well as in solution [23], a novel crystal polymorph [21], called the δ-phase, has been assigned tentatively to the facial isomer [21,22,24]. The δ polymorph exhibits a substantial blue shift of about 0.2 eV in its photoluminescence spectrum. This could lead to the development of Alq$_3$-based OLED devices which emit blue, rather than green, range of the spectrum.

In this paper, we review recent results on the internal dynamics of the Alq_3 molecule, studied using two-dimensional exchange NMR spectroscopy, the molecular structure in the α and δ polymorphs of crystalline Alq_3 by ^{27}Al NMR, as well as the structural disorder in amorphous films of Alq_3 as a function of the deposition rate.

OLEDs are fabricated by depositing the organic layer onto the device substrate from the vapor phase. The rate at which the organic layer is deposited on the substrate is known to influence the final device properties [25]. However, no fundamental explanation of this phenomenon based on the structure and morphology of Alq_3 has been forwarded yet. Our studies show that ^{27}Al solid-state NMR is a very useful tool to study amorphous Alq_3 deposits, and may therefore, lead to better understanding of the relationship between processing conditions, film structure, and device properties.

Ligand Dynamics in Alq_3

The internal dynamics of the Alq_3 molecule are crucial for the processing and long-time behavior of OLED devices. Current OLED devices use Alq_3 in the form of amorphous thin films. Both the deposition of these films and their gradual physical aging are kinetically controlled processes. In particular, significant effects of the deposition rate and conditions on the performance of Alq_3-based devices have been demonstrated recently [25–28].

As mentioned earlier, the Alq_3 molecule exists as two different isomers: facial and meridianal. The absence of an axis of symmetry in the meridianal form of Alq_3 leads to the three quinolinolate ligands being distinguishable. Their inequivalence becomes immediately apparent in the proton NMR spectrum in solution [23,29], where a separate set of resonances can be observed for each of the three ligands. It has been shown that the line shape of the proton resonances strongly depends on temperature, suggesting exchange dynamics between the ligands [23]. Two-dimensional NMR exchange spectroscopy is an ideal tool for the quantification of chemical exchange processes [30], provided the exchanging species are well resolved and the time scale of the process is shorter than the spin-lattice relaxation time. Both these conditions are met by Alq_3 in $CDCl_3$.

The two-dimensional exchange spectrum of Alq_3 in $CDCl_3$ solution at a temperature of 310 K and a mixing time of $\tau_m = 200$ ms is shown in Figure 1. There are two different kinds of off-diagonal peaks in the spectrum. One corresponds to the positive cross-peaks between protons of the same type on different ligands (inter-ligand peaks) and the other corresponds to the negative signals between protons of different type on the same ligand (intra-ligand peaks). While the former are indicative of the ligand exchange and the latter are caused by the nuclear Overhauser effect and are not of interest in the present context. By comparing the intensity of the inter-ligand peaks (H2 and H3, as they are better resolved compared to H4) with the peaks on the diagonal, we can get a measure of the ligand-exchange time-scale. This experiment was carried out at various temperatures (310, 300 and 283 K), to study the kinetics of ligand exchange. Under the conditions of Figure 1, the exchange is nearly complete, whereas at lower temperatures, the exchange was found to be much slower, reaching less than 10% and 50% for 283 and 300 K, respectively (at a mixing time of $\tau_m = 200$ ms).

No change in the relative cross-peak intensities was found upon changing the Alq_3 concentration from 13 to 6.5 mg/ml at a temperature of 300 K, which demonstrates that the exchange process follows first-order kinetics.

The observed data is consistent with a simple first-order kinetic model for the exchange mechanism, which involves breaking of the Al–N bond, creating a ligand that is free to rotate around the Al–O bond. It can reconnect either in the same orientation or rotate by 180° after overcoming a rotational energy barrier.

Due to the three-fold axis of symmetry, all three ligands in the facial isomer are identical. Flipping any of the ligands of the facial isomer converts the molecule to the meridianal form. Flipping of two out of the three ligands in the meridianal isomer, leads back to the meridianal isomer, with the ligand identities exchanged, as illustrated in Figure 3, whereas flipping the third one produces the facial isomer equalizing the three ligands.

The complete exchange model can therefore be formulated in terms of four independent reactions:

$$\begin{aligned} \mathrm{ABC} &\xrightarrow{k_1} \mathrm{ACB} \\ \mathrm{ABC} &\xrightarrow{k_2} \mathrm{BAC} \\ \mathrm{ABC} &\xrightarrow{k_3} \mathrm{FFF} \\ \mathrm{FFF} &\xrightarrow{k_4} \mathrm{ABC, ACB}\ldots, \end{aligned} \tag{1a}$$

where ABC *etc.* stands for different permutations of the meridianal and FFF for the facial isomer.

The integrated peak intensities of the H2 and the H3 protons as a function of mixing time τ_m at three different temperatures are shown in Figure 2. The symbols represent experimental values; the lines indicate the best fit of the data according to the above first-order kinetic model. Values for the reaction rates k_1, k_2, and k_3 have been obtained by least squares fitting of the above model to the experimental data, and are given in Table 1. All reaction rates are very sensitive to temperature, changing by up to a factor of 50 as the temperature is raised from 283 to 310 K.

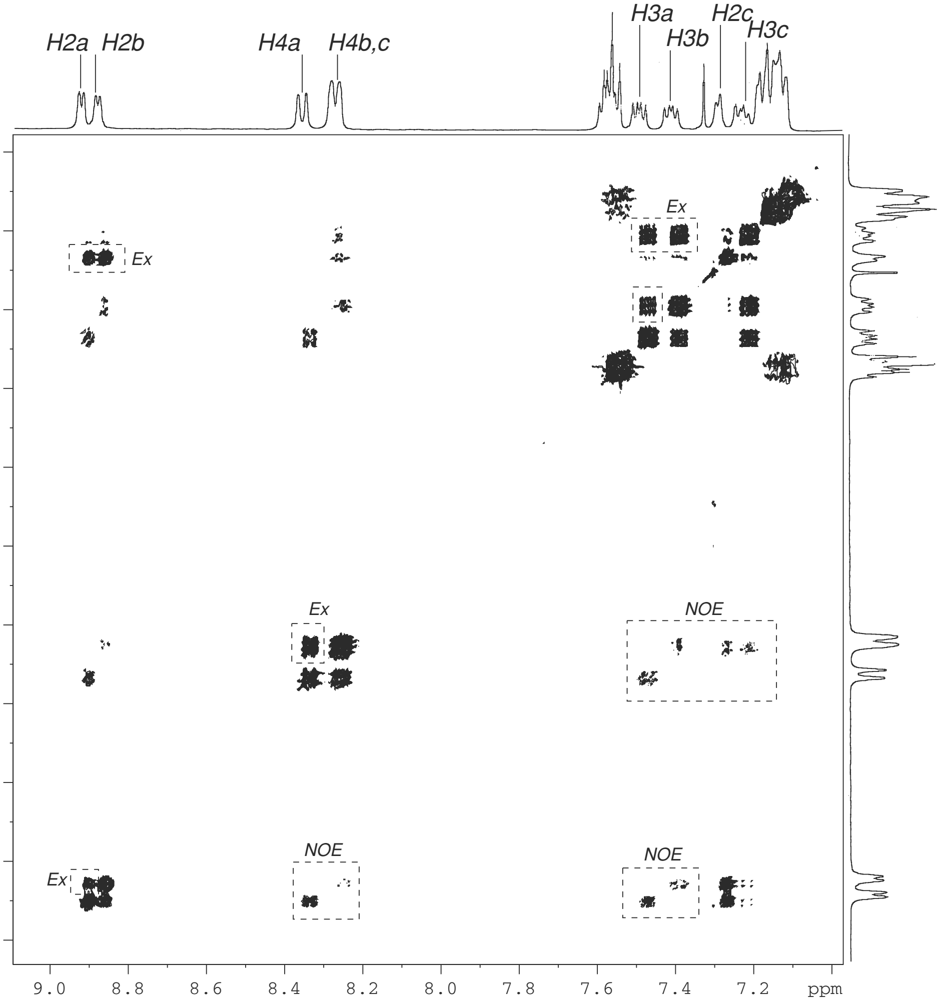

Fig. 1. Two-dimensional exchange NMR spectrum of Alq$_3$ in CDCl$_3$ solution at 300 K and a mixing time of $\tau_m = 200$ ms. Cross-peaks of two different types appear: exchange peaks appear with positive sign between corresponding protons on different ligands (Ex), whereas NOE peaks between different protons on the same ligand appear with negative sign (NOE).

As the rate constants have been determined at different temperatures, it is possible to estimate the activation parameters following Eyring's law

$$k = \frac{k_b T}{h} \exp \frac{\Delta S^{\ddagger}}{k_b} \exp - \frac{\Delta H^{\ddagger}}{k_b T}, \qquad (2)$$

where $\Delta S^{\ddagger}$ and $\Delta H^{\ddagger}$ represent the activation entropy and enthalpy, and k_b denotes Boltzmann's constant.

The activation parameters determined from the Eyring plot, given in Table 2, are of the order of 90 kJ/mol. Such large values would render ligand exchange in Alq$_3$ an exceedingly slow process at room temperature, if it were not for the large, positive activation entropies Δ S‡. The difference in energy between the meridianal and the facial isomer of Alq$_3$ has been determined by numerical simulation at about 20 kJ/mol [15]. The activation barrier is expected considerably above this value for the proposed reaction mechanism, as it involves the breakage of a coordination bond. The observed activation entropies range from 39 to 122 JK^{-1} mol^{-1}, suggesting a highly disordered transition state, which is again consistent with the proposed mechanism.

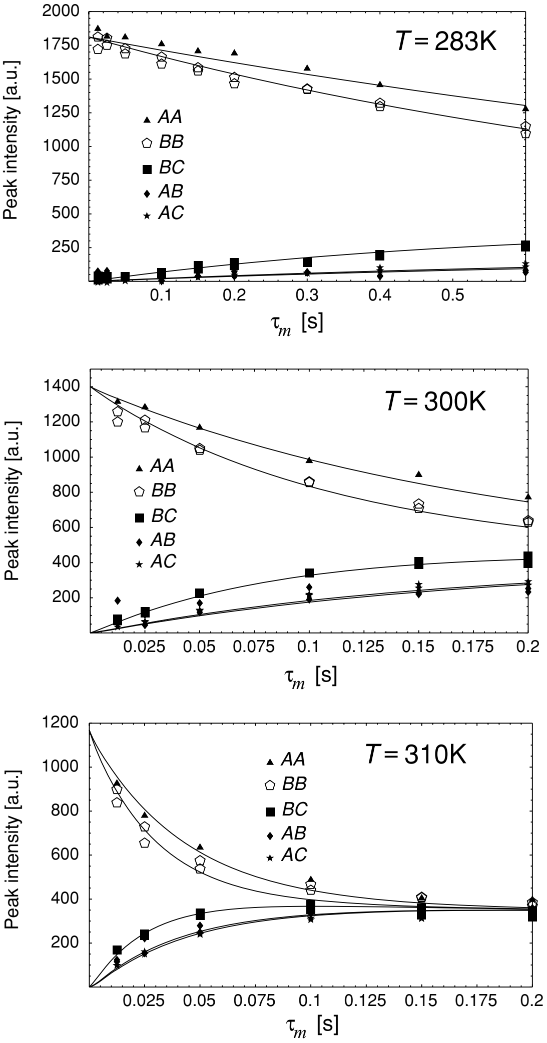

Fig. 2. Integrated peak intensities as a function of mixing time at three different temperatures. Data for both H2 and H3 are shown. The solid lines represent the first-order kinetic model described in the text. Note the different horizontal scale in the top panel ($T = 283$ K)

Table 1: Rate constants determined by least-squares fitting of the experimental H2 and H3 peak intensities. Error margins represent individual 95% confidence intervals.

T(K)	$k_1(s^{-1})$	$k_2(s^{-1})$	$k_3(s^{-1})$
283	0.29 ± 0.75	0.00 ± 1.00	0.39 ± 0.75
300	2.35 ± 0.60	0.14 ± 0.60	4.99 ± 0.60
310	6.68 ± 3.00	0.65 ± 6.00	22.01 ± 3.00

Characterizing the Isomers of Alq_3

^{27}Al, with a spin of $I = 5/2$, is the only stable isotope of aluminum. In most solids, the central magnetic transition of ^{27}Al is easily observed by NMR spectroscopy under MAS. As is common for half-integer nuclei, even though the quadrupolar interaction does not affect the frequency of the central transition within first-order perturbation theory, it causes a noticeable second-order broadening of the resulting line shape. This broadening is reduced, but not completely removed by magic angle spinning.

The quadrupolar coupling is due to the interaction of the nuclear electric quadrupole moment with the gradient of the electric field $\mathbf{V} = \nabla\mathbf{E}$, where $\mathbf{E}$ is the electric field caused by all charges in the system *except* the nucleus. In its principal axes frame (PAS), the EFG can be characterized in terms of the anisotropy δ and the asymmetry η, where $\delta = V_{zz}^{\mathrm{PAS}}$ and $\eta = (V_{yy}^{\mathrm{PAS}} - V_{xx}^{\mathrm{PAS}})/\delta$

The shape of the central line reflects both the quadrupolar interaction and the anisotropic chemical shift. Under MAS, the chemical shift anisotropy is averaged to zero, whereas the second-order quadrupolar coupling is only partly averaged. This leads to a narrowed powder pattern with a width controlled by the quadrupolar anisotropy (δ) and the Larmor frequency, and with a shape characteristic of the quadrupolar asymmetry (η). The shape of the central spectral line under MAS can therefore be used to characterize the EFG in crystalline polymorphs of Alq_3 or its distribution in amorphous Alq_3 deposits.

The values of δ and η are expected to substantially vary between the facial and the meridianal isomer. In the meridianal isomer, the three oxygen and the aluminum atoms lie approximately in a plane. Therefore, the EFG tensor at the aluminum site has to be approximately planar, leading to the expectation $\eta \approx 1$. In the facial isomer, due to the threefold symmetry, EFG tensor at the aluminum atom would be uniaxial with the expected value for $\eta = 0$.

Table 2: Activation parameters obtained from Eyring analysis of the rate constants given in Table 1. Standard errors of regression are indicated.

	k_1	k_2	k_3
$\Delta H^{\ddagger}$/(kJ/mol)	83.0 ± 1.7	95.0 ± 7.0	106.0 ± 2.3
$\Delta S^{\ddagger}$/(J/molK)	38.7 ± 5.9	56.8 ± 23.6	122.3 ± 7.0

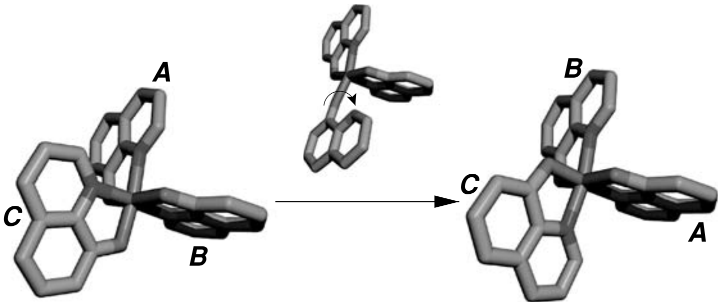

Fig. 3. Schematic representation of the elementary mechanism of exchange that forms the basis of the first-order kinetic model. Breaking the N–Al bond of the C-ligand isomer-Alq_3 allows it to rotate by 180° about the Al–O bond. This rotation leads to an interchange of A and B, whereas the rotating ligand C retains its identity. (See also Plate 121 on page XVII in the Color Plate Section.)

One-dimensional ^{27}Al MAS spectra of three solid modifications of Alq_3 are given in Figure 4. The α and δ polymorphs were obtained by train sublimation [21]. A highly disordered form of Alq_3 was also obtained by depositing the Alq_3 onto a cold substrate from the vapor phase at a very high rate.

The line shapes obtained from the α and δ phases closely correspond to theoretical powder patterns with values of $\eta = 1$ and $\eta = 0$, respectively. This result, therefore, provides a conclusive proof for the hypothesis that the recently discovered delta polymorph indeed does consist exclusively of the facial isomer.

By contrast, the spectrum obtained from the amorphous sample cannot be represented by a single set of (δ, η) values. Rather, the broadening reflects structural disorder in the amorphous packing. This observation has led us to systematically investigate amorphous Alq_3 deposits obtained at different vapor-deposition rates.

The NMR spectrum of the disordered Alq_3 phase shows that the line shape is much more rounded when compared to either of the crystalline phases. The broadening of the spectrum has been identified due to the inhomogeneity of the sample. This shows that in the rapidly deposited material, there is structural disorder at the molecular level.

Variable Deposition Rate Studies

It is known that varying the rate of thermal deposition of organic materials can influence the quality of the film deposited and thus influence the device performance [25]. This has been attributed to the homogeneity and defect density of the films. Slower evaporation rates are expected to produce films with lower defect density and higher homogeneity. These factors are in

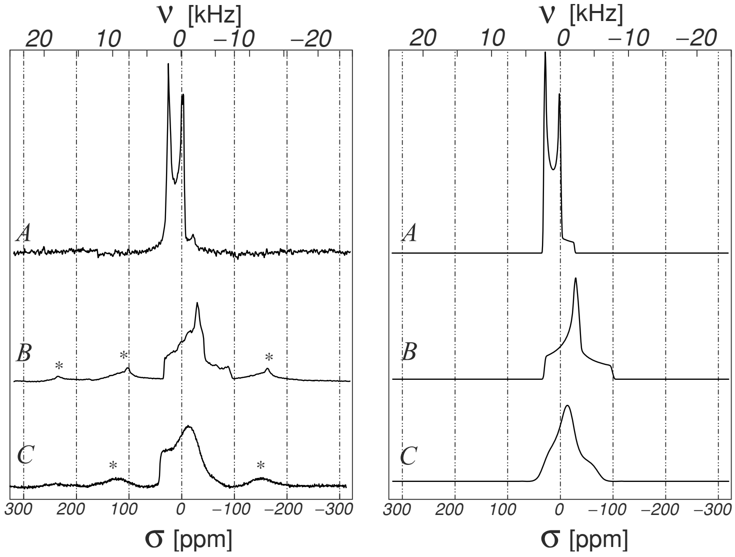

Fig. 4. One-dimensional ^{27}Al spectra under magic angle spinning of different modifications of solid Alq_3 at a field strength of $B_0 = 7.05$ T. Left: Experimental data; Right: Simulations with best-fit values for δ and η. (A) δ-Alq_3; (B) α-Alq_3; (C) dis-Alq_3 (disordered phase obtained by rapid vapor deposition onto a cold substrate, cf. text). The MAS speed was 10.1 kHz in all cases. All spectra were recorded under identical conditions. Spinning side bands are indicated by asterisks.

turn believed to affect carrier mobility of the resulting devices[25].

However, a complete understanding of the relation between the morphology of Alq$_3$ and the device performance has not been achieved yet. One obstacle in establishing this relationship lies the difficulty to characterize the molecular structure of such amorphous films. Due to the absence of long-range order, X-ray diffraction (XRD) yields only very little information. By contrast, our results show that considerable detail on the structural disorder at the molecular level can be extracted from the ^{27}Al MAS line-shape.

Samples for XRD and NMR were prepared by thermal evaporation of train sublimed Alq$_3$ in an Auto 306 Edwards vacuum coater at a pressure of 2.6 mPa. For the NMR measurement, films of 1 μm thickness of Alq$_3$ were deposited on glass substrates kept at room temperature with film growth rates of 0.03, 0.1 and 1 nm/s. At the same time, OLED devices were prepared at the same deposition rates.

The X-ray scattering patterns (not shown) consist of a single, very broad feature centered at $2\theta = 10$. There is little variation between the films obtained at 0.04 and 0.3 nm/s, while the 1 nm/s, film merely exhibits a slightly broader diffraction pattern.

1D ^{27}Al NMR spectra under MAS of the Alq$_3$ films obtained at different evaporation rates are shown in Figure 4. In contrast to the XRD patterns, the ^{27}Al spectra show clear differences. At slower evaporation rates, sharper features appear in the NMR spectra, indicative of a lesser degree of structural disorder.

The line shapes obtained at different deposition rates cannot be fitted using a single set of values of anisotropy (δ) and asymmetry (η) of the EFG tensor. Neither they can be fitted by combining the spectra obtained for the facial and meridianal isomer in different ratios. It must therefore be concluded that the amorphous packing leads to molecular distortions of Alq$_3$and a corresponding distribution of EFG tensors, which is reflected in the NMR line-shape.

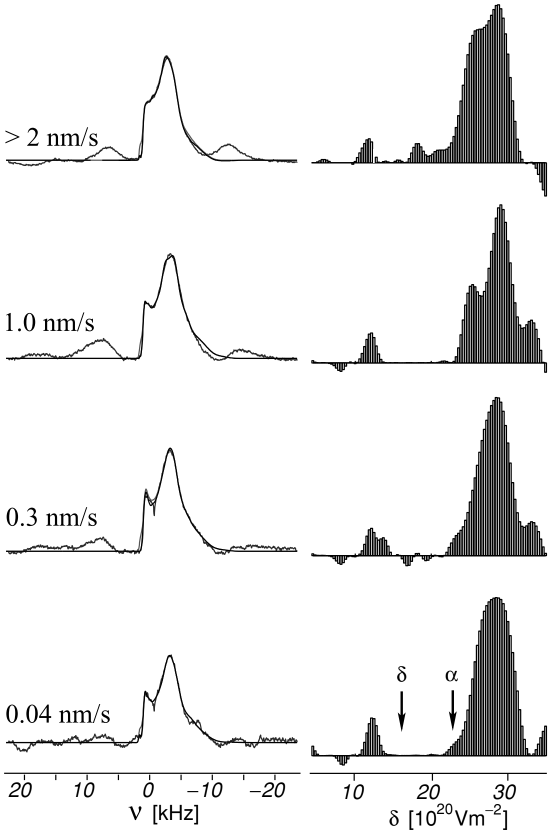

Fig. 5. COF fits of ^{27}Al MAS of amorphous Alq$_3$ obtained at different deposition rates. The insets show the distribution of the anisotropy parameter (δ) of the EFG tensor. The asymmetry parameter (η) is constant in all the fits.

Distributions of delta values were obtained from the measured spectra using the conjugate orthogonal function (COF) method [31]. The distribution of the anisotropy (δ) parameter was extracted assuming a fixed value of $\eta = 0.9$. In principle, a combined distribution $P(\delta,\eta)$ could be determined from the measured spectra. However, the COF analysis showed that the sensitivity and resolution of the current spectroscopic method are not sufficient for this. The COF fits for the various deposition rates are given in Figure 5. The resulting distribution of the quadrupolar anisotropy are bimodal, with a larger primary peak, and a much smaller secondary feature that appears at a smaller value of δ. There is a consistent shift in the position of the major peak to higher δ values with decreasing deposition rate. At the same time, the major peak narrows, indicating less disorder in the more slowly deposited samples. The bimodal distribution suggests the presence of two distinct conformations of the Alq$_3$ molecule. It is tempting to assign the small peak at a lower δ to the facial isomer, which exhibits a smaller EFG anisotropy than the meridianal form also in crystalline forms of Alq$_3$. This would allow us to estimate the content of facial isomer in the amorphous samples at $8\% \pm 4\%$. However, a more sensitive NMR technique, such as variable angle correlation, is necessary to confirm this. Such experiments are currently underway in our laboratory.

The observed dependence of the molecular order on the deposition rate correlates with changes in the charge transport properties. Figure 6 shows the variation of electroluminescence quantum efficiency with the current density of OLED devices prepared at different deposition rates. There is a significant difference in the performance

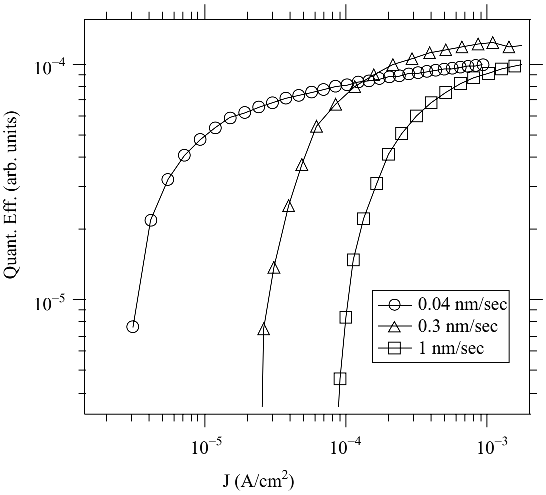

Fig. 6. Quantum Efficiency of the devices obtained by different thermal deposition rates(cf. text).

of the devices prepared at various evaporation rates. This must be due to structural changes at the molecular level, techniques such as XRD fails to pick up, in contrast to ^{27}Al NMR spectroscopy.

Conclusions

The kinetics of exchange between the inequivalent ligands in the meridianal isomer of Alq$_3$ have been studied at different temperatures by 2D exchange proton NMR spectroscopy. The ligands were found to exchange on a time scale of about 5 s^{-1} at room temperature, and the exchange pattern can be explained using a simple first-order mechanism based on 180° flips of the ligands. Using ^{27}Al solid-state NMR, it was found that the α polymorph consists of the meridianal isomer and the δ polymorph consists of the facial isomer. 1D ^{27}Al MAS NMR spectra of amorphous Alq$_3$ films obtained at different deposition rates have been studied. Our results show that ^{27}Al solid state NMR is a powerful tool to study the structure and morphology of Alq$_3$-based devices, capable of quantifying the molecular disorder in amorphous Alq$_3$ deposits.

Solid State NMR of Xerogels

J.L. Yarger,[1] D.A. Buttry[2] G.P. Holland[1]
[1] *Department of Chemistry and Biochemistry, Arizona State University, Tempe, AZ 85287-1604, USA*
[2] *Department of Chemistry, University of Wyoming, and Laramie, WY 82071, USA*

Xerogels, aerogels and other nanoporous solids are an important class of materials in electrochemical and catalytic process design. The preparation of these materials by sol–gel processing has become an important field in materials science [1]. In hydrolytic processes, the texture and structure of sol–gel-based materials largely depend on synthetic parameters, such as (i) solvent, (ii) temperature, (iii) monomer to water ratio, etc. Considerable work has been done to identify the relevant synthetic parameters in order to control the surface and porosity of xerogels (and aerogels). NMR spectroscopy has been extensively used to investigate the effect of these parameters in the sols, prior to gelation, or in the xerogels, after aging and drying [2–5].

Xerogels (*xero* means dry) are derived from sol–gel precursors by evaporative drying, while aerogels are supercritically (or hypercritically) dried. Both of these sol–gel-based materials typically have high porosity, low density, and therefore, high surface areas. Intercalation into xerogels is attractive, not only because of the high surface area, but also because of the small distances in the solid that must be penetrated by the guest ions [6]. Again, NMR spectroscopy has played a crucial role in structural and surface elucidation of xerogel-based intercalation materials as well as elucidation of transport properties and local environments of the guest ions or material [7,8].

While much of the NMR characterization of xerogels has been devoted to silicate based materials [9–12], we will focus our examples on the vanadate xerogel system [13–17]. We will use our NMR studies of lithium intercalated V_2O_5 xerogels as an extended example of several various solid-state NMR techniques that can be used to help elucidate the structure and dynamics of intercalated xerogel materials [18,19]. Because most of our NMR will focus on observation of the intercalating ions, the techniques presented are broadly applicable to other porous xerogel materials. Characterization of the host material is dictated strongly by the type of NMR nuclei present in specific xerogels. Hence, we will not focus on NMR characterization of the host xerogel, but rather the guest ions.

Vanadium pentoxide xerogels have attracted considerable attention as a next generation cathode for rechargeable lithium batteries [20,21]. NMR studies of vanadium pentoxide xerogels serve as an excellent example of the need for high resolution magic angle spinning (MAS) techniques to properly study such materials. Figure 1 (*left*) shows static ^{7}Li NMR spectra a several V_2O_5 samples prepared at different levels of lithiation. One can clearly see that as lithiation (i.e. reduction of vanadium (V) centers to vanadium (IV)) proceeds, the major resonance broadens and shifts. The peak asymmetry reveals that there may be more than one resonance, meaning that there may be more than one type of site for Li^+ in this high surface area material. However, the static spectrum offers limited possibility of learning details about these various lithium environments. In contrast, Figure 1 (*right*) shows a ^{7}Li MAS NMR spectra the same sample. In these spectra, one clearly resolves two sites. The sharper resonance corresponds to Li^+ at interfacial, ion-exchange sites and the broader resonance corresponds to Li^+ inserted within the sheets of the V_2O_5 layered lattice. In the context of battery materials, the availability of interfacial sites greatly increases the power density for a given material because of rapid and facile Li^+ access to those sites. Hence, high-resolution ^{7}Li solid-state NMR provides an excellent probe for testing the potential of new intercalation materials for the next generation of lithium battery cathodes.

In addition to identification and quantitation of Li^+ binding sites in such materials, solid-state techniques also provide information on dynamics, and, indirectly, on more subtle structural questions. For example, the T_1 (spin-lattice) relaxation time provides information on loss of NMR excitation energy into the surrounding material. For the case of lithiated V_2O_5 xerogels, we found that T_1 for the two sites described above was dominated by interactions between the ^{7}Li nuclear spins and nearby unpaired electrons at V(IV) sites (polaron hopping). Further, it was determined that the T_1 relaxation time for the Li^+ ions inserted within the lattice was substantially shorter than for those at the interfacial sites. This type of information reveals both the extent to which Li^+ interacts with electrons (polarons) within the material and provides information on the spatial relationship between Li^+ and the electron (i.e. the site geometry). In preliminary work, we have modeled these data based on the through-space coupling between unpaired electrons at V(IV) sites and Li^+ ions to determine the sites for the inserted Li^+.

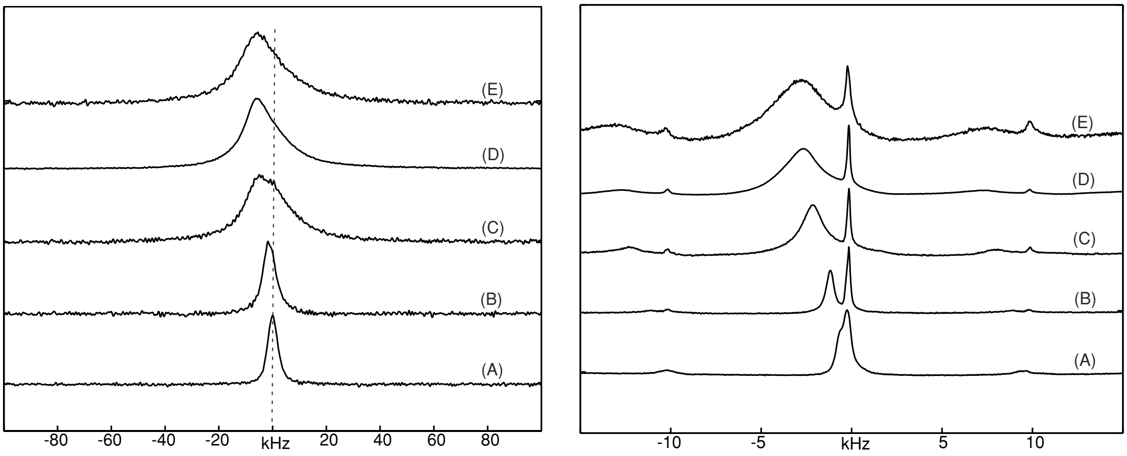

Fig. 1. Room temperature ^{7}Li static (left) and magic angle spinning (right). NMR spectra of lithium intercalated $V_2O_5 * nH_2O$ xerogel. The electrochemically lithiated $Li_xV_2O_5 * nH_2O$ xerogel, where x is 0.03 (A), 0.17 (B), 0.55 (C), 0.84 (D) and 0.98 (E). Spectra were collected on a 400 MHz NMR system with 4 mm MAS probe ($\omega_r = 10$ kHz).

A second issue of critical importance for cathode material design optimization relates to the interplay between ion motion and electron motion and how these depend on their relative locations. Figure 2 shows an example of how electron–nuclear dipole coupling can influence the T_1 relaxation time in lithiated vanadium pentoxide xerogels, $Li_xV_2O_5$. It is widely thought that the motion of Li^+ through a cathode material is often the rate-limiting process that controls power density. The NMR results associated with Figure 2 demonstrate a type of charge pinning in Li^+ insertion materials. This has also been observed in lithium vanadium phosphate cathode material, where it was shown that the extra unpaired electrons were ordered within the lattice and that the charge compensating Li^+ ions were pinned to this ordered unpaired electron sublattice [22]. This suggests that electron-ion pinning may be important in terms of understanding charge transport in such systems.

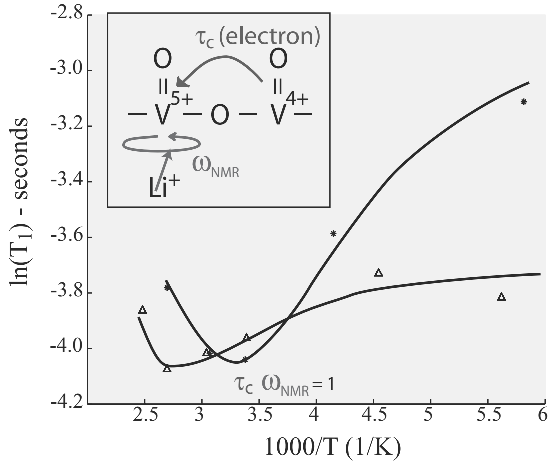

Fig. 2. The natural logarithm of T_1 versus inverse temperature for $x = 0.03$ (△) and $x = 0.17$ (●) $Li_xV_2O_5{\cdot}0.5H_2O$ xerogels. The solid lines represent the best spline fits to the experimental data and are included as a guide to the eye. The ^{7}Li static NMR T_1 was determined from a standard population inversion experiment ($\pi - \frac{\pi}{2}$). All measurements were performed on a 400 MHz NMR system ($\omega_{Li} = 155$ MHz).

Ionic mobility and binding in xerogel materials can further be explored to monitor ion-exchange processes. An example of this is displayed in Figure 3. In the ^{7}Li MAS NMR spectra of electrochemically lithiated V_2O_5 xerogels it was postulated that peak *A* represented interfacial, ion-exchangeable environments, while peak *B* corresponded to Li^+ intercalation sites. This was verified by exposing $Li_{0.2}V_2O_5$ xerogel to a $NaClO_4$ electrolyte solution, and monitoring the ^{7}Li MAS NMR response as a function of exposure time. These results provide strong evidence that peak *A* originates from an intrinsic ion-exchange site at the xerogel interface as it rapidly decays when the xerogel is exposed to Na^+ counter ions. This demonstrates that simple solid-state NMR spectroscopy can be effectively employed to follow charge compensation at surfaces in nanoporous solids like xerogels and further, that these types of environments can be distinguished from interlamellar intercalation sites in these materials.

Considerable effort has been made towards increasing the conductive properties in V_2O_5 xerogel materials by incorporating a conductive polymer within the xerogel matrix. It was shown with solid-state NMR that similar

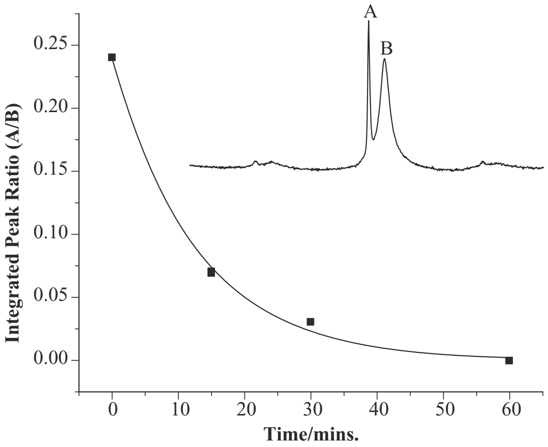

Fig. 3. Time dependence of ion-exchange in $Li_{0.2}V_2O_5$ xerogel exposed to 1 M $NaClO_4$ in propylene carbonate plotted as the integrated peak ratio ($\frac{A}{B}$) as a function of exposure time in minutes. Peaks *A* and *B* correspond to ion-exchangeable (interfacial) and intercalated (interlamellar) lithium sites, respectively.

ion-exchange processes are important in understanding how these V_2O_5 nanocomposites form and function. Two types of lithiated V_2O_5 nanocomposites containing polyaniline (PANI) and poly(aniline *N*-propane sulfonic acid) (PSPAN) have been studied with ^{7}Li MAS NMR [19]. In the ^{7}Li MAS spectra of the PANI/V_2O_5 nanocomposite essentially no ion-exchange site was observed, while the PSPAN/V_2O_5 composite displayed a significant ion-exchangeable component. PANI is cationic causing it to function as an anion exchange material. Therefore, the lack of Li^+ present in ion-exchange sites is interpreted to result due to PANI interacting with these sites during the synthetic process. In contrast, a significant ion-exchange resonance was observed in the PSPAN/V_2O_5 nanocomposite. This was attributed to the fact that PSPAN is a self-doped conducting polymer. It possesses pendent anionic groups that can inherently provide charge compensation during doping of the polyaniline-like groups in the main chains. The ^{7}Li NMR results of these composite materials not only provide information regarding the local Li environment in the material, but also indirectly provide some insight into how the conductive polymer and V_2O_5 xerogel host interact during the sol–gel synthetic process.

For quadrupolar nuclei ($I > \frac{1}{2}$), the quadrupole coupling constant and the asymmetry parameter carry valuable information about the nature of anisotropic interactions [23]. However, in the static and MAS ^{7}Li NMR ($I = \frac{3}{2}$) spectra of $Li_xV_2O_5$ xerogel the quadrupolar effects are masked by the paramagnetic broadening, especially at high V^{4+} concentrations (large Li^+ loadings). Two-dimensional separation techniques have been employed in solid-state NMR spectroscopy to separate competing interactions, such as, dipolar and chemical shift anisotropy interactions [24]. In our case, we use a 2D spin-echo experiment or a three-pulse sequence to separate out the contribution from quadrupolar and paramagnetic interactions of lithium-7 ($I = \frac{3}{2}$) in $Li_xV_2O_5$ xerogel. The 2D contour plot, together with the F_1 and F_2 projections, is shown in Figure 4. The two frequency dimensions are

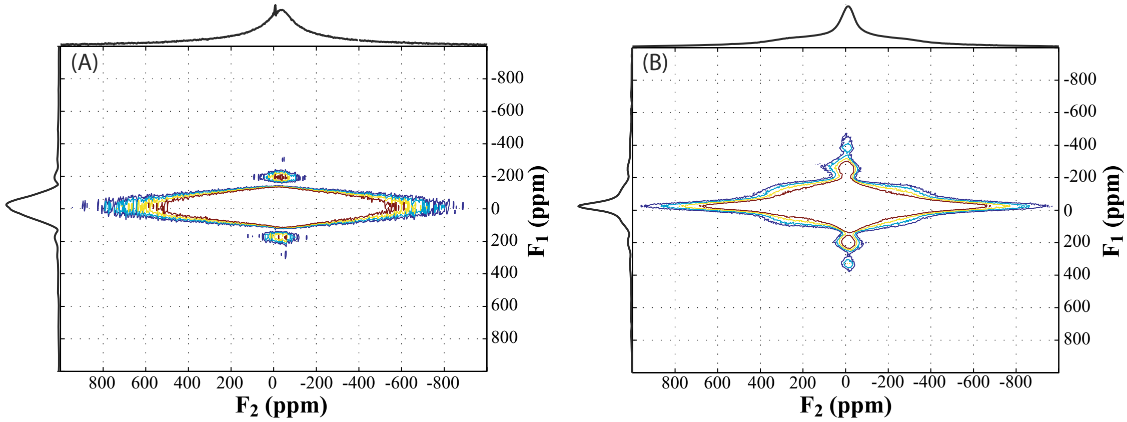

Fig. 4. ^{7}Li two-dimensional static spin-echo NMR spectrum of (A) LiV_2O_5 xerogel ($C_Q = 90$ kHz) and (B) γ-LiV_2O_5 crystalline material ($C_Q = 121$ kHz). F_2 dimension displays static spectrum affected by both quadrupolar and paramagnetic interaction. This method eliminates the paramagnetic interaction in the F_1 dimension allowing a model-free extraction of the ^{7}Li quadrupole coupling constant (C_Q) in this dimension.

asymmetrically correlated with respect to the diagonal. This is caused by the influence of the Li^+–V^{4+} paramagnetic dipolar interactions. From the resolvable satellite transitions ($\pm\frac{1}{2} \Leftrightarrow \pm\frac{3}{2}$) we can identify the paramagnetic frequency shift and the quadrupole coupling constant (C_Q).

The influence of paramagnetic dipolar interaction on the quadrupolar broadened ^{7}Li NMR spectrum of LiV_2O_5 materials is shown in Figure 4. The ^{7}Li quadrupole coupling constant was determined to be $C_Q = 90$ and 121 kHz for LiV_2O_5 xerogel and γ-LiV_2O_5 crystalline material, respectively. It is surprising to find that C_Q is smaller for the disordered xerogel, when compared to the ordered crystalline material. This indicates that though the host material is disordered, the lithium ions are in an ordered high-symmetry environment.

In summary, we show several NMR experiments used to elucidate the structural and dynamic environment of lithium ions in a xerogel host material. By using 2D separation, relaxation, high-resolution MAS, and exchange NMR experiments, we are able to completely characterize the motion and structural environment of lithium ions in vanadate xerogels. All the NMR techniques discussed can be used on any lithium host material.

Solid-State ^{17}O NMR Spectroscopy of High-Pressure Silicates

Sharon E. Ashbrook

Department of Earth Sciences, University of Cambridge, Cambridge CB2 3EQ, UK
Present address: School of Chemistry, University of St. Andrews, St. Andrews, Fife KY16 9ST, UK

Introduction

Oxygen is the second most abundant element on Earth, constituting 30% by weight of the total Earth and 46% by weight of the Earth's crust. Given also the abundance of silicon (15% by weight) and the strength of the Si–O bond, it is perhaps no surprise that the majority of rocks are composed of silicates. The study of these materials, therefore, has an important role in the understanding of both the physical and chemical properties of the Earth. The vertical stratification of the Earth, into a largely aluminosilicate crust, oxide mantle, metallic liquid outer core, and metallic inner core is well known. As shown schematically in Figure 1, the mantle itself may be further subdivided, with the principal component of the upper mantle (down to a depth of 410 km) being olivine, $(Mg_{0.8}Fe_{0.1})_2SiO_4$, an iron-bearing form of forsterite (α-Mg_2SiO_4). A series of phase transitions occurs with increasing depth and pressure, resulting in the formation of the β- and γ-polymorphs of $(Mg,Fe)_2SiO_4$, wadsleyite, and ringwoodite, defining the transition zone [1,2]. At greater pressures still, in the lower mantle, disproportionation occurs forming $(Mg,Fe)SiO_3$ (perovskite) and magnesiowüstite, $(Mg,Fe)O$. The presence of less abundant phases in the mantle, such as garnets, pyroxenes, and high-pressure silica, is also of crucial importance in determining the physical properties of the deep Earth.

This simplified picture disguises a number of important questions within the Earth sciences, however. Although the compositions of the various mantle regions are somewhat constrained, we do not know the exact Si, Mg, Fe, Ca, or Al content of the various phases. We know about the interior of our planet only from secondary evidence, such as seismological measurements, meteorites, rocks brought to the crust from the mantle by geological processes, and the simulation of materials under extreme conditions [3]. In particular, there are many indications from these sources that the inner Earth contains many times the amount of hydrogen (colloquially termed water) than is present in the oceans, with estimates ranging from 200 to 600 ppm [4–7]. The presence of this water is of great interest owing to its influence on a range of physical and chemical properties such as mantle rheology and melting temperatures and pressures. It is now widely believed that nominally anhydrous minerals, such as olivine, wadsleyite, and ringwoodite can incorporate water within their structures [4–7]. The study of the structure and the dynamic behavior of high-pressure solid silicates and, in particular their hydration, is of vital importance.

Oxygen NMR

The study of solid silicates by oxygen NMR would appear to be a natural choice given the presence of oxygen in the minerals present in the crust and mantle and the sensitivity of NMR to the local environment. However, the only NMR active isotope of oxygen, ^{17}O ($I = 5/2$), has both a low sensitivity ($\omega_0/2\pi = 54.2$ MHz at 9.4 T) and an extremely low natural abundance (~0.037%). The additional problem of difficult experimental syntheses for high-pressure silicates, which produce only small amounts of material, results in a considerable sensitivity problem. Although samples may be synthesized with isotopic enrichment, sensitivity remains a crucial factor.

As ^{17}O has spin $I > 1/2$, spectra are broadened by the quadrupolar interaction, often over many megahertz [8]. Magic angle spinning (MAS) is able to remove the quadrupolar interaction to a first-order approximation but is unable to remove fully the second-order quadrupolar interaction [8] and resonances remain broadened. Much attention has been focused on the acquisition of high-resolution NMR spectra for quadrupolar nuclei. One approach is to use composite sample rotation techniques, such as dynamic angle spinning (DAS) [9] and double rotation (DOR) [10], which achieve resolution enhancement though rotation around two different angles. The introduction of the multiple-quantum (MQ) MAS technique [11] in 1995 revolutionized high-resolution NMR of quadrupolar nuclei, and this method has become widespread owing to the ease of its implementation. In 2000, Gan introduced an alternative method for obtaining high-resolution spectra of quadrupolar nuclei, the satellite-transition (ST) MAS experiment [12]. Although slightly more difficult to implement than MQMAS, its high inherent

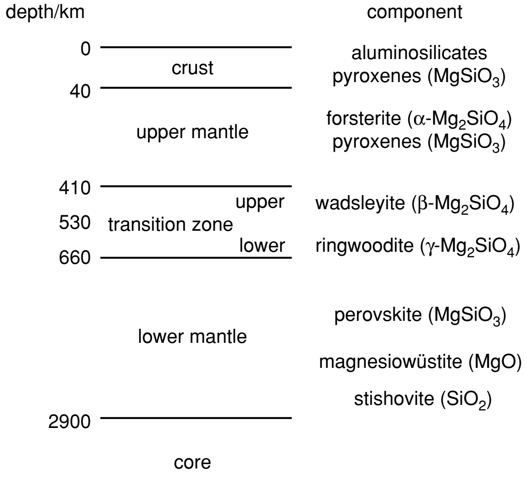

Fig. 1. Schematic diagram of the compositional variation of the Earth.

sensitivity has proved crucial in the study of high-pressure silicate phases, particularly in cases where sample volume is limited.

Despite the problems outlined above ^{17}O NMR has enormous potential in the study of silicate minerals. NMR enables investigation of both the local structure and the dynamic behavior of a system. Both ^{29}Si and ^{1}H NMR have been employed in the study of mantle phases [13–16], but neither can offer the flexibility of ^{17}O NMR. Silicon NMR provides information only on the local Si environment while, on its own, ^{1}H NMR is unable to identify specific O–H pairings, is insensitive to dynamic effects and suffers from problems with a large "background signal." In contrast, ^{17}O NMR (both single and double resonance techniques) provides information on the local O environment, can offer information on specific O–H pairings and often displays a sensitivity to dynamic behavior. Both the ^{17}O quadrupolar and chemical shift interactions are extremely sensitive to changes in the environment on a local scale [17], providing an excellent tool for studying silicates, a group of minerals with wide compositional diversity and structural modifications. Silicate structures tend to be dominated by the SiO_4 tetrahedron. These units can be isolated from each other, and coordinated to other cation polyhedra present in the structure. The nature of the cation has a significant effect upon the Si–O bond length and, hence, the ^{17}O chemical shift. It has been shown for many systems that an increase in ^{17}O chemical shift reflects an increased Si–O bond length. Alternatively, SiO_4 units can be connected to each other by corner sharing, forming Si_2O_7 groups or even long chains. Further polymerization results in silicate sheets and finally three-dimensional silicate frameworks. When corner-sharing tetrahedra are present, at least one oxygen species, denoted a "bridging oxygen," is bonded to two silicons simultaneously. This is reflected in considerable changes in chemical shift and, in particular, in quadrupolar coupling [17]. Bridging oxygen species exhibit C_Q values (~4–6 MHz) that are significantly higher than those for non-bridging species (~2–3.5 MHz). The largest quadrupolar couplings (~6–8 MHz), however, tend to be found for hydroxyl oxygens, providing an excellent opportunity to study hydration.

Sample Preparation

The low natural abundance of ^{17}O (0.037%) necessitates the use of isotopic enrichment in order to obtain good sensitivity. A wide range of enrichment schemes is possible, with both O_2 and H_2O readily available as isotopically enriched starting material. The exact enrichment level employed is usually a compromise between cost and sensitivity. For the high-pressure silicates considered here, the preparation method of choice is usually synthesis from ^{17}O-enriched oxides prepared from H_2O (l), with common enrichment levels between 10 and 75%. The ^{17}O is fixed by reaction of $H_2{}^{17}O$ with reagents such as $SiCl_4$, Mg_3N_2, Ca_3N_2, and AlN liberating a gas (HCl or N_2) and leaving a solid oxide or hydroxide product. These may then be mixed in appropriate stoichiometric amounts to prepare the silicate required. The elements O, Mg, Al, Ca, and Si represent the major components of an Fe-free crust and mantle and allow all major phases to be prepared. Mantle phases may be prepared by simulating the pressure and temperature conditions present in the mantle using either a piston cylinder or a multi-anvil apparatus. Piston cylinder devices produce only relatively moderate pressures (up to 4 GPa, corresponding to a depth of only 120 km) but allow large volumes of sample (~100 mg) to be produced. In comparison, multi-anvil devices allow access to a much greater pressure range (up to 22 GPa, or depths of >660 km) but the volume of material available is much reduced (often only 5–10 mg). Samples are quenched rapidly from the experimental high-pressure and high-temperature conditions as the high-pressure phases are usually kinetically stable at ambient conditions.

MQMAS NMR of Upper Mantle Silicates

Forsterite (or α-Mg_2SiO_4), is the Fe-free form of olivine, the principal component of the Earth's mantle to a depth of ~410 km. The crystal structure of forsterite (*Pbnm*) consists of isolated SiO_4^{4-} units with three distinct oxygen species (O1, O2, and two O3) [18]. Forsterite has become almost a "model" compound for ^{17}O NMR as: (i) isotopically enriched forsterite is relatively easily prepared at ambient pressures in reasonably large quantities [19]; (ii) olivine has a huge importance in the mantle; and

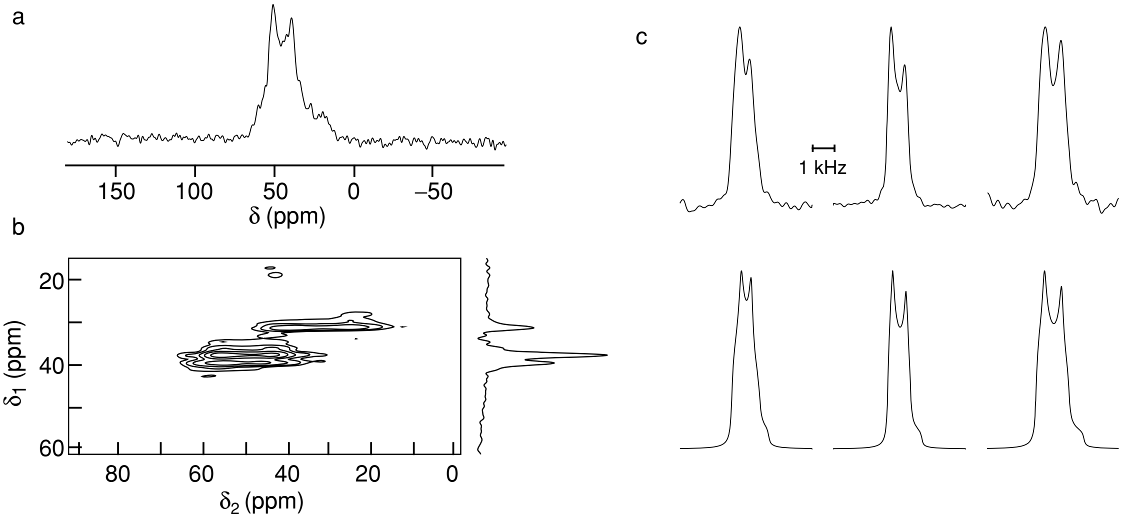

Fig. 2. ^{17}O (54.2 MHz) MAS NMR of 35% isotopically enriched forsterite (α-Mg_2SiO_4). (a) MAS NMR spectrum, (b) two-dimensional triple-quantum MAS NMR spectrum, recorded with a phase-modulated split-t_1 shifted echo sequence, and (c) cross sections parallel to δ_2, along the three second-order broadened ridge lineshapes and corresponding computer fits.

(iii) the non-bridging nature of the oxygen species results in only moderate quadrupolar couplings. As a result, a variety of NMR techniques have been employed in the study of forsterite. The extraction of information from the MAS spectrum alone, however, is hampered by the presence of second-order quadrupolar broadening [20], as shown in Figure 2a. This ^{17}O (54.2 MHz) MAS NMR spectrum of forsterite (enriched to 35% in ^{17}O) reveals a composite lineshape centered at ~50 ppm, with features characteristic of second-order broadening, but resulting from the overlap of three different lineshapes.

In order to obtain accurate chemical shift and quadrupolar information for the three oxygen species spectral resolution must be improved. Both DAS [21] and DOR [22] have been employed to obtain isotropic spectra of forsterite. However, a complete assignment of the ^{17}O high-resolution spectrum was first achieved using MQMAS [19]. Figure 2b shows the two-dimensional ^{17}O triple-quantum MAS NMR spectrum of forsterite (enriched to 35% in ^{17}O), recorded using a phase-modulated split-t_1 shifted echo experiment [23]. The spectrum consists of a series of ridge lineshapes, one for each crystallographically distinct species, lying parallel to the δ_2 axis. The high-resolution or isotropic spectrum, obtained from a projection onto δ_1, reveals three distinct resonances in the ratio 1:2:1. Although MQMAS efficiency varies as a function of the quadrupolar interaction [23], the small differences between the three distinct oxygen species enables the site populations to be determined directly from the relative intensities of the resonances. The position of the center of gravity of each lineshape in the two-dimensional spectrum (δ_1, δ_2) allows the extraction of the isotropic chemical shift, δ_{CS}, and the second-order quadrupolar shift, δ_Q [19]. From δ_Q, the quadrupolar product $P_Q = C_Q(1 + \eta^2/3)^{1/2}$ can be obtained. The individual quadrupolar parameters, the magnitude (C_Q) and asymmetry (η) of the quadrupolar interaction, may be determined from cross sections taken along each ridge, parallel to δ_2. The lineshapes obtained may be fitted using a computer fitting routine to obtain values for C_Q, η, and δ_{CS}, as shown in Figure 2c. The values of the chemical shift and quadrupolar parameters for the oxygen species in forsterite are given in Table 1 [19]. If the relative populations of the sites and the similarity in the coordination environment of O2 and O3 are considered a complete assignment of the resonances is possible, and is also shown in Table 1.

MQMAS has also been employed to study a series of pyroxenes, an important group of rock-forming minerals which occur in nearly all igneous rocks and comprise up to 25% of the upper mantle [24]. Pyroxenes have the general formula $M1M2Si_2O_6$ and consist of infinite chains of corner-sharing SiO_4 tetrahedra. Each tetrahedron contains both bridging and non-bridging oxygen species, providing a more challenging target for ^{17}O NMR. Perhaps the most relevant pyroxene for mantle chemistry is enstatite, $Mg_2Si_2O_6$, of which there are three stable or metastable polymorphs under ambient conditions. Orthoenstatite (*Pbca*) and protoenstatite (*Pbcn*) are orthorhombic [25,26], whilst

clinoenstatite ($P21/c$) is monoclinic [27]. The related mineral diopside, $MgCaSi_2O_6$, is also monoclinic ($C2/c$) [28]. In both orthoenstatite and clinoenstatite there are two types of silicate chains, whilst in protoenstatite and diopside the two chains are related by symmetry reducing the number of distinct O species. The polymorphs may be prepared from ^{17}O-enriched oxides either at ambient pressures or using a piston cylinder apparatus [24].

The ^{17}O MAS NMR spectra of the pyroxene minerals (shown in Figure 3) contain broad and complex resonances centered between 30 and 50 ppm, with little indication of the number and nature of crystallographically distinct oxygen species present [24]. MQMAS yields high-resolution isotropic spectra, as displayed in Figure 3, which reveal the presence of many distinct oxygen species [24]. Orthoenstatite and clinoenstatite exhibit very similar spectra with six distinct species present.

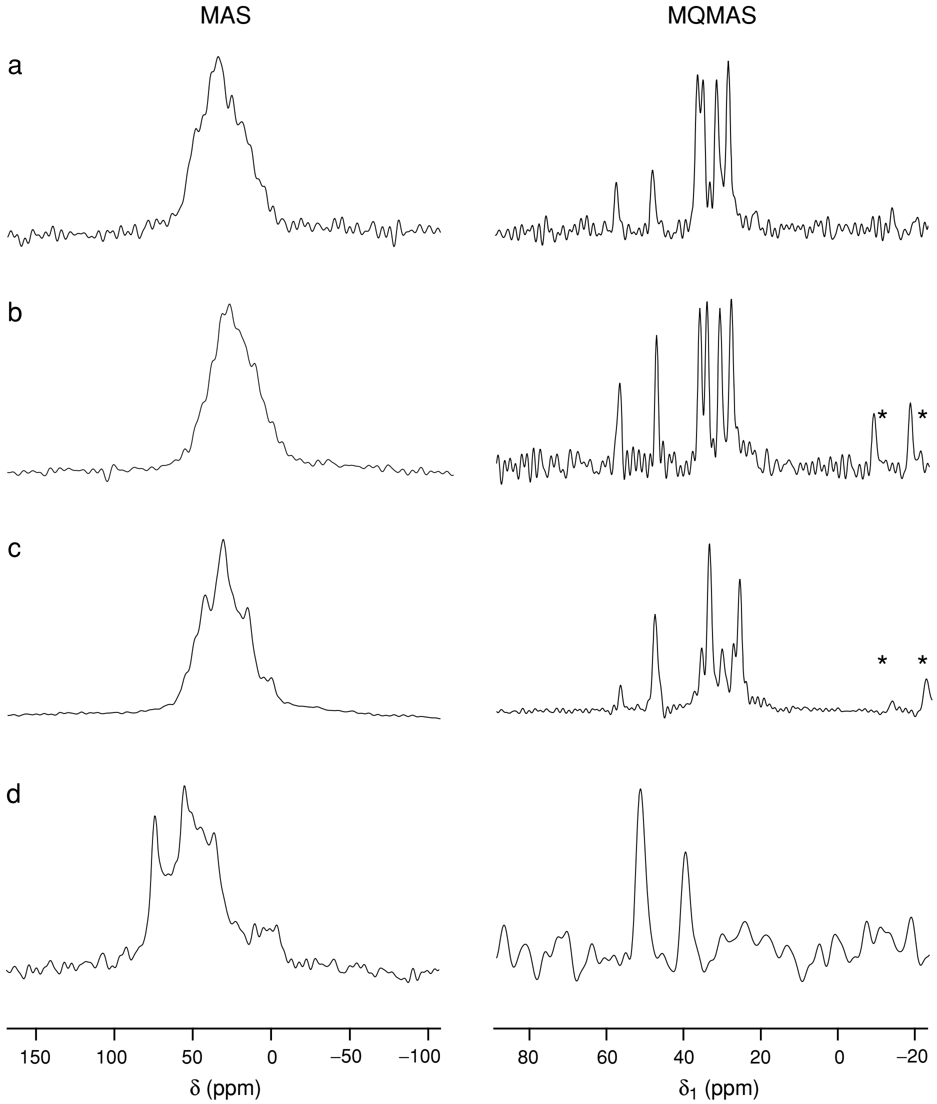

Fig. 3. ^{17}O (54.2 MHz) MAS and isotropic triple-quantum MAS NMR spectra of (a) orthoenstatite ($MgSiO_3$), (b) clinoenstatite ($MgSiO_3$), (c) protoenstatite ($MgSiO_3$), and (d) diopside ($CaMgSi_2O_6$). Nominal levels of isotopic enrichment are (a–c) 35% and (d) 29%.

In each case, four of the resonances possess small C_Q values indicative of non-bridging oxygens, whilst two have the increased chemical shift and quadrupolar interactions characteristic of bridging species. In protoenstatite, owing to the increased symmetry only three resonances are present, one bridging and two non-bridging, although an impurity phase of clinoenstatite is also detected. Diopside also displays three distinct oxygens species, but two are overlapped in the spectrum shown in Figure 3 (recorded at 9.4 T). Measurements at different field strengths allow these species to be separated. The values of the quadrupolar and chemical shift interactions for each species, along with their assignments are given in Table 1 [24]. The different chemical shifts observed in diopside are consistent with deshielding due to the increase in effective cation radius [17,24].

STMAS NMR of Dense Silicate Phases

While α-Mg_2SiO_4 in the form of olivine is the main component of the Earth's upper mantle, the increase in pressure at greater depths results in the formation of the β- and γ-polymorphs, wadsleyite, and ringwoodite. These minerals are thought to be the major constituents of the transition zone (as shown in Figure 1), with the α–β transition responsible for the seismic discontinuity observed at a depth of 410 km and the transition from γ-Mg_2SiO_4 to $MgSiO_3$ (perovskite) responsible for the discontinuity around 660 km [1,2]. The β–γ transition may well contribute to the less pronounced discontinuity around 520 km. These dense phases are of particular interest because of their potential as the repository for the largest reservoir of water in the Earth. Before studies of hydration can be undertaken, however, the anhydrous counterparts must be fully characterized.

Although high-resolution ^{17}O NMR spectra of forsterite were obtained easily using MQMAS [19], the sensitivity of this experiment, particularly at high MAS rates, is not sufficient for the study of wadsleyite and ringwoodite. These phases, found at much greater depths in the Earth, must be synthesized at much greater pressures (16 and 20 GPa) using a multi-anvil press, producing only 5–10 mg of material [29]. Furthermore, sample purity can also be a problem, with pressure or temperature gradients resulting in a mixture of phases, thereby reducing the sensitivity further. Recently, the introduction of the STMAS experiment [12], a method with inherently high sensitivity at both slow and fast MAS rates, has enabled the study of such small amounts of ^{17}O-enriched material on a reasonable timescale. Although of good sensitivity, STMAS does have stringent experimental requirements, such as a stable MAS rate (to within ±2 Hz) and an accurately adjusted spinning angle ($\chi = 54.736^\circ \pm 0.002^\circ$) [12,30].

STMAS has been successfully employed to obtain and assign high-resolution ^{17}O MAS NMR spectra of both wadsleyite and ringwoodite [29,31]. Figure 4a shows a ^{17}O MAS NMR spectrum of ~10 mg of 35% ^{17}O-enriched wadsleyite [29]. The broad complex lineshape results from the overlap of resonances from distinct oxygen species, which are resolved in the STMAS spectrum shown in Figure 4b. In addition to a diagonal resulting from the autocorrelation of the central transition, four ridge lineshapes are observed with relative intensities approximately 1:4:2:1 in order of increasing δ_1. As with MQMAS, the values of C_Q, η, δ_{CS} and P_Q may be extracted from either the position or shape of the ridge lineshapes, and are given in Table 1 [29]. Wadsleyite has a spinelloid structure (*Imma*) and contains Si_2O_7 groups, which results in both bridging (O2) and non-bridging (O3 and O4) oxygens, in addition to an oxygen (O1) coordinated by five Mg [32]. The quadrupolar and chemical shift information extracted from an STMAS spectrum of a sample of ~5 mg of 35% ^{17}O-enriched ringwoodite (with a substantial wadsleyite impurity) are also given in Table 1. Although ringwoodite has a spinel structure (*Fd3m*) with only a single non-bridging oxygen species [33], high-resolution NMR techniques were required to determine the exact nature of the impurity phases [31].

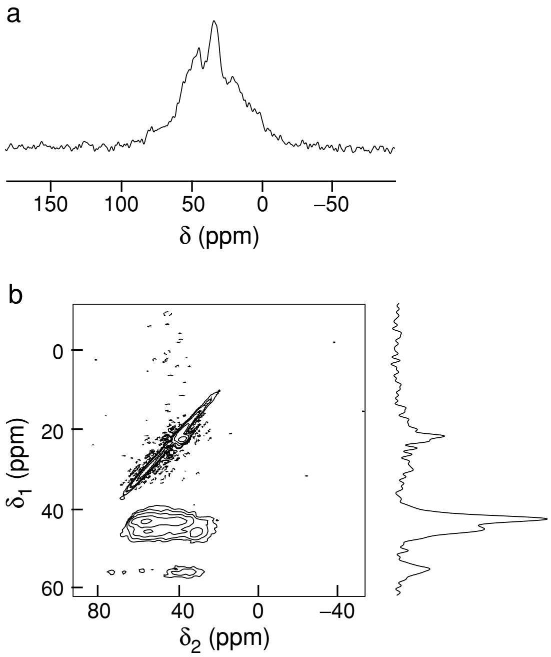

Fig. 4. ^{17}O (54.2 MHz) MAS NMR of ~10 mg of 35% isotopically enriched wadsleyite (β-Mg_2SiO_4). (a) MAS NMR spectrum, (b) two-dimensional STMAS NMR spectrum and corresponding isotropic projection, recorded with a phase-modulated split-t_1 shifted echo sequence.

NMR of Hydrous Magnesium Silicates: Humite Minerals

The suggestion that the mantle contains a large volume of water is supported by the potential of nominally anhydrous minerals, such as olivine and wadsleyite, to incorporate significant amounts of water into their structures [4–7]. The minerals of the hydroxyl-humite group, $n Mg_2SiO_4 \cdot Mg(OH)_2$, have been proposed as possible models of the defect sites accommodating water in olivine [34]. These minerals can be described (rather simplistically) as comprising of n forsterite-like layers alternating with brucite layers, and so may be viewed as hydrated forms of forsterite. Both chondrodite ($n = 2$)

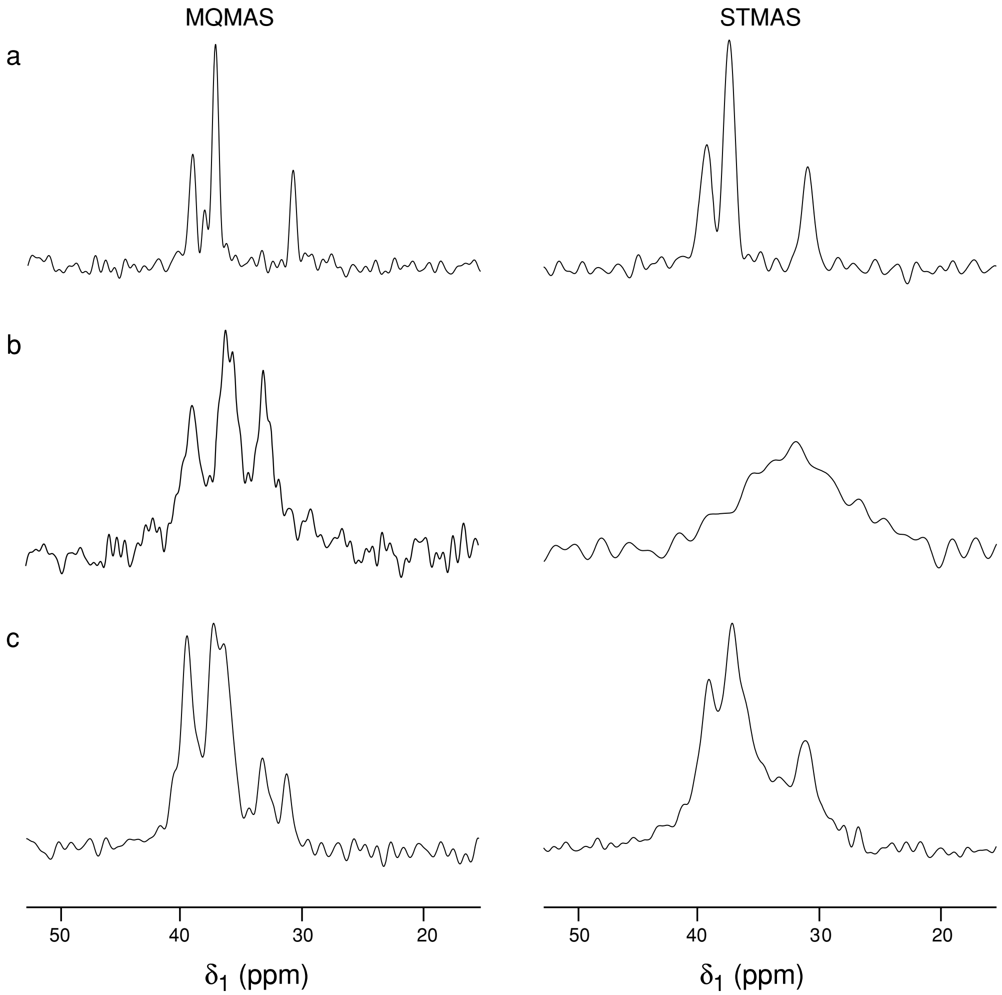

Fig. 5. ^{17}O (54.2 MHz) isotropic triple-quantum MAS and STMAS NMR spectra of (a) forsterite (Mg_2SiO_4), (b) chondrodite ($2Mg_2SiO_4 \cdot Mg(OH)_2$), and (c) clinohumite ($4Mg_2SiO_4 \cdot Mg(OH)_2$). Nominal levels of ^{17}O enrichment were 35% in all cases.

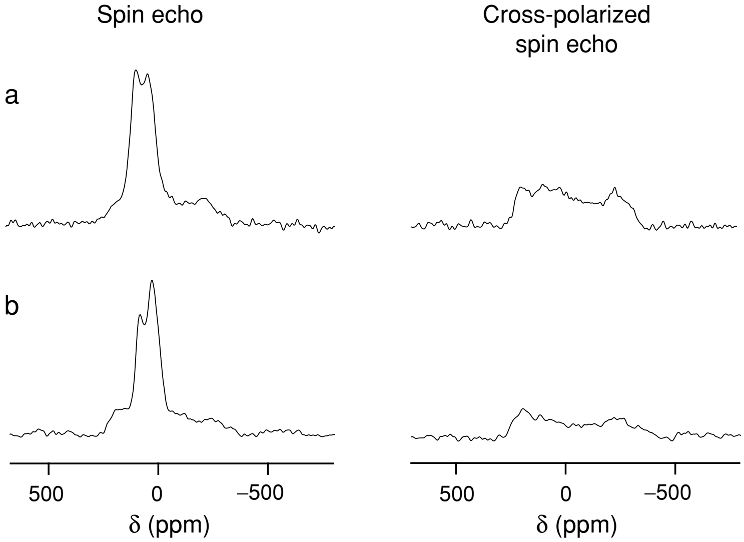
and clinohumite ($n = 4$) are monoclinic with space group $P21/c$, resulting in five (four non-bridging and one hydroxyl) and nine (eight non-bridging and one hydroxyl) distinct oxygen species, respectively [35,36]. Both minerals can be synthesized, isotopically enriched in ^{17}O, at pressures equivalent to the upper mantle using a piston cylinder apparatus [37].

The ^{17}O MAS NMR spectra of chondrodite and clinohumite are both extremely similar to that of forsterite, with a broad complex lineshape centered at ∼50 ppm [37]. Distinct oxygen species my be resolved, however, in MQMAS spectra, as shown in Figure 5, which displays isotropic ^{17}O triple-quantum MAS NMR spectra of 35% isotopically enriched forsterite, chondrodite, and clinohumite [37]. The spectrum of chondrodite is broadly similar to that of forsterite, with a shift of some resonances and the splitting of the central resonance ($\delta_1 =$ 36 ppm) into two as a result of the decrease in symmetry. This latter effect is clearer when a full two-dimensional spectrum is considered. The spectrum of clinohumite contains five peaks and can be clearly seen to resemble the summation of the spectra of forsterite and chondrodite, reflecting the (simplified) description of the crystal structure of clinohumite as layers of chondrodite and forsterite in equal proportion. The relative intensities of the peaks, 1:1:2:2:2, indicate that all eight non-bridging oxygens

Fig. 6. (a) Conventional and (b) cross-polarized ^{17}O (54.2 MHz) spin-echo NMR spectra of static samples of (a) chondrodite and (b) clinohumite.



are observed, but that some are too similar to be resolved at this field strength. A high-resolution ^{17}O triple-quantum MAS NMR spectrum of clinohumite recorded at $B_0 = 16.4$ T was able to resolve seven of the eight distinct species [37], with O3 and O4 still too similar to be distinguished.

Although resolution of the non-bridging oxygen species in clinohumite and chondrodite was achieved with MQMAS, there is little evidence of the hydroxyl species in the brucite-like layer in these spectra. Hydroxyl oxygen species are predicted to possess much larger quadrupolar couplings [17] making their observation non-trivial at moderate B_0 fields, slow MAS rates and low ^1H decoupling strengths. However, the ^{17}O spin-echo NMR spectra of static samples of chondrodite and clinohumite shown in Figure 6 [37], display a composite lineshape with both a narrow feature and a broader component typical of an oxygen species with a much larger quadrupolar interaction. The use of cross-polarization, a technique which edits the NMR spectrum on the basis of spatial proximity to ^1H, retains only this broad species, confirming its assignment as the hydroxyl oxygen. The quadrupolar and chemical shift parameters for this species in both chondrodite and clinohumite, given in Table 1, are very similar to those observed for brucite [37].

Owing to the similarity of the two techniques, the isotropic spectra produced by MQMAS and STMAS are expected to be very similar in nature, and for many crystalline materials this is indeed the case [38]. However, the isotropic ^{17}O STMAS NMR spectra of 35% isotopically enriched forsterite, chondrodite, and clinohumite, shown in Figure 5, do show significant differences from the MQMAS spectra [38]. For forsterite, the two spectra are extremely similar with the small increase in line width in the STMAS spectrum attributed to a very small misset in the magic angle. However, the STMAS spectrum of chondrodite contains a very broad resonance, in contrast to the sharp peaks observed in the MQMAS spectrum. For clinohumite, some of the resonances observed in the MQMAS spectrum remain sharp whilst others appear significantly broadened. Both chondrodite and clinohumite contain a brucite-like layer with two distinct H sites, each of which is half occupied. The large isotropic displacement parameters associated with both sites suggest significant motion of H relative to the other atoms, either vibrational motion within a cavity or even exchange between the sites [39]. This motion of H modulates the electric field gradient experienced by the oxygens and, hence, the ^{17}O quadrupolar interaction. For the central transition (and indeed the multiple-quantum transition employed in MQMAS) this modulation is small. However for the satellite transitions, where a first-order quadrupolar interaction is present, the change in frequency may be significant and a “motional broadening” is observed in STMAS spectra [38]. In chondrodite, all oxygen species are within 3 Å of either H1 or H2, and will all most likely be involved in hydrogen bonding, producing a large effect in the spectrum. In clinohumite, the oxygens in the chondrodite-like layer are also to ^1H and display a significant motional broadening. However, those oxygens in the forsterite-like layer are sufficiently far from ^1H that they remain relatively unaffected by motional processes. It is possible to

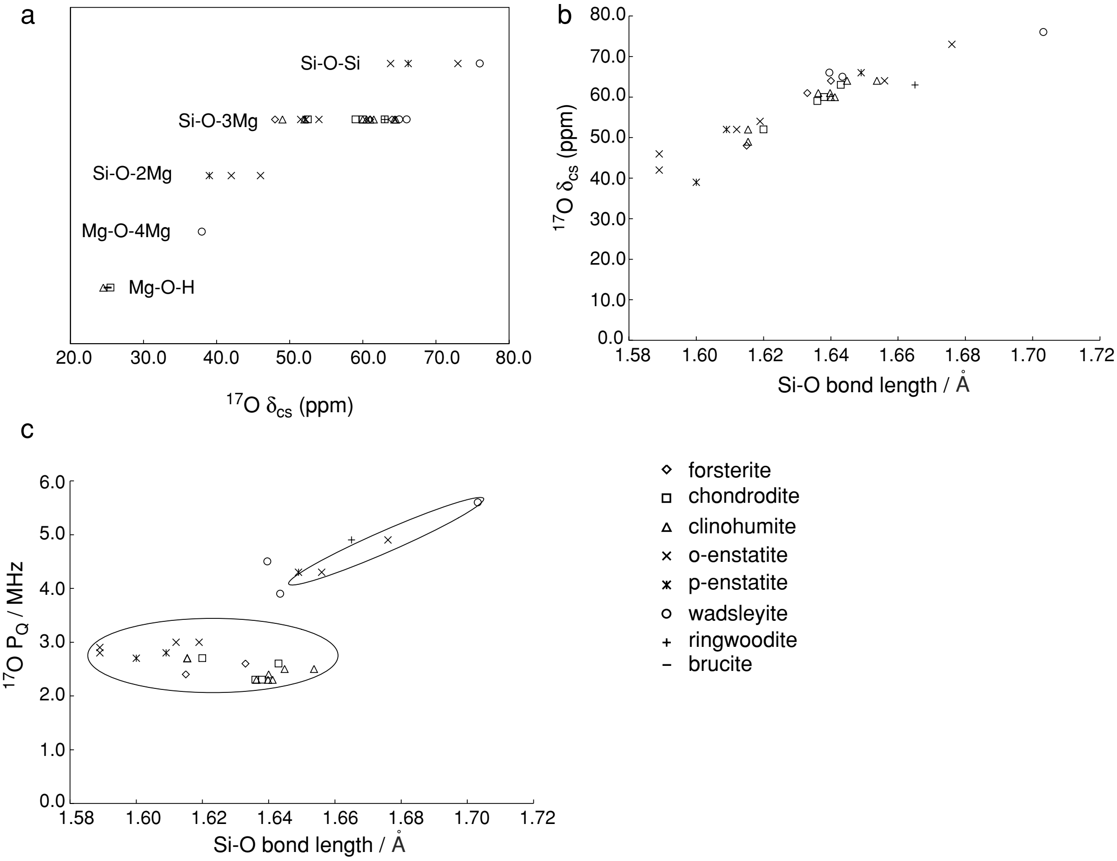


Fig. 7. (a) Variation of the ^{17}O isotropic chemical shift (δ_{CS}) with coordination environment, (b) plot of ^{17}O isotropic chemical shifts (δ_{CS}) against coordination environment, and (c) ^{17}O quadrupolar parameters (P_Q) against average Si–O bond length for a variety of silicate minerals.

observe changes in the line width of the resonances in STMAS spectra of both chondrodite and clinohumite by changing the temperature, confirming the motional origin of the broadening [38].

Discussion and Conclusions

Both MQMAS and STMAS may be employed to obtain isotropic ^{17}O NMR spectra with resolution of distinct oxygen species, and allow extraction of accurate quadrupolar and chemical shift parameters. These values, coupled with a comparison of isotropic spectra between like compounds often allows a complete assignment of the spectrum with reference to the suggested crystal structure. It is then possible to investigate any correlations between the NMR parameters and structural variables such as bond lengths or number and type of coordinating atoms. Figure 7a shows the ranges of the ^{17}O isotopic chemical shift (δ_{CS}) with the local coordination environment in the magnesium silicate minerals considered here. Oxygen species with different environments are reasonably well separated, with bridging species found between 65 and 80 ppm and non-bridging species between 40 and 67 ppm. Those non-bridging species coordinated to 1 Si and 2 Mg are found at significantly lower δ_{CS} than those with 1 Si and 2 Mg. A further decrease in chemical shift is observed for species with no Si bonds, the O coordinated only by 5 Mg atoms in wadsleyite (~38 pm) and Mg–O–H species (~25 ppm). The ^{17}O isotopic chemical shift can be linked directly to changes in the Si–O bond length (the average bond length for bridging oxygens) as shown in Figure 7b. A general positive correlation is observed with an increase in the Si–O bond length resulting in an increase in δ_{CS}. A linear regression analysis yields $\delta_{\mathrm{CS}}/dr_{\mathrm{Si-O}} = +325$ ppm/Å, with a correlation coefficient, R^2, of 0.816. A slightly better fit ($R^2 = 0.822$) can be obtained with a second-order polynomial regression. This increase in chemical shift with Si–O bond length appears general for both bridging and non-bridging oxygens. Figure 7c shows the variation of the ^{17}O quadrupolar parameter, P_{Q}, with Si–O bond length. Unlike the chemical shift, no real correlation is observed and the oxygen species tend to cluster into two distinct groups, non-bridging oxygens between 2 and 3.2 MHz and bridging species between 4 and 6 MHz, in general agreement with literature data for a range of different systems. However, it should be noted that the non-bridging oxygen species in the high-pressure polymorphs of Mg_2SiO_4, wadsleyite, and ringwoodite, show anomalously high P_{Q} values (between 3.8 and 4.8 MHz), much more similar to those expected for bridging species. Work is ongoing both experimentally and through *ab initio* computer simulations in order to gain a deeper understanding of the origin of these effects.

In conclusion, ^{17}O NMR offers great potential for the study of the silicate minerals that make up the Earth's crust and mantle as it is very sensitive to the local structural environment. The low natural abundance of ^{17}O (0.037%) may be overcome through the use of isotopic enrichment, and materials may be synthesized at mantle conditions using either piston cylinder or multi-anvil apparatus. Although the presence of second-order quadrupolar broadening hinders the extraction of information directly from conventional MAS NMR spectra, both MQMAS and STMAS methods can be used to obtain high-resolution spectra where distinct oxygen species are resolved. STMAS is a more sensitive technique and although technically difficult to implement is a vital tool in cases where sensitivity is limited or where only small amounts of material may be available. While removing the anisotropic quadrupolar broadening, both techniques retain the isotropic quadrupolar and chemical shift information enabling, in many cases, the full assignment of the spectra. The correlation of these interactions with local structural parameters, such as bond lengths or coordination environments, will help to provide information in cases where crystal structures are less well known, for example, in the investigation of hydrated minerals. The use of ^{17}O/^{1}H double resonance techniques, such as cross-polarization, are also of significant use in the determination and characterization of hydrated oxygen species. The observation of motional broadening in STMAS spectra offers indications that the combination of both MQMAS and STMAS may be able to provide information on the dynamic behavior of hydrated mineral phases. A combination of ^{17}O NMR methods, therefore, really does seem to offer an ideal opportunity to study mantle silicate minerals and their hydration processes.

Acknowledgments

I would like to thank Dr. Stephen Wimperis (University of Exeter, UK) and Dr. Andrew J. Berry (ANU, Canberra, Australia) who contributed considerably to much of the work described here and to Stefan Steuernagel (Bruker, Karlsruhe, Germany) for access to high-field NMR instruments. I also acknowledge the Royal Society for the award of a Dorothy Hodgkin Fellowship.

The Structure of Oxide Glasses: Insights from ^{17}O NMR

Philip J. Grandinetti and Ted M. Clark
Department of Chemistry, Ohio State University, 100 West, 18th Avenue, Columbus, OH 43210 USA

As a probe of local structure in network forming oxide glasses, ^{17}O nuclear magnetic resonance (NMR) spectroscopy has been an invaluable tool [1–10]. The analysis of oxygen in these glasses is vital because their structure predominately consists of well-defined corner-sharing SiO_4 tetrahedra connected in a continuous infinite three-dimensional network lacking long-range order. The interconnection of two tetrahedra involves a Si–O–Si bond angle, and two dihedral angles, and the variation in these angles is considered to be one of the main sources of disorder in a conventional melt quenched silicate glass.

The best approach for measuring Si–O–Si bond angle distributions is to use methods that provide a detailed and direct measurement of the local environment around oxygen. Unfortunately, the information obtainable from X-ray absorption spectroscopies has been limited for light backscattering atoms like oxygen [11]. In contrast, solid-state ^{17}O NMR, specifically, the ^{17}O quadrupolar coupling and chemical shift parameters provide a simple and direct probe of electronic structure, and is well suited for measuring the local structure around bridging oxygen [12–21].

With the development of 2D NMR methods that separate and correlate anisotropic and isotropic lineshapes [22–24], it is becoming increasingly possible to obtain local structural information for glasses via ^{17}O NMR. In 1992, Farnan *et al.* [4] first demonstrated how the distribution of ^{17}O NMR parameters can be measured in a silicate glass using 2D dynamic-angle spinning (DAS) NMR without any assumptions about the shape of the NMR parameter distributions. Additionally, they demonstrated that the ^{17}O quadrupolar coupling parameter distribution can, in principle, be mapped into the Si–O–Si bond angle distribution in the glass.

A crucial aspect in these structural determinations is an understanding of the relationship between the measurable NMR parameters and the variations in local structure that influence the NMR parameters. The development of such relationships has been an ongoing task for oxygen in oxide glasses, with significant gains being made by the combination of computational methods and experimental investigation of a variety of oxygen environments in crystalline silicates.

For bridging oxygen, a number of structural features play a role in determining the ^{17}O quadrupolar coupling parameters, with the most significant features occurring in the first coordination sphere of the bridging oxygen. In the mid-1980's Oldfield and coworkers [25–27] clearly established on the basis of their ^{17}O magic-angle spinning (MAS) NMR measurements that the electronegativity of the cations coordinated to a bridging oxygen atom is a primary factor influencing the magnitude of the C_q-parameter for the bridging oxygen. In a series of *ab initio* calculations on model clusters focusing on the silicate bridging oxygen linkage Tossell and coworkers [12–14] predicted simple trends for the ^{17}O quadrupolar coupling parameters with Si–O–Si angle. These trends were later experimentally confirmed by Grandinetti *et al.* [17] in ^{17}O DAS measurements on coesite.

Vermillion *et al.* [19] and Clark *et al.* [20] further refined this understanding by examining the effect of additional coordination of the bridging oxygen by network modifier alkali cations. Their findings, obtained using *ab initio* methods on model clusters representing typical bridging oxygen environments in lithium, sodium, and potassium silicates, suggested that the previously established trend in ^{17}O C_q with Si–O–Si angle is systematically shifted to lower magnitudes with increasing number and field strength of coordinating alkali cations. They also found that the previously established trend [12–15] in ^{17}O quadrupolar coupling asymmetry parameter, η_q, with Si–O–Si angle is systematically shifted to higher values by the presence of one coordinating alkali cation, and only slightly shifted to higher values by the presence of two coordinating alkali cations.

In two related papers, Clark and Grandinetti [18, 28] used *ab initio* methods to study a number of clusters with the coordinating cations varied from Group III to Group VI and from Periods 2 to 4, while simultaneously varying the network forming cation–oxygen distance. A general trend, shown in Figure 1A, was observed that the magnitude of C_q increases linearly with increasing network forming cation–oxygen bond distance, and also increases with cation group number, as shown Figure 1B. These findings suggest that group number and cation-bridging oxygen distance can serve as a better predictor of the bridging oxygen quadrupole coupling constant than electronegativity differences [26, 27].

The observation that the magnitude of C_q increases linearly with increasing network forming cation–oxygen

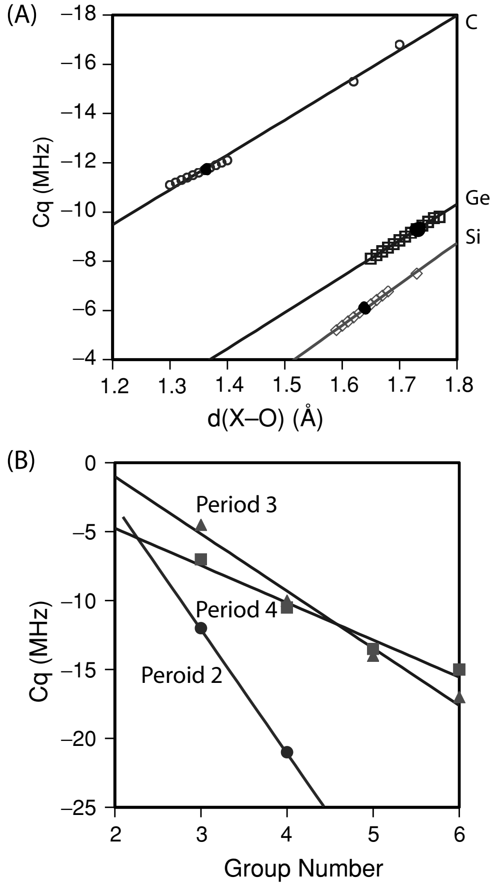

Fig. 1. (A) Comparison of bridging oxygen ^{17}O C_q values for the clusters (OH)$_3$T–O–T(OH)$_3$, where T = carbon, silicon, and germanium, as a function of d(T–O). (B) Bridging oxygen C$_q$ dependence on the group number of coordinating cations for each period. C$_q$ values are calculated for identical cation–oxygen distances and a bridging oxygen angle of 180°.

bond distance was investigated in more detail by Clark and Grandinetti for bridging oxygen atoms in silicates [21]. In this work, *ab initio* calculations were performed for model clusters to examine the dependence of ^{17}O quadrupolar coupling parameters on both Si–O distance and Si–O–Si angle. This work demonstrated that the ^{17}O quadrupolar coupling constant is dependent on both of these structural features, while η_q is primarily dependent on the Si–O–Si angle. Also, it is noteworthy that the strong linear dependence of C$_q$ on Si–O distance helped explain the rather different angular trends for C$_q$ found in coesite [17] and ferrierite [29], since the Si–O–Si angle and Si–O distance correlations for these two materials are quite different [21].

Relationships between ^{17}O quadrupolar coupling parameters and structure in silicates have also been examined using periodic density functional theory (DFT) calculations. These calculations, which are capable of describing quite accurately a system's electronic structure, have been performed for crystalline sodium silicates, the siliceous zeolite ferrierite, and also for plausible sodium silicate glasses that were generated using molecular dynamics [30, 31]. These calculations generally support the previously established trends, i.e. C$_q$ decreases in magnitude with decreasing Si–O–Si angle and Si–O distance, whereas η_q depends only on Si–O–Si angle. Additionally, these investigations found no dependence of the bridging oxygen C$_q$ upon the number of coordinating alkali cations, a finding in contrast to that reported using modeling clusters [19, 20].

Overall, it has become clear that first coordination sphere structural features that appear to be most important in determining the ^{17}O quadrupolar coupling parameters of the bridging oxygen are the nature of the two coordinating network forming cations, the T–O–T′ linkage angle, the T–O bond distances, and the nature and number of coordinating network modifier cations. Contributions from beyond the first coordination sphere of the bridging oxygen appear to be secondary in importance. For example, Xue and Kanzaki [16] performed *ab initio* calculations employing clusters expanded out to four coordination spheres to model each of the silicate bridging oxygen linkages in coesite and obtained a slightly improved agreement with the experimental trends, with corrections on the order of a few percent in the ^{17}O C_q and η_q values.

Equations proposed to summarize the important structural features for the determination of the ^{17}O quadrupolar coupling parameters are

$$C_q(\Omega, n_M) = a\left(\frac{1}{2}+\frac{\cos\Omega}{\cos\Omega-1}\right)^{\alpha} + n_M \Delta C_q^M + m_d(d_{TO} - d_{TO}^{o}) \qquad (1)$$

$$\eta_q(\Omega) = b\left(\frac{1}{2}-\frac{\cos\Omega}{\cos\Omega-1}\right)^{\beta} + \Delta\eta_q^M(n_M), \qquad (2)$$

where Ω is the Si–O–Si bond angle, d_{TO} is the average silicon–oxygen bond distance, and the terms $n_M \Delta C_q^M$ and $\Delta\eta_q^M(n_M)$ account for contributions from modifier cations coordinated to the bridging oxygen. These expressions are not unique in their ability to describe these relationships, and other expressions have been used previously [4,14,15].

Clark and Grandinetti [21] performed a least-squares fit of Equations (1) and (2) to the experimental values for coesite [17], cristobalite [32], and α-quartz [33] as

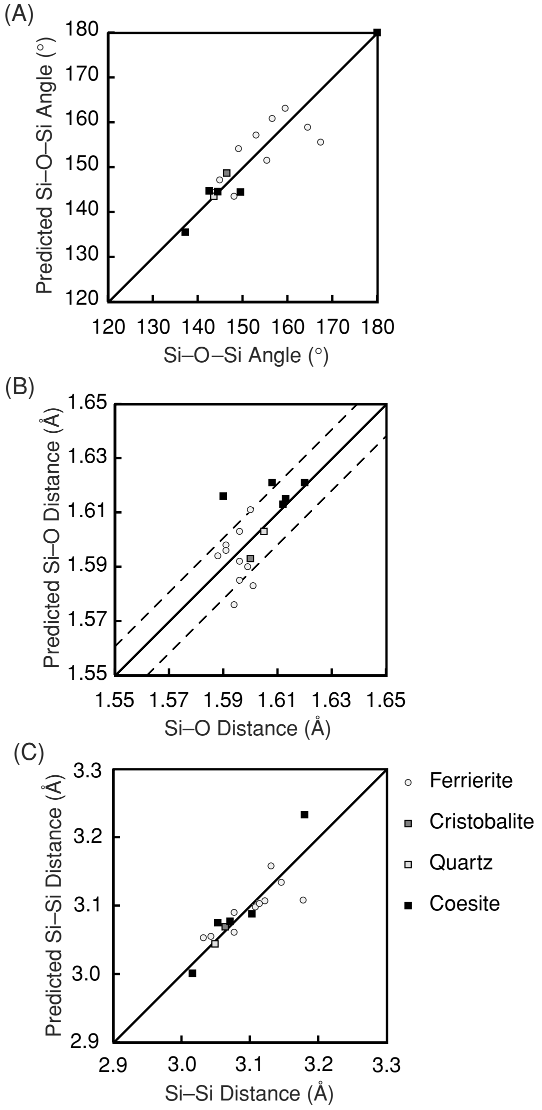

Fig. 2. Comparison between ^{17}O quadrupolar coupling predicted (A) Si–O–Si angle, (B) Si–O distance, and (C) Si–Si distance with corresponding quantities reported from X-ray crystallography [40–42]. Solid diagonal lines represent perfect agreement. Best fit parameters for Equations (1) and (2) are $a' = -6.53\,\text{MHz}, \alpha' = 1.80, m_d = -12.86\,\text{MHz/Å}, d^{\circ}_{TO} = 1.654\text{Å}$, $b = 4.73$, $\beta = 1.12$.

well as the *ab initio* predicted values for ferrierite [29] and obtained the parameter values given in the caption of Figure 2. The resulting parameterized equations describe the relationships between the ^{17}O quadrupolar coupling parameters and the relevant structural features in the first coordination sphere for a bridging oxygen atom in the absence of modifier cations. The precision of these relationships can be seen in Figure 2, where the Si–O–Si angles and Si–O distances predicted by these expressions are shown versus the actual values. Close agreement between predicted and reported values are demonstrated, even though only two structural variables are considered, i.e. the average bond distance and the bond angle. Here, the Si–O–Si angles in Figure 2A are predicted from η_q alone and, with the Si–O–Si angle determined, Equation (1) is used to predict the Si–O distance from C_q, as shown in Figure 2B. After having determined the Si–O distance for a given angle, it is also possible to determine the Si–Si distance.

It is noteworthy that not only the quadupolar coupling constant and asymmetry parameter can be used to measure the Si–O–Si angle and Si–O distance, but also the simultaneous measurement of C_q and η_q for each bridging oxygen site can be used to obtain the correlation between Si–O–Si angle and Si–O distance. This has significant impact for determining two-dimensional structural distributions around bridging oxygen in silicate glasses. This approach requires a good measurement of the quadrupolar asymmetry parameter, which has been historically been more difficult to measure than the quadrupolar coupling constant. Fortunately, this situation has been improved with the development of techniques such as Rotor Assisted Population Transfer (RAPT) [34–37] for enhancing the sensitivity of the MAS detected DAS [17,38,39]experiment, which allows overlapping anisotropic ^{17}O central transition lineshapes to be separated.

Figure 3A is the recently reported ^{17}O RAPT/MAS-detected DAS spectrum of silica glass [43]. From a least-square analysis of the ^{17}O 2D DAS spectrum a three-dimensional histogram, correlating the δ_{cs} (chemical shift), C_q, and η_q of ^{17}O, was obtained. A projection of this three dimensional histogram, showing the two-dimensional correlation between C_q and η_q for silica glass, along with corresponding one-dimensional projections is shown in Figure 3B. With the aid of Equations (1) and (2), the experimental C_q and η_q histograms were mapped into the two-dimensional histogram of the Si–O–Si angle versus the Si–O distance, shown in Figure 3C. This result is the first experimentally measured two-dimensional structural distributions in a glass, and illustrates nearly strong linear correlations between the Si–O–Si angle and Si–O distance in silica glass.

Significant insights into the structure of silicate glasses are now made possible by an analysis using this methodology. For example, in the case of silica glass, it is remarkable that a strong positive correlation is observed between Si–O distance and Si–O–Si bond angle. This trend was unexpected since it is *opposite* of that generally found in crystalline SiO_2 polymorphs, as shown in

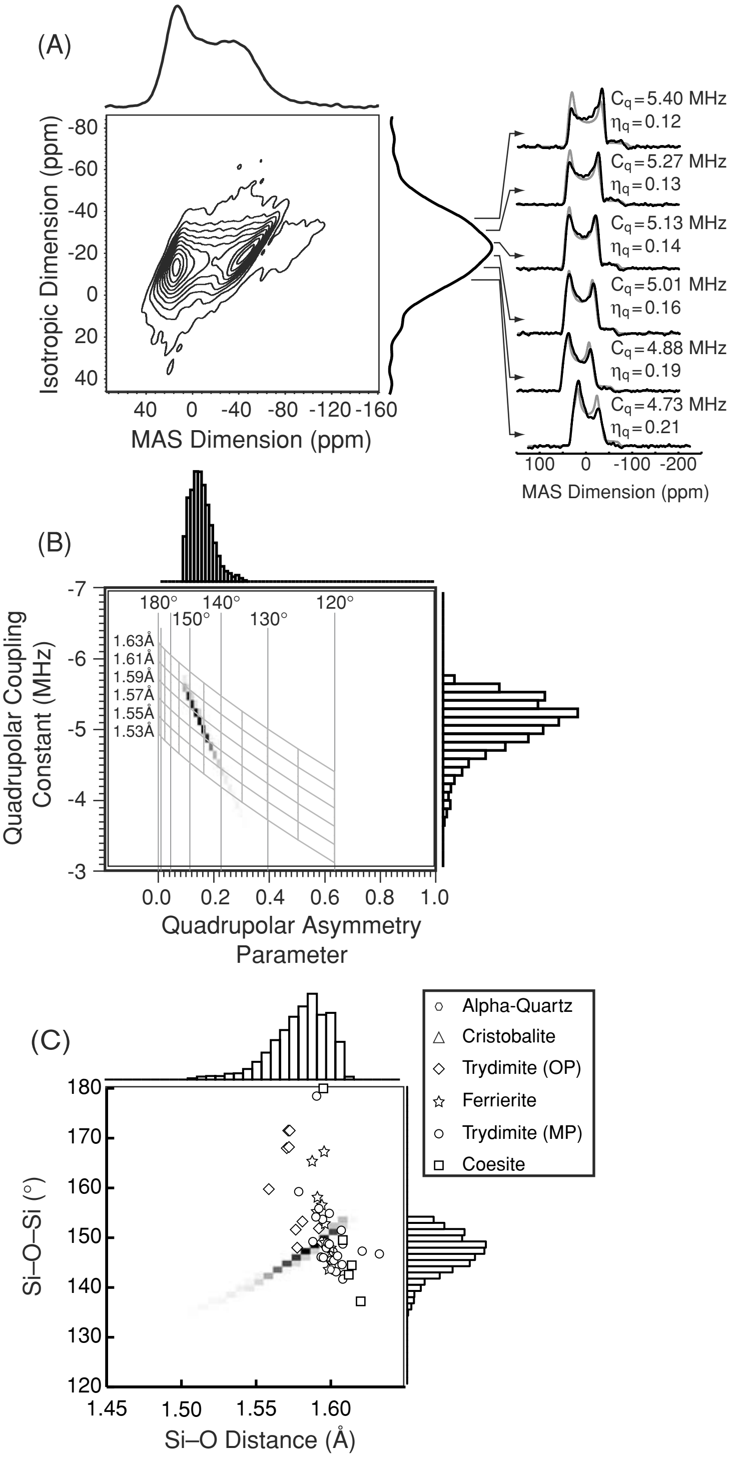

Fig. 3. (A) Experimental 2D ^{17}O RAPT/MAS-detected DAS spectrum of SiO_2 at 9.4 T along with experimental 1D projections onto the MAS and isotropic dimensions. Shown on the right are selected experimental cross sections along with best fit simulations. (B) Two-dimensional histograms along with the corresponding one-dimensional projection showing the correlation between C_q and η_q. Grid lines shown were obtained from Equations (1) and (2) by varying Si–O distance with Si–O–Si angle held constant and the Si–O–Si angle with the Si–O distance held constant. (C) 2D histograms of Si–O–Si angle versus Si–O distance for silica glass derived from NMR parameter distributions, and for various crystalline polymorphs.

Figure 3C. Also, the resulting Si–O–Si bond angle distribution, which peaks at 147° with a standard deviation of 3.8°, is noteworthy for its narrowness in comparison with distributions determined by diffraction or Si-29 NMR measurements [44–46].

In conclusion, ^{17}O NMR is proving to be an extremely robust probe of structure in silicate glasses. As the relationship between the ^{17}O NMR parameters and structure has become increasingly well-understood, it is now possible to apply this knowledge for the interpretation of the two-dimensional NMR spectra of disordered materials. This has led to the experimental determination of correlated structural distributions for oxygen sites in glasses, a significant achievement that is not presently possible by other experimental techniques. With the continued application of this methodology, it will be possible to gain a more complete understanding of many glasses of scientific and technological importance.

Studies of the Local Structure of Silk Using Solid-State NMR

Jacco D. van Beek, Lilyane Beaulieu and Beat H. Meier
Physical Chemistry, ETH Zurich, CH-8093 Zurich, Switzerland

Introduction

The focus of the present article is the description of some NMR methods that can be used to structurally characterize partially disordered biopolymers in solid phase. Silk is not only an attractive and important material of this class, but also it turns out to be a convenient compound to be studied by NMR spectroscopy because it is quite easy to obtain the relatively large sample amounts needed (in the order of 10 mg) with amino-acid specific isotope labelling, in particular with ^{2}H, ^{13}C and ^{15}N. In the following, we will give a short introduction to silks, followed by a description of selected NMR techniques and the results of their application to silks, in particular to the silk of the Eri silkworm *Samia cynthia ricini* (*S.c. ricini*).

Silks are fibrous proteins of considerable economic and scientific interest. They have found utility as textile fibre since thousands of years because of their strength, elasticity, luster, absorbency and affinity for dyes. The material is made by various animals for different biological purposes. Many silks exhibit interesting mechanical properties, e.g. a high toughness comparable to Kevlar combined with an extensibility of 30% or an extreme extensibility of more than 200% [1]. In our days, many new applications for these types of biopolymers are targeted [2–6].

The primary structure of silks is typically highly repetitive and rich in glycine and alanine [7–13]. Spider dragline silk and other silks like the one from the Eri silkworm, *S.c. ricini*, show a primary sequence of the silk protein with poly-alanine repeats of 6–12 monomers in between glycine-rich segments. In this article, we concentrate in particular on these types of silks and the spectra presented are all from *S.c. ricini*. The commercially most important silk from the domesticated silkworm *Bombyx mori* does not fall into this class and we refer the reader to a recent review of Zhao and Asakura [14].

Silks are partially disordered materials, and therefore, particularly interesting for solid-state NMR studies because there are few other methods for their structural characterisation. The linewidth in "high-resolution" magic-angle spinning (MAS) solid-state experiments turns out to be in the order of 5–10 ppm, which is typically an order of magnitude more than obtained with microcrystalline proteins [15–18] and amyloid fibres [19,20] with the corresponding loss in the signal-to-noise ratio. Therefore, not all the benefits of MAS spectroscopy, as obtained for more highly ordered materials, can be realised on silk samples. In particular, it is often not possible to make distance measurements to determine the local structure because the signals from different sites are not spectrally resolved, except for special pairs introduced by selective labelling [21–23]. However, the measurement of backbone torsion angles is an attractive alternative. The knowledge of the (ϕ, ψ) torsion angle pair for each residue in principle fully determines the backbone structure. In practice, however, only secondary structure information can be obtained due to the cumulative errors and long-range distance constraints are necessary to address higher-than-secondary structural questions.

In addition to the native fibres, we will also discuss studies of silk films. These films are formed when the liquid fibroin is directly casted from the posterior silk glands of the silkworm and can be used for immobilisation technology and especially as an immobilisation matrix for enzymes. Their functionality, including permeability, activity of entrapped enzymes and mechanical integrity depend on the orientation of the polymer chains and their conformation. Therefore, it is of interest to understand the relationship between the molecular structure and the diverse macroscopic particularities and utilities of this biopolymer.

The NMR Measurements of Torsion Angles

Torsion angles can be measured through the orientational correlation of spin interactions which have a known orientation of the principal axis of the spatial tensor with respect to the molecular coordinate system. As an example, we use the ^{13}C chemical-shift tensor of the backbone carbonyl functionality of selected amino acids. The orientation of this tensor with respect to the molecular frame at the carbonyl site is known to a precision of a few degrees and is indicated schematically in Figure 1. Therefore, if we are able to selectively transfer the magnetisation between a

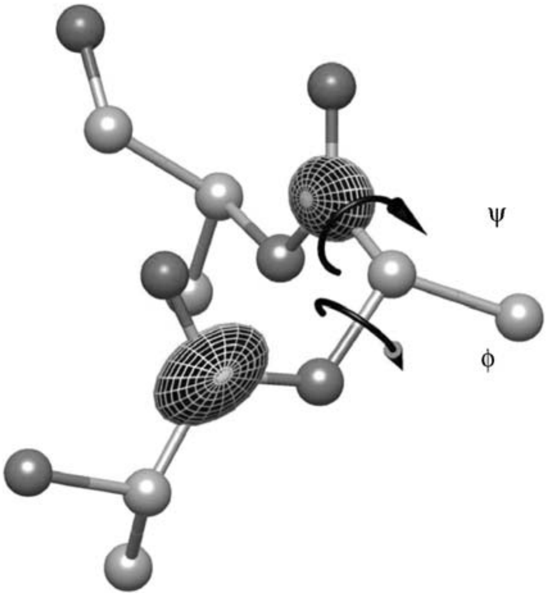

Fig. 1. Orientation of the carbonyl chemical-shielding tensor (yellow ellipses) with respect to the molecular coordinate system in a polypeptide and its relation to the backbone torsion angles. The following empirical rules apply [55–59]: The principal axis associated with the most shielded CSA principal value σ_{33} is perpendicular to the peptide plane. The principal axis associated with the intermediate component of the CSA tensor σ_{22} is almost colinear with the C=O vector. More precisely, for proteins, experimental determination of the angle between the bound direction and the principal axis σ_{22} falls into a range 0–12°. (See also Plate 122 on page XVII in the Color Plate Section.)

selected pair of carbon spins, or to excite double-quantum coherence involving the two selected spins, the two-dimensional CSA–CSA correlation spectrum would fully characterize the relative orientation of the two molecular segments described by the angle pair (ϕ, ψ), as schematically illustrated in Figure 2. The "selected" amino acids mentioned above are usually singled out by isotopic labelling schemes [24–27].

Obviously, a complex material like silk is not composed of isolated two-spin systems and the correlation spectrum will critically depend on the number of spins involved as well as on the experimental methods applied. Coherent ^{13}C–^{13}C polarization transfer experiments (e.g. rf-driven spin diffusion or double-quantum excitation/reconversion) typically favour the strongest coupling at the expense of weak coupling, not only through the inverse sixth power dependence of the spectral intensity from the intermolecular distance but also, in addition, through the effect of "dipolar truncation" [28]. They can in fact be set up, such that predominantly next–neighbour interactions are observed, which is particularly useful for double-quantum selection in the double-quantum–single-quantum correlation experiment (DOQSY) [29–32]. Nevertheless, even in this favourable situation, the evaluation of the structural parameters (ϕ,ψ) from the spectra is not trivial because of disorder in the material: there is no single angle-pair (ϕ,ψ) which could explain the spectra but there is a distribution of such angles which must be characterised. Notwithstanding these complications, a "model free" determination of the parameter distributions is often possible [30,31,33,34]. Alternatively, information about (ϕ,ψ) may also be obtained from the chemical-shift distribution of the ^{13}C resonances in a MAS spectrum using empirical rules [27,35–38] or from initial-rate studies in spin-diffusion spectra (vide infra) [39].

Experimental DOQSY spectra of alanine-labelled silk from *S.c. ricini* fibre and cast-film samples are presented in Figure 3 along with the simulated spectra and the distribution in (ϕ,ψ), which leads to the simulated spectrum [30]. The resulting distribution in (ϕ,ψ) allows for a relatively detailed characterisation of the alanine sites. Similar work for the glycine sites will is described elsewhere [31] and yielded results comparable to the measurements on spider dragline silk [40]. Therefore, *S.c. ricini* seems, in fibrous form, to have a similar structure to that observed for spider dragline silk depicted in Figure 4, while it adapts rather a different form in the cast film with α-helical structures for the alanine-rich parts [30] and with substantially disordered glycine-rich parts. [31]

Geometrical Information on the Molecular-to-Nanometer Scale

Proton-driven "incoherent" ^{13}C–^{13}C polarisation transfer is another option to probe the relative orientation of molecular segments. Proton-driven spin-diffusion (PDSD) on static samples is a well established technique for determining local structure (for a review see [41,42]). Because the length of the spin-diffusion period of the experiment is only limited by T_1 relaxation, it can be up to 10 s and the method allows to probe structures with sizes greatly exceeding a single bond length. The polarisation transfer follows a kinetic master equation in this experiment [43] and the dependence on the internuclear separation is between the inverse third and sixth powers of the distance, depending on the details of the experiment [42]. In the limit of quasi-equilibrium (QE), when the spectrum does not depend on the mixing time anymore, the spectrum becomes particularly easy to interpret as it reflects only the relative orientation of the CSA tensors of the spins that are correlated, and no longer the distances. Figure 5 shows a

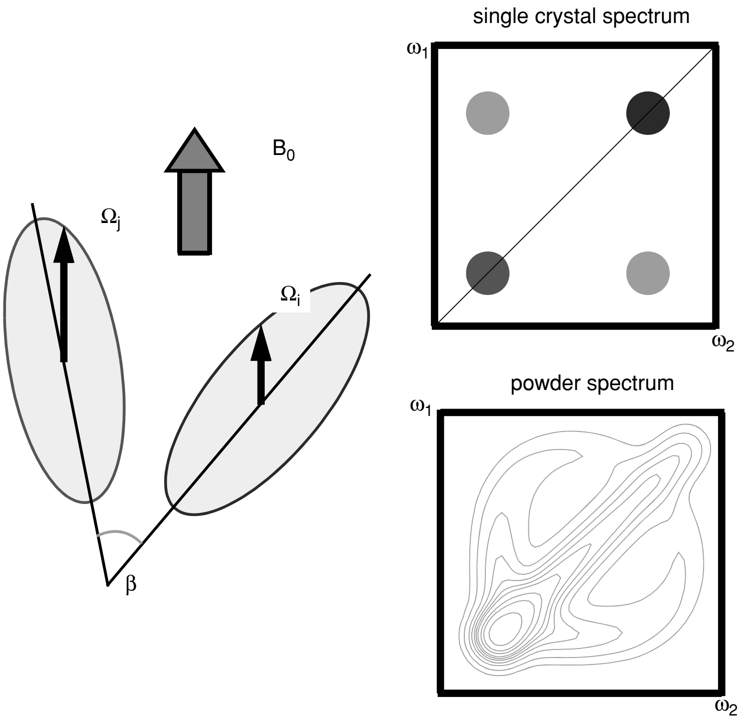

Fig. 2. Principles of two-dimensional CSA–CSA correlation spectroscopy using, e.g. PDSD. The single-crystal spectrum (B) depends on the relative orientation of the two CSA tensors symbolised in (A) and on the crystal orientation. For a static sample the powder spectrum (C) depends only on the relative tensor orientation (and, of course, on the principal values). The illustration uses the correlation of two axially symmetric tensors that yields only a single Euler angle β. For general tensors, all three Euler angles can be determined. (See also Plate 123 on page XVIII in the Color Plate Section.)

comparison of the DOQSY and PDSD experiments for the proposed labelling strategy, as a function of the backbone torsion angles (ϕ,ψ). In PDSD, spins not involved in magnetisation exchange processes on the time scale of the mixing time give rise to a (often dominant) diagonal signal in the 2D spectrum. This can overshadow the off-diagonal signal, which contains the structural information. In biological materials like silk, where the degree of isotopic labelling may be considerably less than 100% (e.g. our *S.c. ricini* examples are at around 15% for the enriched amino acid), this feature leads to a complication of the spectral interpretation and, if one is interested in determining structural information on a molecular scale (like torsion angles) it is beneficial to apply the DOQSY approach mentioned above. This method actively selects out the signals from close neighbours and suppresses the signals from spins not involved in a double-quantum coherence. Conversely, the PDSD experiment, is, for longer mixing times, sensitive to longer distances exceeding the ones probed by DOQSY by one or two orders of magnitude.

For fully disordered materials, the PDSD QE structure would be a pure "amorphous" spectrum where each cross section along t_1 as well as t_2 has the same shape (but not the same integral) [42]. In materials with sizeable domains (consisting of several monomers in each spatial dimension), the QE spectra can characterise both the local structure within a domain and the domain size [41]. If well-isolated domains exist, they can lead to a QE where the spectra do not change appreciably with the mixing time anymore. However, if the mixing time would be increased drastically, the "amorphous" spectra would again result.

A disadvantage to the PDSD experiment on static samples is the slow exchange of magnetisation coupled to a strong dependence on the frequency difference of the corresponding diagonal signals, which may lead to spectra difficult to interpret. The rate constant for the magnetisation exchange can be significantly enhanced, and made rather independent of the frequency-difference, if the sample is rotated slowly (10–100 Hz) during the mixing period of the experiment (slow magic-angle spinning (SMAS; [44]).

The SMAS-PDSD experiment can also be performed with short mixing times in the initial rate regime. In this approach the buildup of each point in the spectrum, as a function of the mixing time, is followed. The local structure can then be obtained by fitting a structural model to the data [39]. Since the isotopic labelling degree in

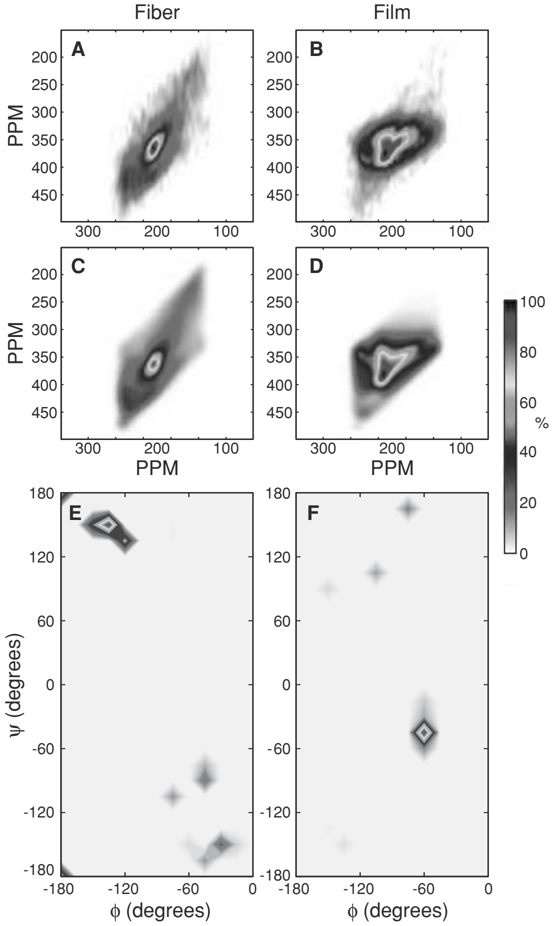

Fig. 3. Experimental 2D DOQSY spectra of (A–B) two different silk samples from the silkworm *S.c. ricini* with (C–D) corresponding to the best fits of these spectra and (E–F) to the distribution functions obtained from the fit. The samples were labelled with 1-^{13}C alanine and prepared either as a fibre or a cast film. The samples were measured a ^{13}C resonance frequency of 100 MHz. The grid resolution in (ϕ,ψ) was 15°. (See also Plate 124 on page XIX in the Color Plate Section.)

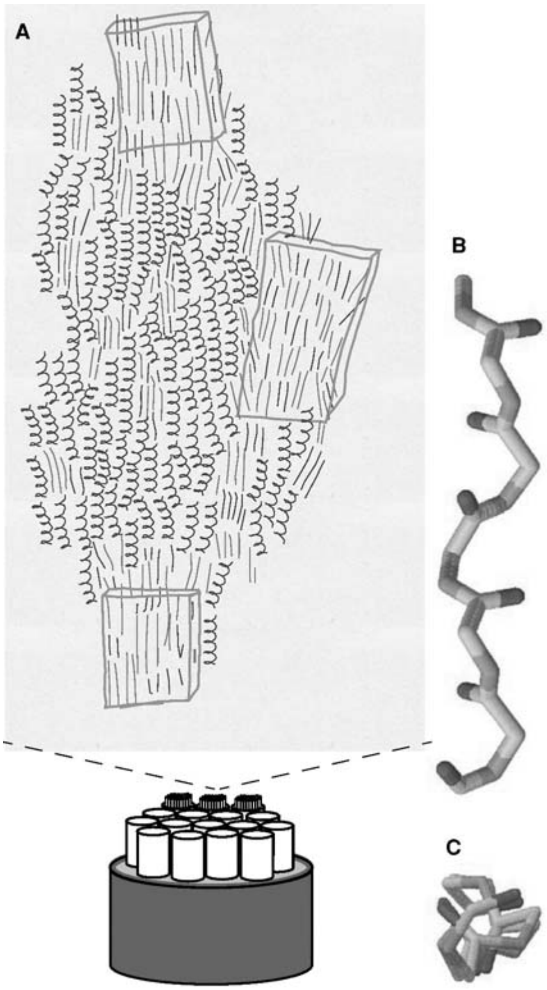

Fig. 4. Schematic model for the structure of spider dragline silk. Reproduced from Ref. [40], with permission. (See also Plate 125 on page XIX in the Color Plate Section.)

silk samples is often relatively low and non site-specific, i.e. all glycines or all alanines are labelled to a certain statistical degree, the intra- and inter-chain distances expected are comparable in length. This is in contrast to the DOQSY approach, where one, to good approximation, selectively filters out the signals from spin-pairs with the minimal possible distance. This distance is usually in fact the one between intramolecular neighbours. While a full 3D structural model is required to explain the data for the SMAS-PDSD experiments, the DOQSY Spectra can approximatively be described by two-spin systems. In our experience, the SMAS-PDSD spectra are often not sensitive enough towards the local structure in such samples, partly by the low signal-to-noise (SN) in the vital off-diagonal part of the spectrum in the initial rate regime, and partly by the large number of degrees of freedom of such a 3D model. While it is often possible to exclude certain packing models and torsion angles a unique solution is usually not available.

These statistical arguments do not hold, for site-selectively labelled peptides and good results have been obtained using PDSD on labelled model peptides at off-magic-angle spinning (OMAS) conditions [22,23,45–47].

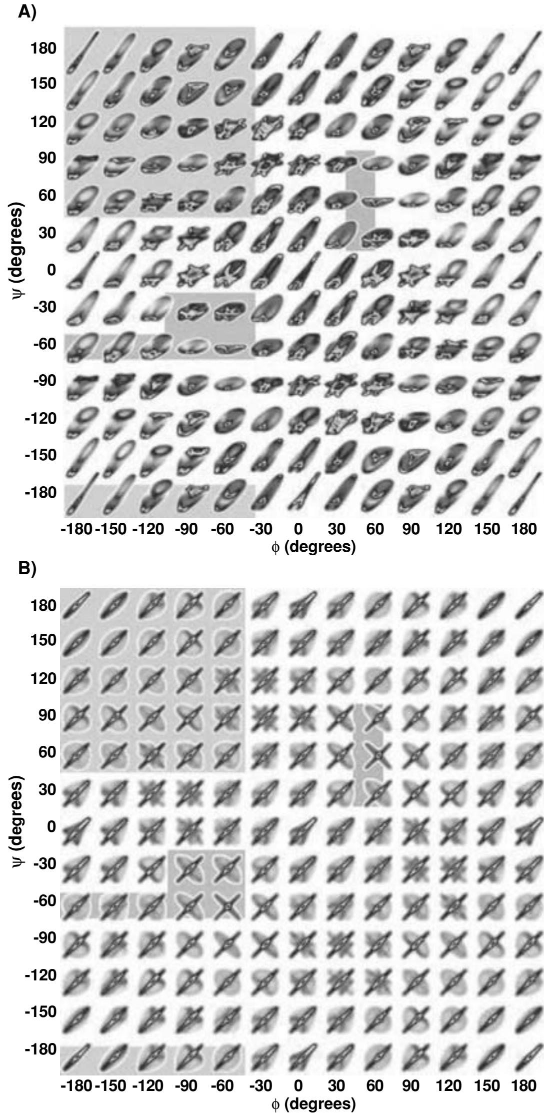

Fig. 5. Torsion-angle dependences of the (A) DOQSY and (B) PDSD experiments (at QE) when applied to ^{13}C=O labelled proteins, assuming an intra-chain contact between neighbouring amino acids. Typical β-sheet and right- and left-handed α-helical regions are marked by orange, dark blue and bright blue boxes, respectively. (See also Plate 126 on page XX in the Color Plate Section.)

Similar to SMAS, the OMAS experiment has a homogenous SD rate constant across the spectrum, but the spectrum is distributed over a smaller spectral area, which leads to a higher signal-to-noise ratio. Figure 6 shows an example of such spectra obtained in specifically labelled model peptides. In such systems QE may be quite easily reached and the analysis is comparatively simple (typically, a 2-spin simulation with only the torsion angles as variables).

The PDSD technique was first applied to static spider dragline silk samples by Kümmerlen et al. [26] and, by correlating ^{13}C=O labelled spins, an average value for (ϕ,ψ) was determined for alanine–alanine and glycine–glycine peptide segments. It was concluded that the segments were part of a β-sheet structure for the alanines and were close to a 3_1-helical arrangement for glycine. Whilst the main conclusions are identical to the ones obtained later using DOQSY [40], the PDSD results for both static [26] and slowly rotating [48] samples were less specific and would not support a similarly detailed analysis in terms of torsion-angle distributions.

SMAS-PDSD spectra from *S.c. ricini* silk are shown in Figures 7a and 8a for various mixing times for casted film and fibre samples, respectively. In the film (Figure 7a), significant cross peaks appeared at clearly shorter mixing times than for the fibre. After 20 s, the spectrum indicates the presence of substantial disorder in this sample on the nanometer length scale.

For the fibre (Figure 8a), the buildup of cross-peak intensity is slow, indicating that either the polarisation transfer between the alanines is very slow, because they are well separated in space, or that the alanines are highly ordered with all the 1-^{13}C CSA tensors close to parallel or anti-parallel to each other. The first explanation is improbable because the primary structure of *S.c. ricini* silk consists of alanine rich segments [47] and it is also incompatible with the DOQSY results discussed above. The second explanation is consistent with the DOQSY findings [30] and X-ray studies [49], which show the occurance of micro-crystalline domains with β-sheet structure. In contrast to the PDSD results of Kümmerlen et al. [26], the SMAS-PSDSD results of Figure 8 are able to detect some weak cross-peak intensity due to the enhanced efficiency of spin diffusion under SMAS.

A quantitative interpretation of the SMAS-PDSD spectra is rather involved but it is interesting to compare the measured spectra with the predicted spectra of simple model structures using numerical simulations. For the film sample, the spectrum at 250 ms shows the characteristic of a single α helix (b) or of an ordered bundle of helices (c). The spectra at longer mixing times indicate, that the cross-peaks cannot be explained by a single helix. The description by a bundle of biaxially ordered helices is better but still not fully convincing and further disorder is certainly present. Note that in the interpretation of the experimental and simulated data, the diagonal is usually not considered because it does not give information and is complicated by the presence of signals from nonexchanging spins.

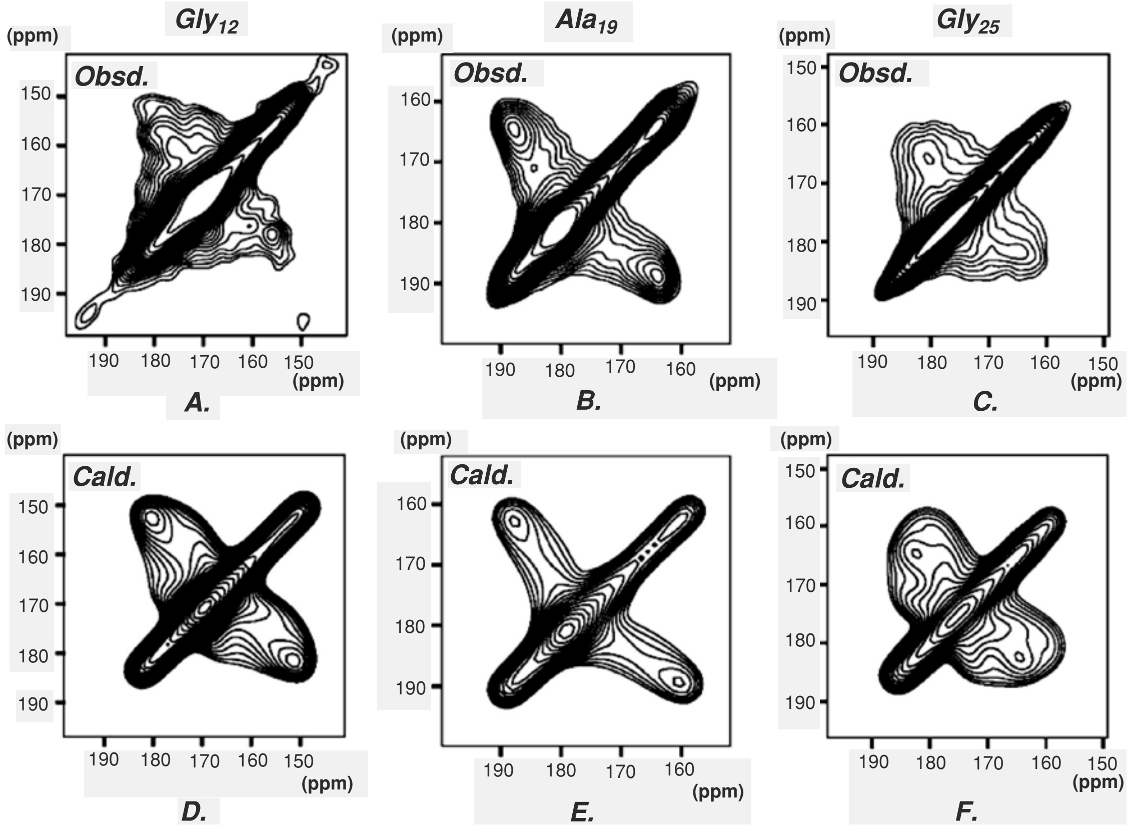

Fig. 6. 2D spin-diffusion NMR spectra of selectively doubly labelled model peptides, (A) GGAGGGYGGD[1-^{13}C]G$_{11}$[1-^{13}C]G$_{12}$(A)$_{12}$GGAGDGYGAG, (B) GGAGGGYGGDGG(A)$_5$[1-^{13}C]A$_{18}$[1-^{13}C]A$_{19}$ (A)$_5$GGAGDGYGAG, and (C) GGAGGGYGGDGG (A)$_{11}$[1-^{13}C]A$_{24}$ [1-^{13}C]G$_{25}$GAGDGYGAG, after TFA treatment, and their corresponding simulated spectra. Reproduced from Ref. [60], with permission.

For the fibrous sample, the simulations of a single β strand, or an idealised parallel β-sheet, indicate that very little cross-peak intensity is expected even if standard (ϕ,ψ) values for β-sheets are used instead of the more extended form postulated by Kümmerlen [26]. Again, the SMAS data are in good accordance with the DOQSY results. While the simulated spectra for a parallel or an anti-parallel arrangement of the β-sheets differ, it was not possible to determine the intermolecular arrangement from the spectra. The buildup rate of the cross-peaks in the SMAS spectra of both the film and fibre sample have been estimated from the initial rate regime and are reported in Figure 9, together with estimates from the simple models described above. Considering the approximations, the spectra represent a nice reconfirmation of the results extracted from the DOQSY spectra and they allow for the qualitative assessment of the disorder on a supramolecular scale.

Conclusions

To determine the local structure in partially disordered solid proteins, it is often attractive to perform NMR experiments without sample rotation. This reduces the signal-to-noise ratio in the experimental spectra, but on the other hand, there is often a much stronger dependence of the spectra on the parameters of interest and the increased spectral area typically yields a more strongly overdetermined problem in the data

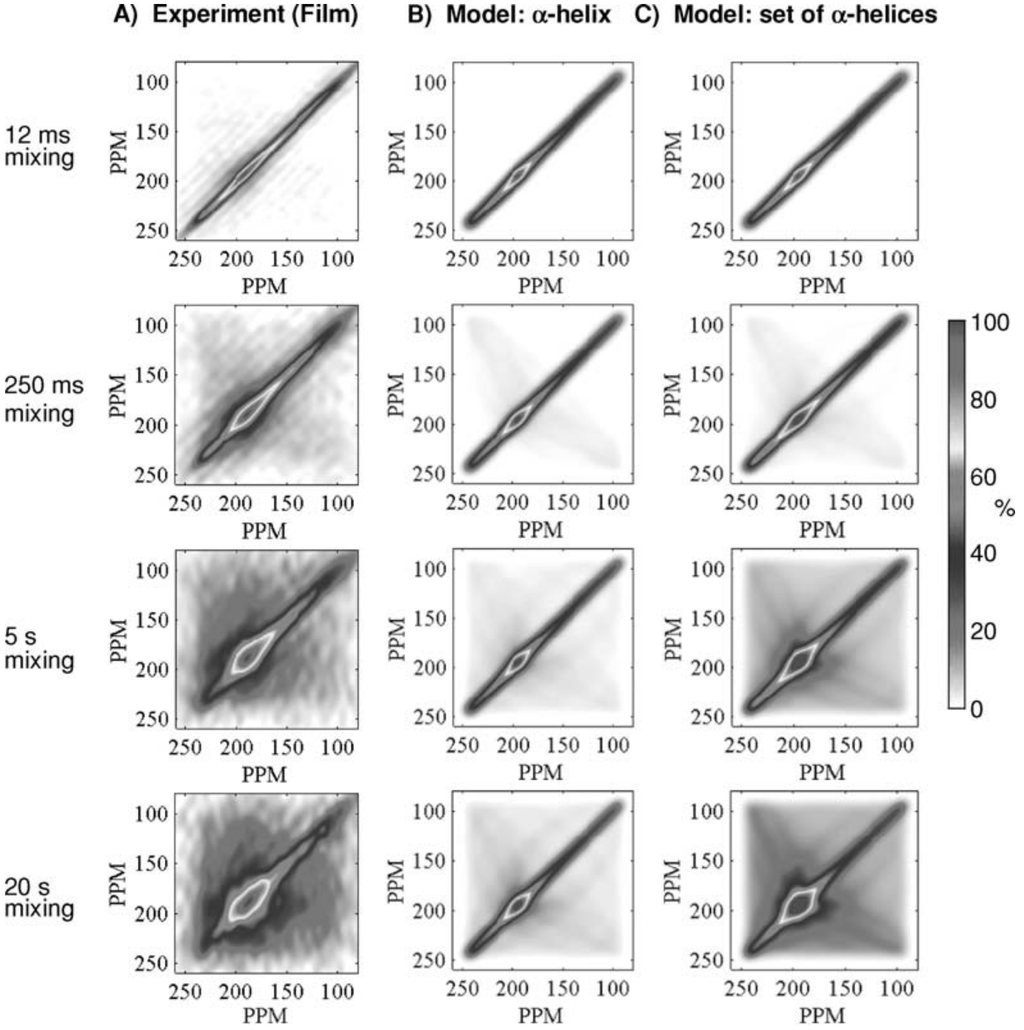

Fig. 7. (A) 2D ^{13}C PDSD spectra of *S.c. ricini* 1-^{13}C alanine labelled silk film recorded under SMAS using mixing periods of 12.5 ms, 250 ms, 5 s and 20 s. (B) Corresponding simulations for a $(\mathrm{Ala})_{100}$ segment organised in an α-helical structure. (C) Corresponding simulations for $(\mathrm{Ala})_{12}$ segments organised in an ordered array of α-helical structures. For a model peptide of poly(alanine)n ($n = 12$ or $n = 100$) arranged in an α-helix, the set of Euler angles used for the simulations was (-27.4°, 96.6°, -1.1°). As a first model (in B), one $\mathrm{poly(alanine)}_{100}$ helix has been considered. As a second model (C) 30 short α-helices ($n = 12$) have been taken into account: the helices were parallel and translationally symmetric to each other and the inter-helical distance between them has been set to 7 Å. (See also Plate 127 on page XXI in the Color Plate Section.)

analysis. In particular, for the case of less than 100% isotopic enrichment of the amino acid to be investigated, DOQSY experiments are best suited to give the backbone torsion angles connecting neighbours in primary sequence. The knowledge of these angles determines the secondary structure. Information about the further environment can be obtained by spin-diffusion experiment and by DECODER [50,51] type experiments on oriented silk samples, not discussed here [27,40,52–54]. The SD long-range information is, however, not specific enough to be able to construct an atomic model of the structure.

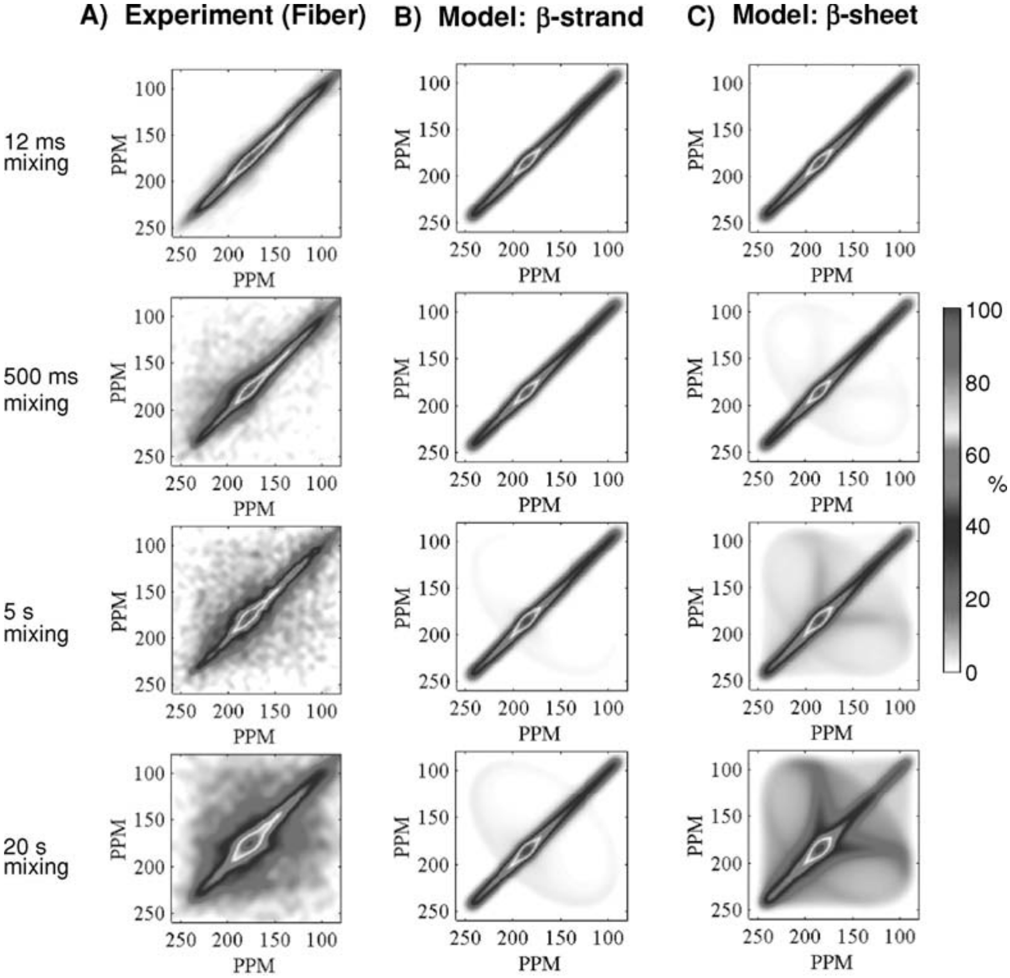

Fig. 8. (A) 2D ^{13}C PDSD spectra of *S.c. ricini* 1-^{13}C alanine labelled silk fibre recorded under SMAS using mixing periods of 12.5 ms, 500 ms, 5 s and 20 s. (B) Corresponding simulations for a $(Ala)_{100}$ segment organised as a β-strand structure. (C) Simulations corresponding to 30 strands of 12 residues each. The three Euler angles between neighbouring carbonyl tesnors used in the model were (173.2°, 120.5°, −12.4°). Two structures have been constructed. The first one is a long β-strand containing 100 alanine residues (B). As a second model, 30 β-strands containing 12 alanine residues have been taken into account (C). The relative orientation of all five layers is the same and the strands are anti-parallel. Such a model leads to a very ordered β-sheet. The inter-strand and inter-layer distances have been set to 6.10 and to 5.33 Å, respectively. (See also Plate 128 on page XXII in the Color Plate Section.)

The silk fibres of the Eri silkworm *S.c. ricini* were found to be structurally quite similar to spider dragline silk from *Nephila edulis:* the alanine residues are arranged in β-sheets, while the glycine residues form predominantly 3_1 helical structures. If cast films are produced, the alanine-rich domains adapt an α-helical form instead.

Introduction

Granular materials are a class of systems of widespread interest, touching fields as diverse as food and pharmaceutical production processes, storage and packing of agricultural products, waste disposal and recycling, or powder technology; but also natural phenomena of equal economic importance such as avalanches, sand transport by wind or water, and sedimentation. Motion of a granular substance frequently evokes the impression of chaotic behavior, but granular particles experience the same physical forces like any other moving object, in particular gravity, friction and interparticle forces. It is the correlated motions of a large number of particles which require their treatment as a coupled system, and therefore, a statistical description of the motion processes.

However, such a statistical description of motion is not restricted to granular materials. In fact, fluid dynamics uses the same type of formalism, describing the transport of finite fluid volume elements, while the trajectory of an individual molecule is ill-defined, with only time- and ensemble-averaged properties being available. In many senses, a granular medium can be considered as a close-up shot of a moving fluid, with a much reduced number of particles. The disadvantage of this could be that the particle number under some experimental conditions is not sufficient any longer for a proper averaging in the statistical sense; but at the same time, the observation of small numbers of particles, or even single ones, becomes feasible, at least in principle.

The resemblance of granular material dynamics to certain characteristics of phase behavior in "normal" matter (solids, liquids and gases) has quite naturally triggered much theoretical work attempting to find proper means to model and describe granular motion, but the ubiquity of granular media themselves and their huge economic importance have provided further impetus. Questions arising are either of everyday nature (the famous case of the shaken cornflakes box, an exercise in particle segregation), or comparatively far-fetched (much has been learnt by analyzing and modeling the shape of desert and underwater dunes that could be applied to understand the current and ancient atmospheric conditions on Mars and several moons in the solar system).

Many phenomena of interest in granular media are connected to transport properties. While transport through granular media, such as unconsolidated soils, falls into this category, it is similar to the well-covered field of flow in structured media, which has been investigated in great detail by NMR methods for a long time. In this article, we want to point out the difficulties and possibilities in NMR investigations of transport of granular media, i.e., the particle motion itself. Despite the large importance of such works, they remain scarce in the literature, one reason being the limited applicability of conventional NMR methods.

NMR of Transport in Granular Media—an Overview

The essential difficulty in tackling granular motion by NMR is the fact that the particles are very often solids in the NMR meaning of the word, i.e., their spectral features contain very broad lines, and sometimes sensitive nuclei like ^{1}H are even mostly absent, such as in dry sand grains. Provided that the sample indeed contains protons in sufficient quantity, pure *imaging* is still possible employing methods which had been specifically developed for solids (single-point acquisitions or multi-pulse line narrowing techniques). The encoding of *velocity* with pulsed field gradients (PFGs), however, consumes a minimum time of a few hundred μs in the best case, which is still one order of magnitude longer than the transverse relaxation time of solids. Only permanent-gradient techniques bear the potential to measure motion in some, but not all, solid granular particles directly, but no such effort has yet been made. The way out of this dilemma is either to obtain indirect information about the granular motion by measuring the transport of the surrounding fluid (which can be a liquid but frequently is a gas) or the particles have to be labeled with some narrow-line compound; this could be either a liquid imbibed into porous particles and held by capillary forces (particles made from a catalyst carrier material were used in [1]), or a liquid core covered by

Graham A. Webb (ed.), Modern Magnetic Resonance, 1581–1587.
© 2008 *Springer.*

a solid shell. Nature provides the latter particles in the shape of oil-filled seeds, such as mustard, sesame [2, 3] or poppy [1], which possess relatively even shapes and sizes. Liquid-filled hollow spheres are also manufactured for a wide range of pharmaceutical applications [4, 5].

Of the many conceivable geometries, research has been concentrated on only a few. Mueth *et al*. have looked into the velocity distribution of spherical particles inside a Couette cell [3, 6]. Shaken or vibrated beds were investigated by Kuperman *et al*. [7–9] and more recently by Yang *et al*. [10, 11]. Both segregation processes and localized velocities were measured for rotating horizontal cylinders half-filled with granular particles [2, 4, 5, 12, 13]. Finally, gas-fluidized beds were investigated because of their proximity to a common reactor type used in chemical engineering [1]. For a complete survey, see [14]. This contribution will focus on the latter two geometries as examples.

Gas-Fluidized Bed

A gas-fluidized bed consists of a granular system filled into a vessel which is subjected to a continuous gas stream. The intense exchange between the gas and the surface of the solid pellets favor gas phase reactions, hence its large industrial potential. The different stages of motion can be classified similar to phases in condensed matter [15, 16]. In the absence of flow, the medium behaves like a solid—if the whole array is tilted relative to the vertical axis, it will keep its overall shape until the angle of repose is reached. Above a certain threshold of gas flow rate, the bed becomes "fluidized", i.e. it will follow a tilt by liquid-like deformation so that the surface remains horizontal. In this stage, the particles have gained a slightly increased free volume, so that the total density of the bed is reduced. At higher flow rate, bubbles are formed, which drive those particles immediately above them upward, until dispersive components make them slide down around the bubble. The situation very much resembles a boiling liquid, the density is reduced further. Increasing the gas flow rate usually has the effect of increasing the average bubble size, which eventually reaches the diameter of the confining cell. Under these conditions, a pulsatile motion known as "slug phase" is observed. Depending on the cohesive forces and the inertia of the particles, they will eventually be driven out of the reactor cell. It is easy to imagine that boundary conditions, such as wall effects, even distribution of the air stream, but also particle size and shape, "stickiness" and size dispersion affect the transition between the phases.

Because optical methods can access only the vicinity of the container wall, where the unwanted wall effects are strongest, the advantage of NMR which can sample arbitrary volumes of the bed is obvious. The state and dynamics in the granular bed can then be characterized by the following approaches: (a) 1D imaging measures either the vertical extension of the bed or the signal intensity at any given layer, both being related to the particle density in the array; (b) the average particle mobility can be characterized by a number of parameters of increasing complexity, starting from dispersion coefficients via distribution functions of displacements within a given time (propagators) to higher-order information such as velocity changes, eventually leading to estimates of the collision time and the time-dependence of displacements; (c) velocity imaging combines both approaches and assigns average velocities or dispersion coefficients to the spatial position inside the bed.

In Figure 1, measurements of the average bed density normalized to the case in the absence of air flow are

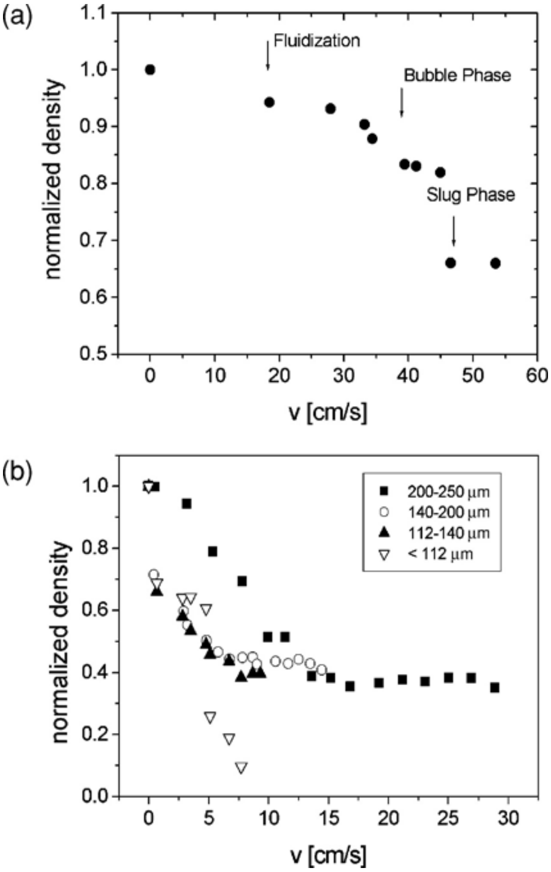

Fig. 1. Densities of gas-fluidized beds for different particle sizes, normalized by the density in the absence of flow. v indicates the average air velocity. (a) poppy seeds, (b) catalyst particles of different diameter ranges.

presented. As for all other experiments on fluidized beds, the measurements were taken out on a Bruker DSX 200 console equipped with a vertical 4.7 T magnet at MARC, RWTH Aachen, Germany.

A glass tube with an inner diameter of 21 mm was filled with either poppy seeds (diameter 500–800 μm but not spherical), or ground and sieved commercial catalyst pellets (Al_2O_3) saturated with acetone having size ranges given in the figure. The stepwise density changes are readily identified for the poppy seeds, but blurred for the smaller catalyst pellets. According to the categories given, e.g. in [16], the full spectrum of "phases" is not always expected; small particles with their relatively larger cohesive forces can be difficult to fluidize, while wall effects can become dominant for larger particles. Keeping these uncertainties in mind, all presented results must be regarded as somewhat imperfect states of granular flow which, however, are suitable for demonstrating the typical features of the dynamics.

It should be noted that, in order to obtain a value for the relative density, which is unbiased by relaxation effects, a single point acquisition technique had to be used which allowed signal acquisition during 10 μs following a low flip-angle pulse; the 1D profile was then reconstructed from 128 such encoding steps after sufficient averaging. A simple frequency-encoding sequence turned out to be unsuitable to provide a quantitative measure for the spin density; the relatively high particle velocities and short transverse relaxation times generate a combination which makes the use of a time-consuming velocity-compensated pulse sequence difficult, particularly for the catalyst pellets. From an experimental point of view, the adsorbate in these pellets was evaporating on a timescale of many hours. This is one example for experimental difficulties which require a careful consideration of the use of standard methods for moving samples when being applied to granular media.

The simplest motion-related quantity, which can be measured by NMR, is the dispersion coefficient. It is related to the velocity autocorrelation function (VACF) by

$$D(\Delta) = \int_0^\Delta \left(1 - \frac{\tau}{\Delta}\right) \langle \boldsymbol{v}(0)\boldsymbol{v}(\tau)\rangle d\tau \qquad (1)$$

if the VACF depends on the time differences τ only [5]. This condition can be violated, e.g. in the bubbling phase, when the system is macroscopically heterogeneous and each measurement probes a different particle distribution. It is assumed, however, that sufficient averaging does provide a reasonable approximation to the dispersion coefficient.

$D(\Delta)$ was determined using a standard diffusion encoding sequence, including a pair of pulsed field gradients of duration δ and strength $\boldsymbol{G}$, defining the wave vector $\boldsymbol{q} = (2\pi)^{-1}\gamma\delta\boldsymbol{G}$. Analyzing the initial slope of the normalized signal intensity, $\tilde{S}(q, \Delta) = S(q, \Delta)/S(0, \Delta)$, renders the dispersion coefficient [17]:

$$D(\Delta) \approx -(4\pi^2\Delta)^{-1} \lim_{q\to 0} \frac{\partial \ \ln|\tilde{S}(q, \Delta)|}{\partial q^2} \ . \qquad (2)$$

Figure 2a compares the increase of $D(\Delta)$ with air velocity for catalyst pellets with different size ranges. As expected, smaller and lighter particles are more affected by the driving air flow. By comparison with the density measurements in Figure 1, the sudden increase of the dispersion coefficient at an air velocity of 12 cm/s for the largest particles is indicative of the transition to the bubbling phase—when higher velocities begin to appear due

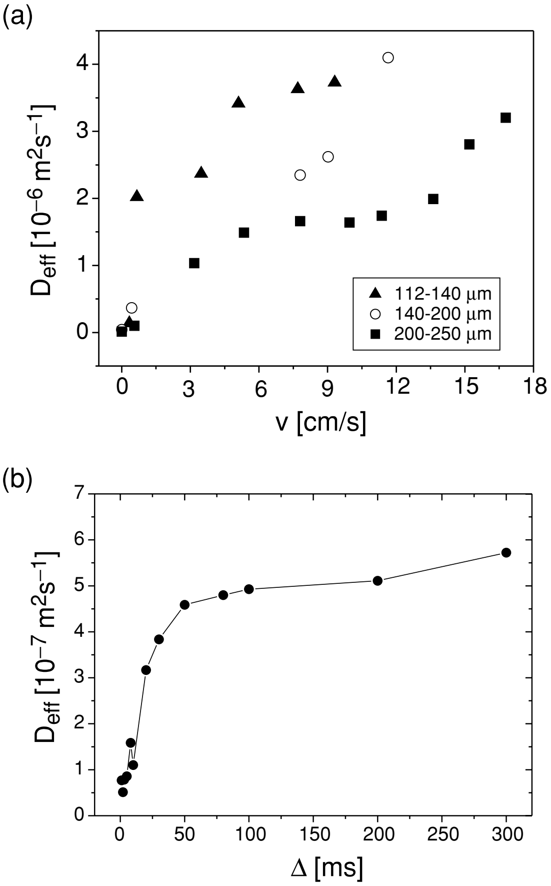

Fig. 2. (a) Dispersion coefficients for catalyst particles as a function of air velocity and particle size. (b) Dispersion coefficients for poppy seeds as a function of encoding time.

to the fast-moving bubbles—, this value being shifted to lower air velocities for the smaller particles. For the results of Figure 2a, encoding took place during a fixed interval $\Delta = 1.4$ ms, which is much longer than the average time between collisions, but short compared to the time required for an individual particle to sample a region with a statistical representation of all possible void structures and velocity distributions. Such a representative elementary volume had been identified as the characteristic structure beyond which dispersion processes become time-independent. The initial concept was formulated for fluid flow in fixed beds [18], but a similar volume can be defined for the fluidized bed, if wall effects can be neglected.

An example of the time-dependence of the dispersion coefficient is sketched in Figure 2b, which was obtained for poppy seeds, using a multi-PFG technique compensating for coherent motion contributions. It is this long-time limit, approached around $\Delta \approx 100$ ms for the case shown, which is of relevance for understanding processes that affect the efficiency of the fluidized-bed reactor as a whole. It is preceded by a regime which possesses some ballistic characteristics, where particles move in groups, for instance driven by an individual gas bubble; this regime shows an almost linear increase of $D(\Delta)$ with Δ. The truly ballistic regime would be observed on time scales much shorter than the time between collisions. Ongoing research attempts to access this time scale by reducing the encoding intervals to well below 1 ms and choosing the granular system appropriately.

The next, more complex function describing motion in the system is the so-called propagator [19]. It still represents an averaging over a large region or the whole bed, but provides the distribution of displacements $\boldsymbol{R}$ during a time Δ, and thus the velocities are averaged over this period. The propagator $\overline{P}(\boldsymbol{R}, \Delta)$ appears in the definition of the signal intensity as a function of encoding by wave vector $\boldsymbol{q}$:

$$\tilde{S}(\boldsymbol{q}, \Delta) = \int \overline{P}(\boldsymbol{R}, \Delta)\ \exp[i2\pi\boldsymbol{q} \cdot \boldsymbol{R}(\Delta)]\, d\boldsymbol{R}, \tag{3}$$

and is obtained via inverse Fourier transformation.

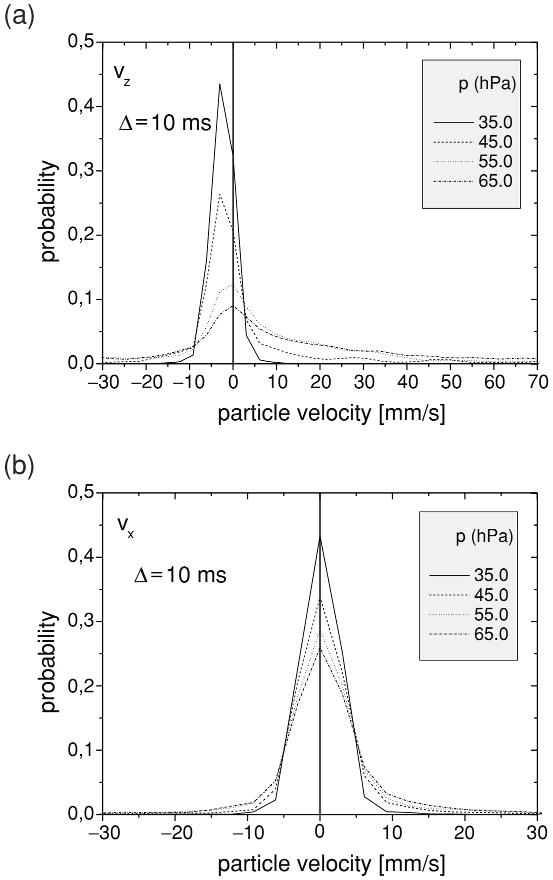

Fig. 3. Propagators for poppy seeds at different air pressure drops (a) parallel (Z) and (b) perpendicular (X) to the air flow direction.

Already the visual appearance of the bubbling phase in fluidized beds hints to a strongly asymmetric velocity distribution: a small number of fast particles moving upward is compensated by the remaining particles slowly moving downward. This impression is confirmed and quantified by the shape of the propagator averaged over the whole sample volume inside the resonator. Figure 3 demonstrates the influence of an increasing air flow rate on the propagator shapes for a bed of poppy seeds at a relatively short encoding time, $\Delta = 10$ ms. As expected, the distribution of vertical (Z) velocities is asymmetric, with a long tail of positive (upward) velocities gaining in weight for higher flow rates. For some conditions, the most probable velocity is actually negative, while mass balance requires the average to remain zero. The transverse velocities (X) have a symmetric distribution about zero because of the absence of a net transverse motion.

Finally, the combination of imaging sequences with a velocity-encoding module allows the local description of motion in terms of pixel-averaged velocities, or indeed propagators. One example, again for poppy seeds in the bubbling phase, is shown in Figure 4. Two-dimensional imaging (phase- and frequency-encoding) was combined with a preceding pair of velocity-encoding gradients at a separation of $\Delta = 4.7$ ms. Data were taken in a horizontal slice of 5 mm thickness near the center region of the bed of 27 mm height. For the chosen air flow

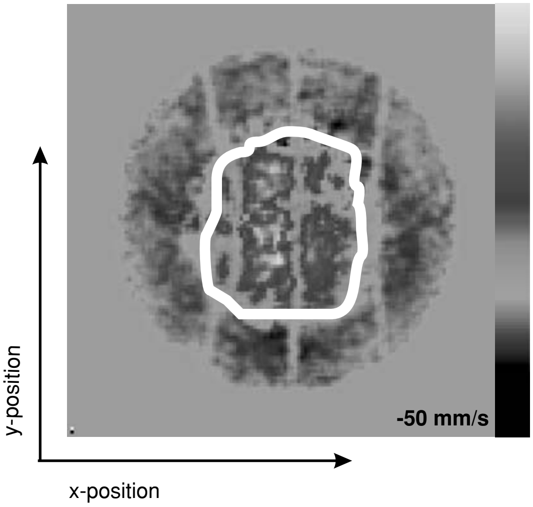

Fig. 4. Map of the vertical velocity v_z for a bed of poppy seeds of 44 mm diameter in the bubbling phase obtained in a horizontal slice of 5 mm thickness. The white line denotes zero vertical velocity. The vertical stripes are artifacts of the imaging reconstruction process. (See also Plate 130 on page XXIII in the Color Plate Section.)

rate, motion is characterized by a fountain-like behavior, where a relatively small fraction of particles in the central region is transported upwards with large velocities, while the particles further out and toward the cylinder wall move downward with smaller velocity values. The white line in Figure 4 separates the region with positive and negative velocities. The result was obtained from the difference of two differently encoded images to remove systematic phase errors; each image took 90 min. These results first demonstrate the feasibility of obtaining velocity images in a fluidized particle bed, but for the relatively small number of particles used in this particular case, the strong fluctuations in the velocity field, and therefore, the need for a large number of data accumulations becomes evident.

Rotating Drum

The first NMR measurements on granular flow in a partially filled rotating drum have been reported in 1993 [2]. Since then, continuous efforts have been made to either visualize the complex patterns arising from segregation effects between two types of particles distinguished by size and/or mass [12, 20, 21], or the actual velocity pattern by means of tagging sequences [13] or velocity encoding techniques [4, 5]. In particular, [5] uses the example of granular flow for a detailed demonstration of the experimental techniques and interpretations of the role of coherent and incoherent motion, providing maps of velocities, VACF correlation times and dispersion coefficients with spatial resolution.

As a demonstration of the essential features of granular flow in a rotating cylinder, Figure 5 presents velocity components in the two orthogonal directions normal to the rotation axis, being combined to a magnitude image and a vector plot. A PMMA cylinder of 88 mm inner diameter and 560 mm length has been filled to half its volume with mustard seeds (diameter 1.5 ± 0.2 mm) and was rotated at $\Omega/2\pi = 0.453$ per s. Experiments were performed on a horizontal 310 mm bore Oxford 1.9 T magnet at New Mexico Resonance, Albuquerque, NM. A double-echo pulse sequence consisting of one slice-selective $\pi/2$ pulse and two refocussing π hard pulses was used in order to compensate for background gradients [5]. The results were taken from [22].

The experimentally obtained velocity fields can be understood with the help of the theoretical interpretation given in Figure 6 [22] for an idealized situation. For small rotation angles, the granular bed will follow the motion like a solid object until the particles at the highest (top right in Figure 6) position will fall downward, generating an avalanche of other particles. Above a certain threshold rotation rate Ω, this series of individual avalanches will turn into a periodic process where the velocity field of all particles can reasonably be well described by average quantities which depend only on position. In Figure 6a, this situation is explained: all particles within the top layer of thickness r_0 (subset “1”, $r < r_0$) are sliding parallel to the surface, i.e. in direction d, with a velocity dependence

$$v_d(r) = v_{max}(1 - r/r_0)^2 - \Omega r \qquad (4)$$

while the particles in the bottom (subset “2”, $r > r_0$) rotate like a solid body with $v_d(r) = \Omega r$. An increase of Ω will lead to deviations from this ideal case, in particular the surface becomes curved [23]. The experimental results of Figure 5 can be interpreted by these different influences. The surface is clearly warped, but remains stationary during the course of the experiment. Figure 5a and b shows the expected smooth behavior of v_x and v_y in the bottom part of the granular bed. Figure 5c features the almost immobile region near the rotation axis and the strong dependence of velocities near the surface. Figure 5d finally visualizes the vectorial components of motion in the plane perpendicular to the rotation axis; the velocity vectors perfectly parallel to the surface can be easily identified, as the significant wall can slip, particularly at the bottom of the cylinder, where the column height of the granular material, normal to the cylinder wall, is largest.

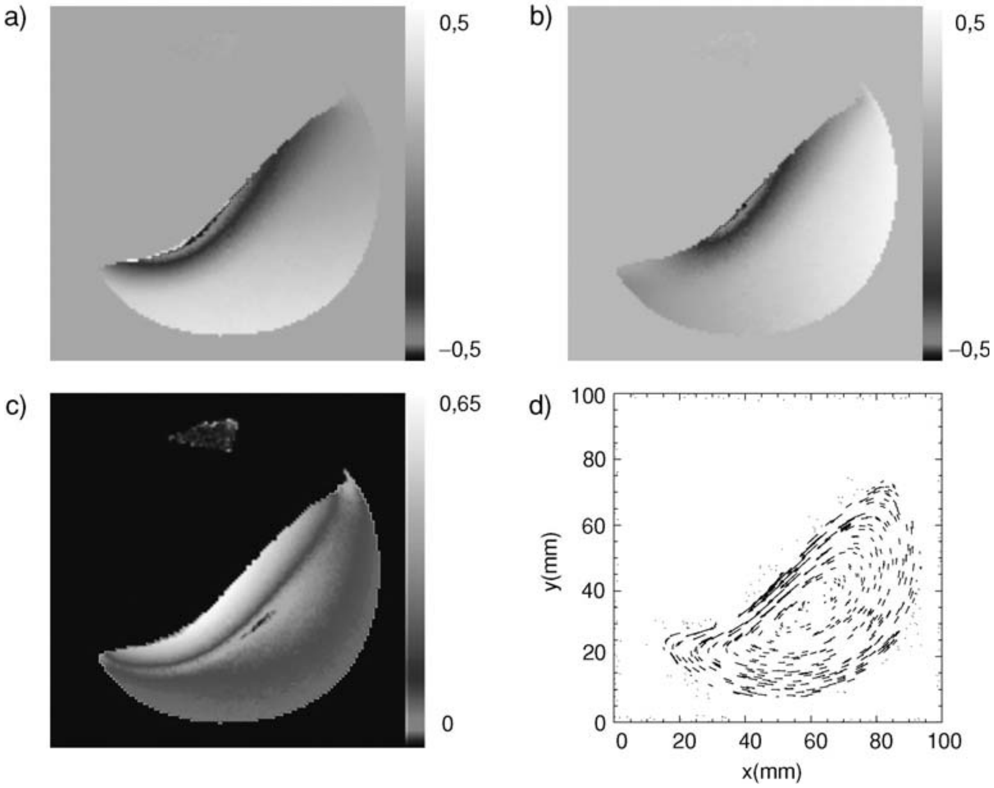

Fig. 5. Velocity maps of a bed of mustard seeds inside a cylinder of 88 mm inner diameter rotating at $\Omega/2\pi = 0.453$ per s; the images were taken from an axial slice of 20 mm width. (a) component v_x, (b) component v_y, (c) magnitude $(v_x^2 + v_y^2)^{1/2}$, (d) vector representation of the sum of (a) and (b). Numbers indicate velocities in m/s. (See also Plate 131 on page XXIV in the Color Plate Section.)

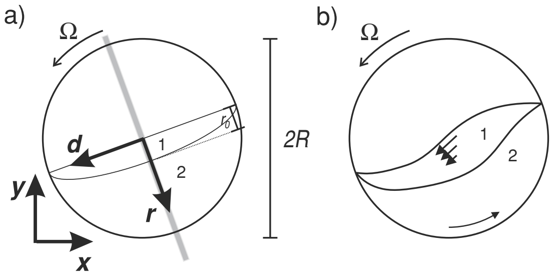

Fig. 6. Velocities for a granular bed inside a cylinder rotating with Ω. "1" denotes the region where granular flow occurs, "2" represents solid body rotation. (a) The surface orientation, which defines the vectors $\boldsymbol{d}$ and r relative to the gravity axis along $-y$, is determined by the angle of repose. (b) For larger Ω, the surface plane is deformed into a sinusoidal shape.

Summary

Granular systems in many ways still are a challenge for the theoretician, particulary if their dynamic behavior shall be understood. To develop and verify suitable methods, however, getting experimental evidence is inevitable. While this is feasible for averaged quantities, such as flow resistance or dispersion parameters, a more detailed knowledge of particle motion might become necessary. Most techniques are optical and are thus limited by the opacity of the granular medium and the presence of a large number of interfaces, restricting accessibility to the surface region of the granular array. NMR does not have this disadvantage and is, at least in principle, able to provide any kind of information about the dynamics of granular systems. It does, however, require systems containing a liquid-like marker component which has a relaxation time that is sufficiently long to allow all necessary manipulations of the spin system for making the encoding schemes applicable.

Such systems will frequently be of model character and are not identical to the real industrial application, but they are entirely sufficient to provide an extensive database with which theoretical descriptions can be developed.

Acknowledgments

We are grateful to R. Savelsberg for preparing and performing the first fluidized bed experiments, to E. Fukushima for helpful comments to this manuscript, and to M. Küppers for continuing support in the current part of this project. Part of this work was done during a productive stay of one of the authors (C.H.) at New Mexico Resonance, Albuquerque, and we would like to thank the whole team of NMR for their assistance and helpful contributions. Financial support by the DFG (Bl 231/25-2) is gratefully acknowledged.

Part III, Section 2:
Applications in Food Science

Foreword to Applications in Food Science

The range of chemicals, structures and materials represented by foodstuffs is enormous. At one extreme sugar is the purest mass produced chemical available. Beverages such as coffee, tea or wine are structurally homogeneous but may contain thousands of chemicals covering a vast range of concentration. Solid foods represent a higher level of complexity combining high levels of heterogeneity and chemical complexity. All these levels represent a challenge to magnetic resonance, and it is not surprising that in this section all available magnetic resonance methods are represented.

The challenge that foods represent to magnetic resonance have been amply exemplified in the biennial series of international conferences “Applications of Magnetic Resonance to Food Science”, the proceedings of which are a summary of state of the art of the subject [1–5]. However these books are summaries of work in progress they do not represent a review of the knowledge of particular areas.

Within this section the authors have been selected as authorities in their fields who are in a position to write an overview of their subjects. Given the scale of the field some selectivity and sharp focus has been required. However each time each author has produced an article which is complete in itself. Overlap, therefore, is inevitable, and a necessity, when each article is a comprehensive survey of its subject matter.

Whilst the entries have been divided by the magnetic resonance technique in the main, I have included section on the applications of a variety of techniques to specific systems. This is needed if the reader is to appreciate the range of problems that confront the spectroscopist and the way in which an approach using a range of techniques can tackle them.

Glossary

agar: A polysaccharide obtained form sea weeds containing galactose units

anthocyanins: Water soluble pigments occurring in many plants

Brix: A system of calculating sugar concentrations based on specific gravity

carrageenans: Sulphated polysaccharides derived from seaweeds

casein: General name for a group of proteins occurring in milk

catechins: generic name for a group of polyphenolic (QV) compounds

couette: A viscometer consisting on concentric cylinders

cutin: A waxy compound occurring in plants especially on leaves

cytoplasm: region within a cell in which the organelles are embedded

durum: Of wheat; a hard type of wheat used in making pasta

epicatechin: a member of the catechin group of compounds

extrusion: A thermomechanical process in which a screw system forces a product through a restricted opening

flavonoid: Polyphenolic (QV)compounds occurring in plants, thought to have role in protection against degenerative disease

galactomannans: A polysaccharide based on the sugar units galactose and mannose

gellan gum: A polysaccharide produced by bacterial fermentation

gliadins: A subset of gluten proteins soluble in ethanol water mixtures

gluten: A mixture of proteins which constitute the major storage proteins of wheat. The determining factor in the viscoelastic behaviour of dough

hemicelluloses: Complex carbohydrates occurring in plant cell walls

high molecular weight subunits: Protein subunits of gluten mainly responsible for the elasticity of dough

isoflavones: A sub group of the flavonoid group of compounds

kaempferol: One of the flavonoid group of compounds

lignins: A highly condensed polymer of phenolic compounds occurring in plants

lintnerization: Partial acid hydrolysis of starch

Maillard reaction: A non enzymic reaction between amino acids and sugars leading to brown colourations and complex chemical products

myofibril: The contractile unit of muscle fibre

myricetin: One of the flavonoid group of compounds

nutrigenomics: The study of how dietary chemicals interact with the genotype and gene expression

oleaginous: Of plants, oil bearing

organoleptic: The sensory properties of a food

pectin: A polysaccharide occurring in plants, widely used in food as thickener

phloretin: A flavonoid present in apples

polyphenols: Compounds consisting of a number of phenolic groups, most of which are thought to have antioxidant activity in vivo

quercetin: A compound belonging to the flavonoid group

renneting: Process of clotting of milk by enzymic action used in cheese making

resveratrol: a phenolic compound found in grape skins and wines

syneresis: separation of a liquid layer from gel

theaflavins: A complex molecule occurring in black tea formed by the oxidation of flavonoids

thearubigins: A group of chemicals similar to theaflavins also occurring in black tea

theophylline: A purine derivative which can act as muscle relaxant

trigonelline: A derivative of nicotinic acid present in green coffee

turgor: pressure within cells that contributes to the mechanical rigidity

vacuole: A sac within the cell that has functions of transport and storage, in plants it contributes to waste disposal and turgor (QV)

vanillin: The active principle in the flavour vanilla

water-holding capacity: The amount of water that may be held in a system without drip loss

High Resolution Solution State Methods

Characterization of the Chemical Composition of Beverages by NMR Spectroscopy

Jurkica Kidrič[1] and Iztok Jože Košir[1,2]
[1]National Institute of Chemistry, SI-1000 Ljubljana, Slovenia; and
[2]Slovenian Institute for Hop Research and Brewing, SI-3310 Žalec, Slovenia

Introduction

Characterization of the chemical composition of beverages is important for establishing their quality and authenticity and in connection with their organoleptic properties. It enables screening for the possible addition of toxic materials and the determination of compounds important for human health. A fine example of the latter are polyphenols found in wine, fruit juices, and tea; they have a wide range of biological and pharmacological effects, including anticarcinogenic, anti-inflammatory, and antioxidant activity [1,2].

Beverages are complex mixtures of different classes of compounds present at a broad range of concentrations. In the past, various analytical techniques have been used in the analysis of beverages, most frequently HPLC, GC, capillary electrophoresis, and conductometry. Because of the compositional complexity of beverages and the wide concentration range of components classical chemical analysis requires time consuming sample preparation. In the case of compounds at low concentration, separation, derivatizaion, and preconcentration are common steps in the procedure. To date, NMR has assumed an outstanding position in the field of chemical analysis of food products. Though NMR is less sensitive than the mentioned methods, sample preparation for NMR is simpler and less time consuming. NMR is nondestructive, selective, and capable of simultaneous detection of a great number of low molecular mass components in complex mixtures. The great advantage of NMR also is the possibility of detecting different nuclei in different spatial and electronic environments. As a consequence, it is the preferable technique for molecular structure determination and the study of molecular interactions in solution. With development of high-field (500–900 MHz) NMR spectrometers with superconducting magnets and the possibility of recording two- and multi-dimensional spectra, NMR has become a powerful method for analyzing at the molecular level complex mixtures like beverages. The use of 2D homo- and hetero-nuclear experiments, pulse sequences for the suppression of strong signals, and special probes, such as the so-called nano probe for μl quantities of samples, has enabled the characterization of minor compounds like anthocyanins [3]. The cold or cryogenic probe also is very promising. By cooling the key probe components to cryogenic temperature significant gains in sensitivity (up to 4 times in comparison to the room temperature probe) can be achieved and for a given amount of sample the experiment time is reduced by a factor of 16. The problems with signal overlapping and the limit detection may be overcome by the use of NMR hyphenation with techniques such as HPLC and MS spectrometry (LC-NMR, fully automated capillary scale LC-NMR, and LC-NMR/MS) [4–6]. Another way to overcome the problem of overlapping in NMR spectra of complex liquid mixtures is the application of diffusion-ordered spectroscopy (DOSY) [7].

NMR sensitivity can be further improved by combining hyphenated techniques with cryoprobe and by the incorporation of an online postcolumn solid-phase extraction (SPE) system for online preconcentration of analytes prior to transfer to NMR tube [4].

Alcoholic Beverages

Alcoholic beverages comprise a large group of beverages containing varying amounts of alcohol (ethanol). Large scale of production includes beer, wine and China rice wine, and distilled spirits such as brandy, whisky, rum, gin, cognac, vodka, and China distilled spirit. The components of alcoholic beverages are very complex and over 1300 compounds have been identified in various beverages. Using NMR for studying the chemical composition of beverages attention was paid mostly to wine and more recently to beer.

Wine

Water is the dominant component in wine. Ethanol, glycerol and other higher alcohols, sugars, organic acids, and various ions are present at high concentrations, while other aliphatic and aromatic alcohols, amino acids, phenolic compounds, and esters are present at much lower concentrations.

Graham A. Webb (ed.), Modern Magnetic Resonance, 1597–1603.
© 2008 *Springer.*

Already in 1976, it was demonstrated that NMR could be successfully used as a quick test for the determination of ethanol in wine, wine like beverages, and liquors [8]. Low-field (hence low cost) NMR spectroscopy has found application for the direct and rapid analysis of ethanol in wine and other alcoholic beverages [9]. A procedure to determine adulterations with diethylene glycol or methanol in natural wine has been described [10,11].

^{13}C NMR was introduced in wine analysis by Rapp *et al*. [11]. It has been shown that ^{13}C NMR can successfully be used for the detection of sugars, alcohols, organic acids, and amino acids [12,13], and that amino acids can be used as fingerprints for monitoring of European wines [14]. Spraul and Hofman have demonstrated the usefulness of LC-NMR for detecting sugars in wine concentrate, and for distinguishing α from β glucose [15]. ^{1}H and ^{13}C NMR spectra of wines of different variety, vintage, and geographical area differ in the intensity of particular signals and in the appearance of some signals [16]. This offers the possibility to follow the variability in their chemical composition on the ground of ^{1}H and ^{13}C NMR spectra. Use of 1D and 2D homo- and hetero-NMR experiments enables a reliable assignment of ^{1}H and ^{13}C resonances of some organic acids and alcohols normally present in wines in higher amounts. Using WET suppression for simultaneous suppression of strong signals ^{1}H and ^{13}C assignment of 17 amino acids and of γ-aminobutyric acid commonly present in wine has been possible [17] (Figure 1).

Brescia *et al*. have characterized the geographical origin of Italian red wines from Apulia using analytical and NMR data (^{1}H shifts) in combination with multivariate statistical methods. Heavy metals and amino acids seem to be the species most responsible for the discrimination of the analytical and the NMR data sets, respectively [18].

The NMR technique of high-resolution DOSY has been applied to the complex mixture of compounds that constitute Port wine in order to achieve improved interpretation of the composition changes between wines of different ages [19].

Wine polyphenols have attracted much attention in connection with the so-called “French Paradox” (i.e. despite of the fact that the French consume a high fat diet they have low rates of coronary heart disease). This has been attributed to the phenolic compounds found in red wine frequently consumed in France. SPE-^{1}H NMR in combination with chemometric analysis has been used for monitoring changes in phenolic composition of Cabernet Sauvignon produced in the Southern region of Brazil over 1986, 1987, and 1995 vintages in order to corroborate the standardization process of this beverage [20]. The combination of NMR with LC and MS methods enabled the characterization of phenolics in the phenolic extract from red wine of the variety Bordô [6].

Anthocyanins, the most important group of plant pigments, are responsible for the color of red wines. They are also considered to be safe color additives in the food industry. Considerable research efforts, concerning their stability, includes structural determinations, the studies of multiequilibria in solution, and the characterization of exchange processes among the different species by NMR

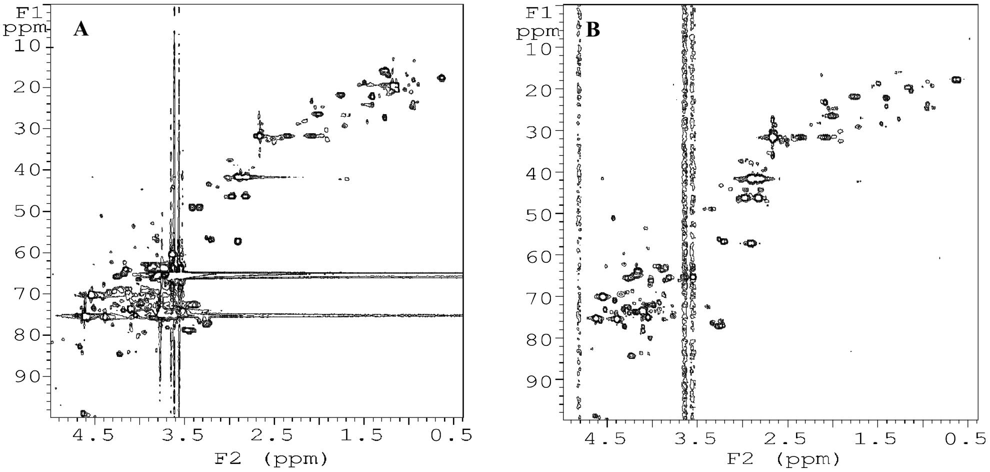

Fig. 1. Part of GHSQC (A) and WETGHSQC (B) spectra of wine in the region between 0.40 and 5.00 ppm in the ^{1}H dimension and between 0.00 and 100.00 ppm in the ^{13}C dimension. In the WETGHSQC experiment WET suppression was applied on water frequency at 4.80 ppm, on ethanol at 3.64 ppm, on glycerol at 3.62 ppm, and on unassigned signals at 3.55 and 3.53.

methods [21]. The identification of vitisin A, an anthocyanin occurring in some wines has been reported [22]. The anthocyanins in a particular LC fraction of red wines from the Coastal wine-growing region in Slovenia have been identified by NMR [3]. The structures of malvidin-derived wine pigments were determined by ^{1}H NMR and MS [23]. ^{1}H and ^{13}C analyses of anthocyanin-derived pigments isolated from red wine has been reported [24,25].

Special attention has been paid to resveratrol found in high content in some European and USA red wines, and particularly in Brazilian red wines. Resveratrol is known for its biochemical and pharmacological effects, including anticarcinogenic, antioxidant, and anti-inflammatory. *trans*-Resveratrol in commercial Brazilian red wines has been determined by ^{1}H NMR spectroscopy [26]. The assignment of ^{1}H and ^{13}C NMR spectra of resveratrol derivatives has been published [27].

The NMR studies of the structures of norisoprenoid glucosidic precursors of wine flavor have been reported [21].

The suitability of proton NMR for the quantitative determination of polydimethylsiloxanes (PDMS) in foodstuffs, particularly in wine, has been demonstrated [28]. PDMS are used in various stages of food processing as structure-shaping food additives and existing regulations of FDA and EU require the amount of added PDMS to be controlled.

The nature of undesirable insoluble deposits adhering to the inner glass surface of bottles of red wine has been investigated by solid-state ^{13}C NMR [29]. The deposit is composed of a phenolic polymer of anthocyanins, procyanidins, and proteins. Weekley *et al*. have extended high-resolution NMR spectroscopy to the analysis of full bottle wine samples [30]. In this work examples of full bottle ^{13}C NMR spectra are provided and the application of the method to the measurement of acetic acid content, the detection of complex sugars, phenols, and trace elements in wine is discussed.

It has been shown that using 5 mm diameter probehead with a 400 MHz spectrometer it was possible to measure fluorine-containing compounds directly in wine with a detection limit of 1.0 mg/l[31].

^{11}B NMR has been used for determining boric acid esters in wine [32]. Boron was found in at least three different molecular species that occur in variable proportions.

Troup and Hunter have discussed the achievements and uses of electron paramagnetic resonance in wine industry [33]. They presented the first observation of free radicals in red and white wines and found that the radical concentration, and therefore the antioxidant action, of white wines was increased by skin and oak wood exposure.

Beer

Beer is a fermented beverage made from malted grains (usually barley), hops, yeast, and water. Fruits, herbs, and spices may also be used to give beer a particular character. The different combination of ingredients, production processes, and storage conditions give rise to an enormous variety of beers [34]. There has been great interest in studying the chemical composition of beer as this information is valuable for the assessment of beer quality and the development of new products. Besides water and ethanol, the major components of beer are carbohydrates that comprise fermentable sugars (e.g. glucose, maltose, and maltotriose), glucose oligosaccharides (dextrins), and arabinoxylanes. Important components in beer also are iso-α- and β-acids responsible for the bitterness of beer and a range of polyphenols. The latter have an impact on foam stability, taste, and clearness of beer and, being antioxidants, also on human health.

The direct characterization of beer by NMR has been carried out by Duarte *et al*. [35]. With the aid of 1D and 2D NMR experiments about 30 compounds were identified. Many different metabolites such as adenosine, cystidine, histidine, phenylalanine, polyphenols, tryptophan, tyrosine, and uridine were also identified using 1D and 2D NMR experiments [6].

Since beer is a very complex mixture of a lot of different compounds occurring in a wide concentration range the signal overlapping and problems with the limit of detection may arise. These problems may be overcome by the use of LC-NMR/MS and DOSY technique. LC-NMR/MS has been used for the identification of dextrins with degree of polymerization up to nine monomers [36]. The preliminary application of DOSY technique to beer has been presented by Gil *et al*. [37]. It was found that this technique was useful mainly for aliphatic and aromatic compounds in beer.

HPLC-NMR has been used for the characterization of hop and beer bitter acids [38,39]. NMR data show clear distinction between cis and trans forms of the iso-α-acids, and unequivocally assign the structure of their acyl side chains.

Differentiation between different types of beer and the classification of different types of beer regarding different raw materials used in their production has become important since the final product should be clearly declared if it is not produced only from the malt originating from barley. For this purpose, NMR spectra can be used as fingerprints. Using the combination of ^{1}H NMR spectra and PCA method most ales, lagers, and alcohol-free samples could be distinguished based on their aromatic composition [35,40]. Also, it has been shown that the low-field NMR region is highly sensitive toward different types of beer fermentation [40].

SNIF-NMR method has been used in the studies of different stable isotope ratios to investigate their values in connection with raw materials from which the sugars used in the fermentation process have originated [41].

Nonalcoholic Beverages

The main difference in the chemical composition between alcoholic and nonalcoholic beverages is the absence of ethanol in nonalcoholic beverages. This simplifies the NMR characterization of composition since it is only the water signal that dominates in the spectra and should be suppressed by one of the suppression techniques.

Tea

Tea is made from the tender leaves of two varieties of the plant *Camellia sinensis*: *assamica* and *sinensis*. Tea was discovered in China where it has been consumed for its medicinal properties since 3000 BC. Tea was introduced to Europe in 17th century and, later, to America and Africa. Tea has become the most popular beverage after water throughout the world and has attracted more and more attention because of reported health benefits owing to its content of antioxidants and, particularly, for its potential for preventing cancer and cardiovascular diseases. Many kinds of tea are produced that can be classified principally into three types: green (unfermented), oolong (semifermented), and black (fully fermented). The important components of tea are the methylxanthine alkaloids, including caffeine and theophylline, polyphenols-flavonoids anthocyanins, catechins, quercetin, kaempferol and myricetin, and volatile and aromatic components. Aminoacids, carbohydrates, lipids, vitamins, minerals, and trace elements were also found. In the manufacture of black tea, catechins can be oxidized to form orange-colored theaflavins and brownish thearubigins. The overall chemical content of tea is influenced by genetic strain, climate, altitude of growth, type of soil, use of fertilizers, and even the processing of tea leaves.

The complete and unequivocal ^{1}H and ^{13}C assignments for a range of green tea polyphenols have been reported [42]. The same authors also assigned ^{1}H and ^{13}C resonances of theaflavin, theaflavin monogallate, and theaflavin digallate [43]. Using 2D NMR the structures of procyanidin and proanthocyanidin oligomers have been elucidated [44,45]. NMR has been used to clarify the antioxidative molecular mechanism of catechins [46]. It has been shown that NMR can be used to analyze simultaneously catechins, amino, organic, phenolic, and fatty acids, and sugars from a single green tea extract [47]. In this study, the data of just under 200 green teas from China, Japan, Vietnam, India, Indonesia, and Bangladesh were collected. It has been pointed out that the geographical origin may be indicated by the chemical composition of green teas provided that a representative number of samples for each population is available. Solution ^{1}H and ^{13}C spectra of commercial samples of green and black teas in acetone-d_6 and DMSO-d_6 and the solid-state NMR spectra have been recorded and ^{13}C chemical shifts of (+)-catechin in solution and in the solid state assigned [48]. Differences observed in chemical shifts are mainly due to the formation of stronger, intermolecularly hydrogen bonded species in the solid, with respect to those formed in solution.

Catechins have received considerable attention due to their diverse pharmacological activities, the commonly discussed mechanism of which is their antioxidative activity. ESR study on the structure-antioxidant activity relationship of tea catechins and their epimers has been performed [49]. Significant differences were found between the scavenging effects of the catechins and their epimers if their concentrations were low. The scavenging abilities of catechins were stronger than those of their corresponding epimers.

Tea infusions and dry tea leaves contain substantial amounts of aluminum, a powerful neurotoxicant that also has a potential for skeletal and hematopoietic toxicity. Hence, the consumption of large amounts of tea may significantly contribute to direct intake of aluminum. It has been shown that ^{27}Al NMR can be used nondestructively to determine aluminum at the ppm level in 0.5 cm^3 of complex matrices such as tea infusions and leaf digests [50]. ^{27}Al NMR has been used for characterization of aluminum complexes in tea extracts [51,52]. These studies provide evidence that Al forms complexes with catechins and organic acids.

Coffee

The beverage commonly called coffee is made from the roasted and ground beans of the coffee "tree"—a tropical evergreen shrub. There are three species of coffee "tree," arabica, originating from Ethiopia, liberica from West Africa, and robusta from the Congo. There are many different varieties of coffee beans due to the wide range of climatic differences in these areas. Coffee is composed of more than 700 compounds. Coffee's chemical composition is determined by a complex interaction of agricultural factors, roasting, blending, and brewing. In the order of abundance the water-soluble constituents ranging from 8% to 0.1% are phenolic polymers, polysaccharides, chlorogenic acids, minerals, water, caffeine, trigonelline, organic acids, sugars, lipids, and aroma compounds.

An extensive study using high-resolution ^{1}H NMR has been performed on expresso cups of two arabica and one robusta samples, and one water extract from ground green coffees and the chemical changes due to the roasting process have been followed [53].

^1H spectra of coffee in aqueous solution show a complicated pattern of signals. From the ^1H spectrum in H_2O/DMSO/HCL (HCL was added for better resolution and DMSO for dissolution of less hydrophobic molecules) it was possible to identify lactic, citric, free quinic, acetic, and formic acids whose concentration could be directly measured. The caffeine molecule was clearly identified as well as chlorogenic acids. The signals due to trigonelline and the signals of the methylene groups of the fatty acids were also observed. ^1H spectra of chloroform extracts are dominated by the signals from caffeine and triglycerides. Many other signals can be related to hydrophobic aromatic substances which were not detectable in the aqueous phase. Many aldehyde carbonyl signals from aldehydes were found. The signal found at 1.84 ppm seems to be a possible marker of the robusta variety. It was also possible to observe the resonances due to sterols.

The effect of roasting has been studied by observing the relative integrals of several selected resonances. The most pronounced is an increase of the concentration of free quinic acid during the roasting and a decrease of the concentrations of citric, chlorogenic, and formic acids. A decrease of the amount of trigonelline and an increase of the amount of its degradation product *N*-methyl pyridine is notable.

Significant differences in the relative intensities of signals originating in aldehydes from the three coffee samples have been observed. The Columbian sample, with a typical sweet and fruity taste, shows a higher content of aldehydes with respect to the Kenya sample.

The ^1H NMR spectra of a complex mixture such as coffee are difficult to interpret in details. Using multivariate statistical analysis it is possible to simplify the spectral data into a series of principal components that cover almost all the spectral variability. This allows for rapid comparison between many spectra, and the identification of differences within or between sample sets from the NMR data. The inherent ability of NMR to provide information about the chemical composition of a sample will allow the identification of source of variation. In this way the presence of inherent differences between coffees produced by different manufacturers and those produced by the same manufacturer has been demonstrated by identifying 5-(hydroxymethyl)-2-furaldehyde as a marker compound using the structural characteristics determined by NMR [54].

Using NMR and LC-MS it has been shown that antibacterial components in the coffee extract are protocatechuic acid (3,4-dihydroxy benzoic acid), chlorogenic acid, and caffeic acid [55].

Electron paramagnetic resonance has been used for the characterization of free radicals in soluble coffee [56]. Coffee solutions exhibit the strong free radical scavenging ability.

Fruit Juices

Fruit juices contain organic acids, sugars, amino acids, phenolics-particularly anthocyanins, vitamins, β-carotene, mineral salts, flavors originating from essential oils, and may contain some alcohol. The concentrations of organic acids, sugars, and amino acids are of comparable order of magnitude to those in wine. Composition and concentration of phenolics vary with the sort of the juice.

Rapp *et al*. have demonstrated the usefulness of ^{13}C NMR for the identification and quantification of amino acids in fruit juices and juice concentrates [12].

Belton *et al*. have assigned the ^1H NMR signals of different fruit juices to characterize several classes of compounds [57,58]. Significant spectral differences between cultivars were found. The results point to the usefulness of NMR in speciation and authentication studies and in the analysis of biochemical changes occurring in fruits and their juices. Vogels *et al*. have demonstrated the usefulness of NMR (peaks in the ^1H spectra) combined with PCA for detecting the adulteration in orange juices [59]. Colquhoun has studied the chemical composition of plum, raspberry, and strawberry purees/juices by ^1H NMR and chemometric methods [60]. For pure juices spectral differences are so great that visual identification is possible. To distinguish pure from adulterated juices (addition of small, fixed amount of plum, or apple juice to raspberry juices), multivariate analysis of NMR spectra is necessary.

Several quercetin and phloretin glycosides in an apple peel extract have been identified by HPLC-NMR/MS [61]. NMR provided the information on the identity of the compounds, the α and β conformations and the position of the glycosides on quercetin and phloretin. The paper by Gil *et al*. describes the application of NMR spectroscopy and LC-NMR/MS to the direct analysis of grape juice [6]. It has been shown that LC-NMR/MS can overcome the problems of signal overlap and the low peak intensity and aids significantly in the identification of aromatic compounds. DOSY NMR has been used for analyzing the composition of apple and grape juices [37]. Particularly useful is DOSY analysis in cases were NMR alone leads to ambiguous assignments. A series of compounds having uncoupled methyl signals but differing in size have been identified; the sugar region only allows interpretation in the anomeric region where signal overlap is reduced; in the aromatic region the larger compounds are identified by slower diffusivities.

Liquid- and solid-state NMR spectroscopy have been used to follow the compositional changes in mango juice and mango pulp during ripening [62]. It has been shown that NMR can aid in controlling postharvest quality and in developing appropriate technologies to enhance the marketable lifetime of the mango, one of the most important commercial fruit crops.

NMR with chemometrics has successfully been used in the discrimination between the orange juice and the pulp wash which is paler, more bitter, and regarded as a lower quality product [63]. It has been shown that dimethylproline is a marker compound for discrimination between two types of juice and can be used for orange juice adulteration.

[2] *NIZO Food Research, Kernhemseweg 2, 6710 BA Ede, The Netherlands*

Carrageenan Structure

Carrageenan is the generic name for a family of linear, sulphated galactans, obtained by extraction from certain species of marine red algae (Rhodophyta) [1]. They are composed of alternating 3-linked β-D-galactopyranose (G-units) and 4-linked α-D-galactopyranose (D-units) or 4-linked 3,6-anhydro-α-D-galactopyranose (DA-units), forming the disaccharide repeating unit of carrageenans (Figure 1). The sulphated galactans are classified according to the presence of the 3,6-anhydro-bridge on the 4-linked galactose residue and the position and number of sulphate groups. The most common types of carrageenan are traditionally identified by a Greek prefix indicating the major component of the sample. To describe more complex carrageenan structures a uniform letter code nomenclature has been developed by Knutsen *et al.* [2]. The three commercially most important carrageenans are called ι (iota)-, κ (kappa)-, and λ (lambda)-carrageenan, the corresponding letter codes are G4S-DA2S, G4S-DA, and G2S-D2S,6S. Two other types, called μ (mu)- and ν (nu)-carrageenan, which are the biological precursors of respectively κ- and ι-carrageenan, are often encountered in commercial carrageenan.

Experimental Setup

Sample Preparation

In general, carrageenan samples are sonicated prior to recording the spectra and the NMR experiments are carried out at elevated temperature to reduce the viscosity of the solution. Samples for ^{13}C NMR are prepared at relatively high concentrations (50–100 mg/ml in D_2O) as compared to ^{1}H NMR samples (5–10 mg/ml in D_2O). The solution is buffered by the addition of 20 mM Na_2HPO_4 to avoid hydrolysis at the elevated temperature used during the acquisition.

Sonicated carrageenan for ^{13}C NMR spectroscopy is preferably prepared according to the following procedure. A carrageenan solution (5 mg/ml in 20 mM Na_2HPO_4) is sonicated for at least three times 30 min in melting ice (Heat Systems XL 2020 sonicator, 12 mm tip, power 475 W, frequency 20 kHz). After centrifugation at elevated temperature, the sonicated solution is dialyzed against phosphate buffer (20 mM Na_2HPO_4) and water and lyophilized. ^{13}C NMR-samples are prepared by dissolving the sonicated carrageenans (70 mg/ml) in D_2O containing 20 mM Na_2HPO_4 and 10 mM internal standard (DSS). Sample preparation for the ^{1}H NMR experiments typically involves dissolving the carrageenan sample (5 mg/ml) at 80 °C in D_2O containing 1 mM DSS and 20 mM Na_2HPO_4, followed by sonication for at least 1 h in a sonicator bath (Branson 2510).

Internal Standards

The use of an appropriate internal standard is of importance to obtain valid chemical shift data. The IUPAC commission for molecular structure and spectroscopy recently recommended the use of 2,2-dimethyl-2-silapentane-3,3,4,4,5,5-d_6-5-sulfonate sodium salt (DSS) as the primary reference for both ^{1}H and ^{13}C NMR spectroscopy in polar solvents. For most purposes the difference between DSS and TMS when dissolved in the same solvent are negligible and, therefore, the data from DSS and TMS scales may be validly compared without correction [3]. Recently, the application of DSS as internal standard for NMR spectroscopy of carrageenans is studied and reported by Van de Velde *et al.* [4]. Moreover, this publication summarizes the chemical shift data of common internal standards, such as DMSO, MeOH, TSP, and acetone, relative to DSS and as a function of temperature and pD. Chemical shifts (δ) given throughout this chapter are relative to internal DSS standard ($\delta = 0.000$ ppm for both ^{1}H and ^{13}C according to the IUPAC recommendations [3]).

Methodology

^{1}H and ^{13}C NMR spectra are generally taken at 65 °C on a 500 or 600 MHz spectrometer. For ^{1}H NMR typically 64 scans are taken using 90° pulses with an interpulse delay of 5 s (T_1 values for the resonances of the anomeric protons of κ- and ι-carrageenan at 600 MHz are approximately 1.5 s [5]). ^{1}H decoupled ^{13}C NMR spectra are generally recorded using 90° pulses and interpulse delay

of 1.5 s and acquiring 30,000 scans (T_1 values for the anomeric carbons of κ- and ι-carrageenan at 400 MHz are approximately 0.5 s [5]).

Quantitative applications of NMR techniques require a number of special precautionary measures. It is of paramount importance to ensure that the inter-pulse delay amounts to at least 4–5 times the longest T_1 value of the resonances used for the analysis [5,6]. For ^{1}H NMR of samples containing mono- or disaccharides relatively long inter-pulse delays have to be applied. On the other hand ^{13}C NMR spectra of carrageenans can be recorded using relatively short inter-pulse delays. An additional complicating factor for ^{13}C NMR is a possible variation of the NOE effects for the different carbons. However in the case of carrageenans all carbon atoms of the repeating unit have one proton attached. Based on this, one would expect little variance in the NOE effect for the different carbons. Experiments with a mixture of κ- and ι-carrageenan using continuous composite pulse decoupling and gated decoupling produced apart from signal to noise ratio (S/N), the same result for the intensity ratio of the anomeric carbon resonances [5].

Analysis of the Major Carrageenan Types

^{1}H-NMR Spectroscopy

Proton NMR spectroscopy is the preferred method to quantify the composition of carrageenan samples. ^{1}H NMR has the advantage of a relatively high sensitivity. Therefore, spectra of samples with low carrageenan concentration can be recorded in a couple of minutes. Generally, 5 mg sample is sufficient to record a ^{1}H NMR spectrum. Moreover, minor components can be detected at concentration down to 1%, due to the high S/N ratio. The quantification of different carrageenan types in a sample by ^{1}H NMR spectroscopy is based on the resonances of the α-anomeric protons (D- and DA-units) in the region from 5.0 to 5.7 ppm (Table 1 and Figure 2A) [4,6]. The signals for the β-anomeric protons (G-units) are less suitable for either identification or quantification purposes. This is the main drawback of proton NMR spectroscopy for carrageenan identification. Moreover, this limits this method to rather homogeneous samples,

Table 1: Chemical shifts (ppm) of the α-anomeric protons of carrageenans referred to DSS as internal standard at 0 ppm[a]

Carrageenan	Monosaccharide[b]	Chemical shift (ppm)
β (beta)	DA	5.07
ι (iota)	DA2S	5.29
κ (kappa)	DA	5.09
λ (lambda)	D2S,6S	5.55
ν (nu)	D2S,6S	5.50
μ (mu)	D6S	5.24

as resonances of some common additives and contaminants can interfere with the major carrageenan types (*vide infra*).

^{13}C-NMR spectroscopy

A typical ^{13}C NMR experiment takes approximately 12–18 h to reach a reasonable S/N. However, due to the high chemical shift dispersion in a ^{13}C NMR spectrum each carbon atom of the repeating unit of a carrageenan variant gives rise to one single signal and the various carrageenan variants show unique and characteristic patterns (Table 2 and Figure 2B). Therefore, ^{13}C NMR spectroscopy is needed for an unambiguous identification of carrageenan samples. The ^{13}C NMR spectra of gel forming κ- and ι-carrageenan have been interpreted, using studies on model synthetic monosaccharide derivatives [7] or oligomeric polysaccharide fragments [8,9]. A well-resolved spectrum of λ-carrageenan was obtained much later [10,11] due to some technical difficulties, which are usually explained by the high viscosity of λ-carrageenan solutions. It should be noted that the biological precursors (μ- and ν-carrageenan) and many other possible carrageenan diads given in Table 2 are usually found only as components of hybrid polymeric molecules.

Analysis of Minor Components

In addition to the common carrageenan repeating units, the NMR spectra of carrageenan samples may show resonances originating from minor constituents and/or contaminants. These signals can result from substituents of the carrageenan backbone, such as pyruvic acid acetals and *O*-methyl groups. Contaminants originate either from the red algal biomass, which were not removed in the carrageenan isolation procedure [1,12] or from compounds (inorganic salts, sucrose, galactomannans) added by manufacturers to improve and/or control some

Table 2: ^{13}C NMR chemical shifts for the most common carrageenan structural units[a]

[a] Carrageenan (30 mg/ml), DSS (10 mM) and Na_2HPO_4 (20 mM) in D_2O recorded at 65 °C.

[b] Codes refer to the nomenclature developed by Knutsen *et al.* [2].

functional properties of carrageenan samples (solubility, viscosity, gel strength, etc.). These additives are generally encountered in standardized commercial carrageenan samples. Low molecular weight contaminations and additives can be removed by dialysis, prior to recording the spectra. The identification of these components is described below and their chemical shifts are summarized in Table 3.

Carrageenan Substituents

NMR spectra of carrageenans may reveal the presence of *O*-methyl substitution of the carrageenan backbone. For example, as 3-linked 6-*O*-methyl-D-galactose residues in κ-carrageenan from *Kappaphycus alvarezii* [13] and in methylated ι-carrageenan from *Clavivlonium ovatum* [14]. These residues give specific signals for OMe at 61.0 ppm in ^{13}C NMR and 3.41 ppm in ^{1}H NMR relative to DSS [4,14]. Pyruvic acid is a common component of many complex carrageenans. It forms a cyclic acetal at positions 4 and 6 of 3-linked galactose residues. This substituent can be identified by characteristic signals of its carbons together with specific substitution effects on the corresponding carbon atoms of 3-linked D-galactose [15]. The ^{13}C NMR chemical shifts of these characteristic signals are 27.6, 103.6, and 178.0 ppm for, respectively, the methyl, acetal, and carboxyl carbon atoms. The pyruvic acid acetals are also detected in the ^{1}H NMR spectra by the methyl proton resonances with a chemical shift of 1.44 ppm relative to DSS [4]. In addition to the methyl

Table 3: NMR chemical shifts for minor components and additives observed in carrageenan samples

		Chemical shift (ppm) relative to DSS as internal standard	
Component/substituent	Observed unit	^{13}C NMR	^{1}H NMR
6-*O*-methyl-D-galactose	Methyl group	61.0	3.41
	C-6	73.9	
	C-5	79.4	
Pyruvic acid acetal	Methyl group	27.6	1.44
	Acetal	103.6	
	Carboxyl	178.0	
Floridean starch	C-1	102.6	
	C-1	74.3	
	C-5	74.0	
	H-1		5.35
iso-Propanol	Methyl group	26.4	1.17

signal, specific substition effects on the chemical shifts of the other protons are observed in the anomeric proton region of the ^{1}H-NMR spectra [15].

Contaminants

Floridean starch, a branched (1-4,1-6)-α-D-glucan structurally related to plant amylopectins, is a reserve polysaccharide of red seaweeds. It is soluble in water and can accompany carrageenans in the extraction and precipitation steps. Apart from the detection of glucose in an acid hydrolysate, the presence of floridean starch can be confirmed by the well-known set of signals of 4-linked α-D-glucopyranose residues in the ^{13}C-NMR spectrum (Table 3) [16]. In the ^{1}H NMR spectra, floridean starch is detected by the signal of the anomeric proton of the α(1 → 4)-linked D-glucopyranosyl at 5.37 ppm [16]. The resonance of the anomeric proton of the α(1 → 6)-linked D-glucopyranosyl appears at 4.98 ppm. Floridean starch can be removed by starch degrading enzymes or by any procedure of separation of acid and neutral polysaccharides. *iso*-Propanol is generally applied in industrial processing to precipitate carrageenans from the extraction liquid [1]. In the ^{1}H NMR spectra *iso*-propanol gives a characteristic triplet at 1.17 ppm and in the ^{13}C NMR spectra the methyl carbon is detected at 26.4 ppm.

Galactans of the agar group (differ from the carrageenan as the 4-linked units have the L-configuration) may be present in carrageenans, when mixed algal populations containing both agarophytes and carrageenophytes are used for carrageenan manufacture. The ^{13}C NMR spectral data of these so-called D/L-hybrids [6], may require complementary chemical analysis to unambiguously identify the agar-like structures. Some red algae contain water-soluble sulfated xylomannans and neutral xylans, but these polysaccharides are usually absent from the common carrageenophytes and only accidentally may be found in carrageenans. ^{13}C NMR spectra of both types of polysaccharides were published and may be used for their identification [17–19].

Additives

Commercial carrageenan preparations are often blended with additives such as sucrose and glucose to adjust their viscosity. In ^{13}C NMR spectroscopy, the anomeric signal of α-D-glucopyranose residue of sucrose may overlap with that of DA2S residue of ι-carrageenan at about 94 ppm. Nevertheless, the presence of sucrose can be unambiguously detected by its other signals in the ^{13}C-NMR spectrum of the mixture [6]. These additives do not disturb the NMR analysis and can in general be detected apart from the different carrageenan forms. Only the resonance of the anomeric proton of glucose overlaps with the resonance of μ-carrageenan in ^{1}H NMR. If necessary, glucose and sucrose together with inorganic salts can be removed by dialysis or ethanol precipitation.

The gelling properties of carrageenans can be considerably improved by addition of several galactomannans or mannans of some higher plants [20,21]. NMR studies were used to elucidate the possible modes of interaction between polysaccharide components in these blends [22]. Since the ^{13}C NMR spectra of galactomannans are well-known [23], the corresponding spectra of mixed preparations recorded at elevated temperatures (above the melting points of gels) can be used to detect the presence of galactomannan additives and to calculate their content relative to carrageenan. In ^{1}H NMR spectra the anomeric proton of the α-D-galactopyranose is observed at 5.0 ppm and that of the β-D-mannopyranose at 4.8 ppm [23].

Flavor–Food Compound Interactions by NMR Spectroscopy

C. Moreau and E. Guichard

Unité Mixte de Recherche sur les Arômes (UMRA, INRA-ENESAD), INRA, 17 rue Sully, BP 86510, 21065 Dijon, France

Interactions between flavor compounds and non-volatile food components (proteins, polyphenols, carbohydrates, polyolosides, etc.) could significantly affect their impact on flavor perception [1,2]. Indeed, the presence of protein or polysaccharides can decrease aroma intensity by forming complexes depending on the nature, the concentration, and the physicochemical properties of aroma compound [3].

Headspace or chromatographic methods have been extensively used to investigate the retention of aroma compounds in food matrices [4,5]. However, these techniques only give indirect information on aroma binding and no information at a molecular scale. Spectroscopic techniques have also been used to study interactions between small molecules and macromolecules since they can give information on the binding site localization and on the nature of the interactions [6–9]. Of all of the spectroscopic techniques, NMR spectroscopy is probably the most effective in investigating ligand–macromolecule interactions as protein–protein, drug–protein, DNA–protein, lipid–protein or small molecules–macromolecules [10–14]. Compared to other spectroscopic methods, NMR is a non-invasive technique and ligand–macromolecule complexes can generally be investigated in their natural environment (pH, temperature, buffer conditions) without spin labeling or fluorescent probe.

A wide range of NMR methods can be used to characterize macromolecule–ligand complexes and gives access to structural and dynamic information on both the ligand and macromolecule [13,15–17]. The choice of which of these NMR methods to use, depends on various factors such as macromolecule and ligand size and nature, equilibrium binding constant, and the complex dissociation rate (K_D). They depend on the facts that, after complex formation, mean perturbations are observed on NMR parameters such as chemical shifts, resonance broadening, relaxation constants, diffusion coefficients, or the nuclear Overhauser effect (NOE). The equilibrium constant, K, for the ML complex, where M is the macromolecule and L the ligand is defined as:

$$\mathrm{M} + \mathrm{L} \underset{k_{\mathrm{off}}}{\overset{k_{\mathrm{on}}}{\rightleftarrows}} \mathrm{ML}; \quad K = \frac{k_{\mathrm{on}}}{k_{\mathrm{off}}} = \frac{[\mathrm{ML}]}{[\mathrm{M}]\,[\mathrm{L}]}$$

The ligand binds to the macromolecule at a rate of k_{on}, the association rate, and leaves its binding site at a rate of k_{off}, the dissociation rate which depends on the ligand concentration, [L], and the interaction strength between the ligand and the binding site, K_D. The dissociation constant of the ML complex is defined as $K_D = k_{\mathrm{off}}/k_{\mathrm{on}} = [\mathrm{M}][\mathrm{L}]/[\mathrm{ML}]$. For such a ML complex, the appearance of the NMR spectrum depends principally on the exchange kinetic determined by the k_{off} rate, but also on the dissociation constant, K_D.

Depending on the NMR method used, the ligand and/or the macromolecule are observed and information on the dissociation constant and complex stoichiometry, binding site localization, and dynamic parameters (diffusion coefficient, relaxation times) can be obtained from the complex.

The most popular method of NMR used to investigate interactions of a specific ligand–macromolecule complex is based on the chemical shift changes (and/or on resonance broadening) of the macromolecule using 1D and/or 2D NMR spectroscopy. The spectrum of the macromolecule alone is recorded and is then compared to the one in the presence of the ligand. Chemical shift changes ($\Delta\delta$) of the macromolecule are induced by the presence of the ligand when it binds to the macromolecule. The observed spectral changes will depend on the exchange rate (τ) at which the complex is formed [18]. Three exchange regimes can be defined on the NMR timescale.

1. The slow exchange if $1/\tau \ll |\Delta\delta|$ in which two resonance sets are observed corresponding to the free and complex molecule resonances.
2. The rapid exchange if $1/\tau \gg |\Delta\delta|$ in which one set of resonances is observed but progressively shifted with the increase concentration of the ligand. Observed chemical shifts (δ_{obs}) of implicated groups in the complex are a weighted average of the free and bound molecule chemical shifts.
3. The intermediate exchange is observed if $1/\tau \approx |\Delta\delta|$ in which a broadening of resonances is observed.

For most of the studied systems, the rapid exchange is observed.

Other information can be obtained using this NMR method. Firstly, the chemical shift changes of specific chemical groups on the macromolecule provide information on the binding site localization. For example, ^1H–^1H TOCSY NMR spectra give information on short- and long-range coupling through chemical bonds and particularly for a protein, on signals of the NH–CHα region which is a fingerprint of the amino acid sequence. 1D and 2D NOE NMR experiments give information on proton coupling through space, thus showing which protons are spatially closed (<5 Å). The binding sites and the spatial position of the ligand can then be determined. 2D ^{15}N–^1H and ^{13}C–^1H HSQC/HMQC NMR experiments, which give proton–nitrogen or proton–carbon correlations, is also widely used in drug screening applications known as the "SAR-by-NMR" [12] but labeling of proteins is necessary.

Moreover, in the rapid exchange regime, information on ligand affinity and complex stoichiometry can be obtained by using NMR titration experiments. By progressively increasing the ligand concentration to the macromolecule solution (or inversely), and by recording spectra for each concentration, the dissociation constant, K_D, of a ligand–macromolecule complex can be calculated based on the chemical shift changes [18]. This method implies to previously assigned macromolecule resonances. However, proton spectra of macromolecules with high molecular weights such as proteins are complex and assignment of chemical shift resonances is difficult. Thus, nuclei such as ^2D, ^{13}C, and/or ^{15}N are generally used to label macromolecules in order to simplify the interpretation of NMR spectra [19]. Other nuclei can be observed in NMR and some works concern ^{19}F NMR spectra of small ligand molecules. However, few or no fluorined aroma compounds are present in food [20,21].

The effect of a ligand binding can also be demonstrated by following the changes of others NMR parameters such as diffusion coefficient or relaxation times. The main difference with the chemical shift method is that macromolecule with high molecular weights and with no labeling can be studied as the resonances of the ligand are preferentially visualized.

Differences in relaxation parameters, the transversal ($1/T1$) and the longitudinal ($1/T2$) relaxation rates, can be used to detect complex formation. Relaxation times characterize the dynamic movements of the molecules. A small molecule that tumbles rapidly in solution has a long relaxation time while a macromolecule has a shorter relaxation time since it tumbles more slowly. Thus, the complex formation will lead to a decrease in the relaxation times [22,23]. As in the chemical shift method, the relaxation parameter is observed in the spectrum of the ligand alone and compared to the spectrum of the complexed ligand and the K_D determination is calculated using NMR titration experiments.

As relaxation parameters, changes of the diffusion rate can be used to detect ligand interaction. Diffusion NMR method, or diffused-edited NMR, also known as affinity NMR in the drug design domain, is based on the diffusion coefficient of the ligand and the macromolecule [24]. A small molecule—free in solution—diffuses more rapidly than a large molecule such as a protein. If this small molecule interacts with the macromolecule, it will adopt the dynamic characteristics of the macromolecule and, then, its diffusion coefficient will decrease in comparison to the one of the free ligand. Diffusion NMR methods are based on the fact that translational diffusion depends inversely on the size of the molecule (Stokes–Einstein equation). Measuring the diffusion coefficient by NMR is based on pulsed field gradient impulsions [25–28]. Each molecule is firstly "coded" in its spatial position using a magnetic field gradient pulse, the "coding" gradient, the molecule then diffuses freely during the diffusion time, Δ, and after the application of a second field gradient, the diffusion information is obtained through signal attenuation. Two types of diffusion NMR experiments can be used. In the 1D NMR experiment, the diffusion parameters are chosen so as to suppress resonances of ligand which do not bind to the macromolecule (diffusion filter) and only resonances of bound ligands are observed [29]. The second experiment is a pseudo-2D NMR experiment (DOSY NMR) leading to spectra in which molecules are separated according to their diffusion coefficient. In the rapid exchange regime, the observed diffusion coefficient, D_{obs}, of the ligand is a time-weighted average of diffusion coefficients of free and bound ligands. By assuming that the diffusion constants of the complex and the free protein are the same, the fraction of the bound ligands can be obtained and the dissociation constant calculated.

Several other methods using NMR experiments are based on magnetization transfer from the macromolecule to the ligand (and inverse) such as transfer NOE [14], saturation transfer [30], and (inverse) NOE pumping [31,32]. More particularly, NOE pumping method combines a diffusion experiment and a classic NOE experiment. In the first step, a diffusion filter allows the suppression of all the NMR ligand signals while conserving the macromolecule signals. During this time, macromolecule magnetization is transferred to the bound ligands. In other words, only binding ligands adopt the magnetic properties of the macromolecule and this information is then detected during the NOE experiment. No signal is observed for free ligand molecules. Thus, using a mixture of different ligands, it is possible to differentiate between bound and free ligands. The first NOE pumping experiment has been applied to ligand–protein interactions and compared to diffusion NMR experiments [31]. The authors showed that diffusion experiments could not explain the interactions between salicylic acid and the L-ascorbic acid since the average diffusion rate (D_{obs}) is close to the diffusion rate of the free ligand. They demonstrated unambiguously the interaction using NOE pumping experiment.

Despite all the works using NMR to study ligand–macromolecule interactions, there are very few studies concerning the interactions of aroma compounds with food molecules. Two principal macromolecules have been studied to probe aroma-binding sites: wine phenolic compounds and β-lactoglobulin, a bovine whey protein. Phenolic compounds—the major components of plants—are able to complex proteins, metal ions, or aroma compounds. In wine, the polymerization degree and self-association of polyphenols and interactions of polyphenol–aroma compounds seem to have an effect on wine organoleptic properties. The β-lactoglobulin is found in various food preparations and since its structure is well established, this protein is widely used as a model in interaction studies. It is known to interact with different aroma compounds and two binding sites seem to exist (the central cavity and the external binding site), however, despite numerous studies, there is a lack of information on aroma biding site localization [2,33–35]. The investigation of the nature and strength of aroma compound–polyphenols or β-lactoglobulin interactions will allow us to better understand flavor perception in food and beverages.

Dissociation constants have been calculated for aromatic flavor and macromolecule complexes using different NMR methods.

^{1}H 1D NMR titrations of procyanidin monomers (catechin and epicatechin) have been realized using two aroma compounds—the benzaldehyde and the 3,5-dimethoxyphenol [36]. In order to investigate titration experiments, ^{1}H chemical shifts and scalar coupling constants (J) of proton rings of monomers have been previously assigned. Firstly, the authors have calculated self-association constants for each compound alone. With increasing concentration, all proton chemical shifts of polyphenol compounds were upfield shifted due to self-association. For the aroma compounds, benzaldehyde and 3,5-dimethoxyphenol were self-associated at concentrations up to saturation. Titration of phenolic compounds, kept at a constant concentration (5 mM), with increasing concentration of aroma compounds lead to an upfield shift of all the flavanol protons that it is characteristic of a rapid exchange on the NMR timescale. The observed chemical shift change, δ_{obs}, of phenolic resonance is a weighted average of the free (δ_{P}) and complex (δ_{PA}) phenolic species, and the chemical shift change, $\Delta\delta$, is defined as $\Delta\delta = \delta_{\text{P}} - \delta_{\text{obs}}$. The dissociation constant, K_{D}, can be calculated knowing $\Delta\delta$ and $\Delta\delta_{\max}$, with $\Delta\delta_{\max} = \delta_{\text{P}} - \delta_{\text{PA}}$ and assuming a 1:1 model. The benzaldehyde complex is stronger ($K_{\text{D}} = 0.0955$ M with catechin and 0.152 M with epicatechin) than the 3,5-dimethoxyphenol complex ($K_{\text{D}} = 0.194$ M with catechin and 0.169 M with epicatechin) whatever the polyphenol but these two aroma compounds have a different affinity for the two phenolic compounds. The increase of the scalar coupling for H_2 and H_3 protons of catechine in the presence of aroma compound also reveals a conformational change of the pyran ring. Moreover, the K_{D} values are higher than the self-association constants of the polyphenol monomers. These titrations were unsuccessful with limonene, isoamyl acetate, and ethylhexanoate due to their low solubility.

The inverse NMR titration, i.e. fixed aroma concentration in the presence of increasing concentration of catechine, has been carried out with all five aroma compounds. The binding affinity order of benzaldehyde and 3,5-dimethoxyphenol is similar to that in the first titration, but K_{D} values are two times larger. The authors underline the limitations of the method, however self-association of macromolecules has not been considered in this experiment. These NMR results suggest hydrophobic interactions between flavor and the polyphenol compounds.

In the same way, Jung *et al.* have investigated the binding of 2-methylpyrazine, vanillin, and ethylbenzoate with two phenolic compounds, gallic acid, and naringin [37]. Titrations were carried out at three temperatures with phenol/aroma molar ratio of 1:1, 1:2, and 2:1. Strong upfield shifts of specific resonances of phenolic and aroma compounds were observed for gallic acid with vanillin and 2-methylpyrazine whereas small chemical shift changes were observed in the presence of ethylbenzoate. Chemical shift changes are smaller with naringin than with gallic acid whatever the aroma concentration. The concentration equilibrium constant, K_{a}, for each complex was determined using NOESY titration experiments assuming a 1:1 stoichiometry and the thermodynamic parameters were calculated. As the temperature increases, K_{a} decreases for all the aroma compounds due to an increase of the kinetic energy of the molecules although the effect is greater for vanillin ($K_{\text{a}} = 51$ and 17 M^{-1} for vanillin and $K_{\text{a}} = 14$ and 12 M^{-1} for ethyl butyrate at 25 and 60 M^{-1}, respectively). Enthalpy and entropy values suggest that ethylbenzoate interacts more weakly than vanillin and 2-methylpyrazine.

The binding of aroma compound to proteins—bovine serum albumin (BSA) or β-lactoglobulin—has been studied by Jung *et al.* by 1D diffusion NMR method [38,39]. In the first study, diffusion coefficients of four aliphatic ketones (2-heptanone, 2-octanone, 2-nonanone, and 5-nonanone) have been measured alone in a phosphate buffer or in the presence of BSA with increasing concentrations of aroma compounds (molar ratio of 0.02 to 0.18) at 25 °C. For each aroma compound, the apparent diffusion coefficient strongly decreases after binding to protein and this decrease is more pronounced with the increase of BSA/aroma molar ratio. For example, the 2-nonanone diffuses at 630 μm^2/s in buffer solution while it diffuses at 140 μm^2/s in the presence of the protein. The association constant, K_a, the number of binding sites, and the free energy of association (ΔG) are measured from the experimental data of the apparent diffusion coefficient (D_{obs}). The association constant decreases as the aroma chain length increases (323 M^{-1} for the 2-heptanone to 833 M^{-1} for the 2-nonanone) as well as an increase in ΔG values for each additional methyl group suggests that there are hydrophobic interactions. Six to eight binding sites have been found for these ketones.

Jung *et al.* [38] have used the NOE pumping method to investigate interactions of aroma compounds to proteins or tannin extracts. From a mixture of three aroma compounds (benzaldehyde, vanillin, and 2-phenylethanol), specific interactions of benzaldehyde and vanillin to BSA have been shown using the same method. Moreover, the binding of ethylbenzoate to polyphenols of tannin extracts has been showed using this method. In another study, the interactions of α- and β-ionone to β-lactoglobulin at ligand–protein ratio of 0.25 to 5 and at different pH values were investigated [39]. The authors showed that binding affinities of two ionones are higher at pH 9 with a binding affinity of β-ionone higher than that of α-ionone. However, large aroma concentrations were used in this study (up to 10 mM) which could affect protein conformation and due to their low solubility, some aroma compounds could not be studied. And with this method, no information on binding site localization was obtained.

In order to determine the binding strength and how aroma compounds interact with polyphenols compounds, Jung *et al.* have realized NOESY (and ROESY) spectra in which the coupling between the hydroxyl groups of polyphenol and adjacent protons can be observed [37]. NOE experiments reveal interaction between protons of vanillin and 2-methylpyrazine and protons of hydroxyl and carboxyl groups of gallic acid. No intermolecular interactions for ethyl butyrate–gallic acid complexes and for aroma compounds–naringin were shown.

Lübke *et al.* have investigated the binding localization of aroma compounds, β-ionone, and γ-decalactone, to β-lactoglobulin using ^1H–^1H 2D NMR spectroscopy [40]. Experiments have been carried out in conditions for which the protein is in a monomeric state. In order to show these interactions, the authors compared the amino acid chemical shifts of 2D TOCSY and NOESY spectra of the protein alone with one of the protein after the addition of the aroma compound. The authors demonstrated the binding of the two aromas on the protein based on changes of cross-peak chemical shifts and, knowing the complete assignment of protein resonances they determined which amino acids were implicated in this interaction [41]. For the protein–γ-decalactone complex, all the amino acids located on the β-barrel which forms the wall of the central cavity are affected whereas for the protein–β-ionone complex, fewer amino acids are perturbed that concern different amino acids and region on the protein. Two cross-peaks are visible after the addition of aroma compound to the protein solution which seem to correspond to the aldehyde proton for the γ-decalactone and to the olefinic protons for the β-ionone. However, their exact assignment cannot be defined due to the crowed region of the protein resonances and further work is in progress.

Recently, DOSY NMR experiments have been performed on two aroma compounds—ethyl butyrate and linalool—in matrices containing a polysaccharide (1%, w/w), *iota*-carrageenan widely used in food as a texturing agent, with different amounts of salt at 30 °C [42]. Using this method, the authors showed that, based on their self-diffusion coefficients, aroma resonances are well distinguished to the polysaccharide peaks and they can directly measure the diffusion coefficients of the aroma compounds at concentrations used in food. By comparing the spectra of the aroma compounds alone and aroma compounds in different matrices, the authors showed that no interactions occurred between ethyl butyrate and the polysaccharide molecules but that sodium ions have an indirect influence on aroma diffusion, probably by acting on the matrix structure. At 30 °C, ethyl butyrate diffuses at 871 $\mu m^2/s$ into the matrix with 0.1% NaCl and at 1004 $\mu m^2/s$ in matrix with 0.5% NaCl. In matrix with 0.1% NaCl, linalool diffuses slightly slower than ethyl butyrate ($D = 669\ \mu m^2/s$). Other experiments are in progress to understand how the nature of the aroma compound and the salt content affect aroma diffusion. DOSY NMR is a powerful method as it can be applied to complex food matrices without labeling and with low concentrations of aroma compounds, however no information on binding site is available.

NMR spectroscopy is a powerful technique used to study weak interactions of small ligand–macromolecule (∼mM) and information on binding site localization and on dynamic parameters (relaxation times, diffusion coefficients) at atomic level. Using changes in NMR parameters, the stoichiometry of the complex, association or dissociation constant values, and enthalpic parameters can be calculated. All this information can be obtained for complexes in their natural environment without degradation or probe addition. Depending on the type of NMR method used, macromolecule or ligand resonances are observed. Firstly, 2D NMR experiments and isotope labeling for proteins with high molecular weights are often necessary, principally to determine binding sites. Methods based on the ligand visualization are suitable for non-labeled proteins with unlimited molecular weights. On the other hand, an excess in ligand concentration can be a main limitation for studying some aroma compounds due to their low solubility. This remark is available for all NMR titrations when concentration of the ligand is increased. Compared to the other techniques, the main advantage of NMR spectroscopy is that we can study molecules in natural conditions (pH, buffer, temperature, etc.) and its gives information on both the dissociation constant and the binding site localization. Moreover, the diversity and the improvement of the NMR methods can allow different approaches in studying ligand–macromolecule interactions.

High-Resolution Nuclear Magnetic Resonance Spectroscopy of Fruit Juices

Ana M. Gil and Iola F. Duarte
Department of Chemistry, CICECO, University of Aveiro, 3810-193 Aveiro, Portugal

High-resolution nuclear magnetic resonance (NMR) spectroscopy has increasingly been used to provide direct and comprehensive compositional information on food complex mixtures. The ability of ^{1}H NMR to detect a wide type of compounds simultaneously and non-invasively makes it an important potential tool for the quality control of fruit juices. Such approach is distinct from the well-established Site-specific Nuclear Isotope Fractionation (SNIF)-NMR method which usually involves ^{2}H observation for the measurement of isotopic ratios and correlation with metabolite origins; this subject will not be described here since it justifies in itself a separate entry in this handbook. Furthermore, this entry will mostly deal with accounts of direct NMR analysis of whole juices, rather than of juice extracts, unless otherwise specified.

One of the earliest reports on NMR of fruit juices describes the characterisation of orange juice and apple juice using a water suppression method based on the selective effects of a paramagnetic agent on the transverse relaxation time (T_2) of water [1]. This resulted in spin-echo 270 MHz ^{1}H NMR spectra of improved sensitivity and resolution of solute resonances otherwise obscured by water. Ten years after this report, the enormous advances in NMR technology and software, leading to high magnetic field instruments and improved pulse sequences, have enabled high levels of water signal suppression and large dynamic ranges to be achieved. These improvements were first applied to the analysis of a selection of fruit juices (grape, apple, pineapple, grapefruit, and orange), at a field strength of 600 MHz, for which a wide range of compounds on the order of micromoles per millilitre were observed, with acquisition times of 7–14 min [2]. The qualitative analysis of fruit juices by high-resolution 1D and 2D NMR has, since then, benefited immensely from the available high-field NMR instrumentation ($>$500 MHz) [3] enabling comprehensive compositional information to be gathered for grape juice [2,4], apple juice [2,5], mango juice [6], orange juice [2,7], and tomato juice [8,9]. Figure 1 shows high-resolution 500 MHz ^{1}H NMR spectra of apple juice and grape juice, whereas Figure 2 shows an expansion of the ^{1}H-^{13}C heteronuclear single-quantum coherence (HSQC) spectrum of a Red Setter tomato juice. Due to the continuous need to detect low abundance compounds, often in crowded spectral, improvements in the qualitative analysis of juices by NMR have become increasingly necessary. Diffusion Ordered SpectroscopY (DOSY) has been explored in tomato juice (Figure 3) [9], apple juice and grape juice [10] as a potential tool to assign compounds with basis on their diffusivity values, in addition to NMR parameters. This method was found to be of value when identifying compounds in less overlapped spectral regions, the diffusivity information loosing resolution in the most crowded regions such as the carbohydrate region in juices. Hyphenated NMR involves the tandem use of NMR with liquid chromatography (LC) and mass spectrometry (MS), in the forms of LC-NMR or LC-NMR/MS. These methods achieve an extreme simplification of the full 1D NMR spectra as a result of chromatographic separation of compounds at the first stage of the experiment. Figure 4 shows an on-flow record obtained for grape juice, under conditions suitable for the analysis of aromatic compounds [4]. The lines shown correspond to spectra of single compounds or simple mixtures. The spread of NMR signals in the aromatic region as a function of retention time clearly shows the extension of spectral simplification achieved. In the case of grape juice, LC-NMR/MS enabled several cinnamic acids and their derivatives to be identified for the first time by direct analysis of the juice. The use of improved methods for qualitative analysis of fruit juices may, naturally, be explored with numerous aims in mind, including the study of biochemical changes with ripening [5,6] or with storage [5], detection of adulteration or contamination. However, the practical use of NMR in particular towards the latter applications necessarily involves vast numbers of samples and this brought about the tandem use of NMR with chemometrics. The potential of NMR for the authentication of orange juices was explored using 400 MHz 1D ^{1}H NMR together with Principal Component Analysis (PCA) and discriminant analysis [11]. In this way, authentic and non-authentic samples could be distinguished with basis on their NMR spectra, taking into account parallel measurements by alternative analytical methods [high-pressure liquid chromatography (HPLC) and atomic absorption spectroscopy]. As a result,

additions of sucrose, beet medium invert sugar or sodium benzoate could be detected, as well as other deviations from authenticity requirements. The problem of orange juice adulteration with pulp wash is, at present, a pressing one in the fruit juice industry and this was addressed using PCA and discriminant analysis of ^{1}H NMR spectra of more than 300 orange and pulp wash juices [7]. It was shown that dimethylproline plays a key role in discriminating between the two sample types, with higher levels in pulp wash. In addition, at least 21 more peaks were identified in the spectra as potential markers of this type of adulteration. An additional study aimed at distinguishing apple juices of different varieties (Spartan, Bramley, and Russet) using PCA and discriminant analysis of their 500 and 600 MHz ^{1}H NMR spectra [12]. Samples were successfully separated in terms of variety, through the analysis of different subregions of the spectra. Different levels of malic acid and of sucrose were found

to be important discriminating variables, as well as some variations in minor constituents.

The potential of NMR to quantify and identify a large number of compounds makes it a leading technique in the emerging area of metabolomic studies. Within this area, a matter of present and increasing interest is the safety testing of genetically modified organisms (GMO) and their food derivatives. The NMR detection of possible unintended effects following a genetic modification has been significantly explored for tomato [8,13–15], a major transgenic crop. Such studies have involved mostly the analysis of tomato extracts and the methods used comprise combination of ^{1}H NMR and statistics [8,13,14] as well as off-line combination of LC and NMR[13,14]. The methodology proposed in ref. [13] and [14] is shown to enable the comparison of compositional alterations in a novel tomato crop with respect to related non-transgenic reference lines. The authors point out, however, that such differences must be statistically demonstrated to be significant compared to those arising from natural genetic and/or physiological variations [14]. The compositional effects of up-regulating flavonoid biosynthesis in tomato (*Lycopersicon esculentun*), in order to enhance its antioxidant capacity, was specifically investigated [8]. ^{1}H NMR of tomato extracts, in tandem with multivariate and univariate methods, was shown to distinguish between modified and non-modified tomatoes, not only with basis on the expected flavonoid increases but also on the levels of, at least, 15 additional compounds. Again, the authors point out that, although meaningful, such changes may fall into the same order of magnitude as natural variations observed in a field-grown crop. Further work along similar lines describes the application of ^{1}H NMR to the detection and quantification of metabolites related to the genetic origins of strawberry fruit quality and to tomato transformants overexpressing hexokinase [15]. In this study, absolute quantification of metabolites was performed by signal integration, with a synthesised electronic reference signal and validated by enzymatic or HPLC measurements.

Absolute quantitation by NMR usually involves signal integration, which is often not a straightforward subject due to extensive signal overlap and to possible intercomponent interactions that may affect visible signal areas. In spite of these difficulties, useful methods have been developed recently for the absolute quantitation of chlorogenic acid and of (-)-epicatechin in cider apple juices by NMR [16,17]. In both cases, 1,3,5-benzenetricarboxylic acid was added to the juice sample as an internal standard, allowing successful quantification of the selected metabolites by signal integration.

Introduction

Analysis of metabolites has always been an essential component in life science research since metabolites are the downstream and even endpoint products of a given biological process, thus carrying rich information about the process [1–8]. Whilst genes and proteins set the stage for what is likely to happen [1–8], metabolites indicate what has actually happened in the levels of proteins, transcriptions, and genes. Therefore, metabolite analyses will undoubtedly be vital to gain insights into life processes and to understand in greater depth the complexity of the whole organisms and their interactions with the environment. In the "post-genome" era, it is the total metabolite complement [3–8] (metabolome), not some parts of metabolites, that becomes the focus of attention. The changes of the metabolome, i.e., metabonomics [7], provide unique, dynamic, integrated, and holistic insights into the changes of the given biological process in metabolic level. These changes can be traced back, in turn, to the activities in the levels of proteins, transcriptions, and genes. The metabolomic studies of organisms (metabonomics or metabolomics) thus have increasingly become the inseparable part of the integrated systems biology strategy. The NMR-based metabonomics approach has become an established method and proven powerful for studying animal systems [7] by scrutinizing the changes of the metabolites in biofluids, such as blood plasma [8–12], urine [4–9,13] and cerebrospinal fluid [14–19], and biopsy tissues [9,20–26]. Since biofluids contain information about biochemistry status of human body as a whole, analysis of the metabolite compositions in biofluids provides information on the responses of human systems to the effects of the internal physiological changes and external stimuli, such as diets, drugs, and diseases. Furthermore, metabolome of tissue samples [20–24] provides information about what is happening *ex vivo* or *in situ* and sometimes can provide direct evidences *in vivo*.

Amongst biofluids, blood plasma consists of macromolecules, such as lipoproteins and immunoglobulin, and a range of low molecular weight metabolites such as amino acids, hydroxycarboxylic acids, and sugars [10–12]. In order to maintain consistency of the internal environments of human body, the content of blood plasma has to be kept reasonably stable until such homeostasis is perturbed by some "abnormal activities." Therefore, changes of the blood plasma metabolome offer a sensitive handle to monitor the changes in human physiology. On the other hand, some waste products have to be disposed for the same purpose of homeostasis and such wastes are excreted and disposed in the form of human urine. Urine contains small amount of proteins, amino acids, hydroxycarboxylic acids, considerable amount of salts, and metabolites of exogenous compounds such as those from diets and drugs [8,27]. Therefore, human urine contains information reflecting the superposition of many biochemical processes taking place in the human body. Urine analysis also provides embedded information about the functioning state of some organs such as kidneys [28], liver [29,30], and heart [31] as well. High-resolution ^{1}H NMR spectroscopy can be used to detect the signals of a wide range of low molecular weight metabolites simultaneously in the complex samples such as biofluids. These signals carry information about the identity, concentration, and interactions of metabolites in the samples. If required, the endogenous and exogenous metabolites detected in such samples can be related to the pathophysiological effects such as the state of health [31–33], dietary, and drug interventions.

Apart from analysis for human and animal samples, recently, high-resolution NMR spectroscopy have been employed to analyze food of plant origins [34–41]. Both liquid samples and tissues have been examined and metabolite resonances were assigned. Some plant extracts [42–46] were also examined for various purposes. Such concept can be easily extended to studies of the plant metabolites or metabolome.

Most of the metabolites are organic compounds and consist of the elements such as carbon, hydrogen, nitrogen, oxygen, and sometimes phosphorus. It is therefore conceivable that ^{1}H, ^{13}C, and ^{31}P are natural reporting probes for NMR studies of metabolism. Sometimes, ^{2}H, ^{13}C, and ^{15}N labeling are also used to provide probes with little or no background signals. ^{19}F NMR has also been used in drug metabolism studies for the similar reasons. However, high-resolution ^{1}H NMR methods are by far the most widely employed methods due to the high sensitivities and many reviews have been published already on ^{1}H NMR studies of biological samples [2–8]. Therefore, this chapter is not aimed to provide a comprehensive review of this literature. Instead, it is aimed to discuss problems related in such studies and possible solutions to them.

In almost all the biofluids and tissue samples, water is the nature's chosen solvent and accounts for more than 80% (w/w) of the whole samples. The concentration of water protons are therefore in the level of 100 M in contrast to that of the metabolites in 10^{-6}–10^{-3} M or even lower. For nuclei other than ^{1}H, NMR detection is not affected by the amount of water. For ^{1}H NMR and related correlation spectroscopy, however, such drastic difference in concentration becomes a huge dynamic range problem and water signals have to be suppressed even though in certain cases these signals also carries important information.

Water Suppression

For biological fluid samples, the ideal water suppression method should have (1) high effectiveness to suppress the water signals that are 10^{5}–10^{9} times more intense than metabolite signals, (2) high selectivity (or sharp suppression profile) to suppress the water signal without suppressing other signals close to water, and (3) high efficiency to suppress water signals within a short duration to minimize magnetization transfer with the exchangeable or interactive protons [12]. Besides, the method should be easy to be implemented in both 1D and multidimensional experiments. For the time being, the water suppression methods in use can be classified into three categories, spectral editing methods based on spin relaxation or translational diffusion properties between water and solutes, presaturation methods based on actively irradiating the water signals, and tailor-excitation methods by using the pulsed field gradient (PFG).

The relaxation- and diffusion-based methods take advantage of the difference between water and solutes in T_1, T_2, or self-diffusion rates. The T_1 and diffusion-based methods are only useful for solutes having T_1 and self-diffusion coefficients drastically different from these of water. For example, in aqueous solution of macromolecules, one can observe signals of macromolecules by the choice of an appropriate relaxation recovery time in the inversion-recovery experiment [47,48]. The gradient-HMQC/HSQC experiments [49] can also be used to saturate the water signals by repeating the (^{13}C or ^{15}N) experiment rapidly. In this case, the water signals can be saturated due to its long T_1 but can be done so only partially. The DRYCLEAN method [50] was based on the difference in diffusion coefficients between water and macromolecules by using a diffusion filter prior to detection. Whilst these methods are of some values for aqueous solution of macromolecules such as proteins, they are not useful for the biofluids (i.e. the solution of small metabolites) since the T_1 and diffusion rates of solutes and water are on the similar scale. A T_2 editing method has also been reported [51,52] and can be applied to some biofluids. This method, however, requires artificially shortening the T_2 of water by adding contaminants [51,52] to the sample, is thus invasive.

The irradiation methods are implemented by applying a secondary irradiation on resonance to the water peak. Amongst them, the simplest one is often referred to as "presaturation method," which combines a single pulse with a weak continuous wave (CW) irradiation on resonance to water signals [53] during recycle delays and necessary durations. The strength of such irradiation has to be controlled to a reasonable level to avoid heating-induced stability problems. Since the chemical shift of water is dependent on the sample temperature, the CW water suppression method requires good spectrometer stability, excellent magnetic field homogeneity and reasonable temperature controlling facilities. Generally, modern spectrometers can meet such demands. The presaturation method can be readily implemented in most pulse sequences and does not affect quantification of spectra with exception for the resonances close to water and interacting with water (via. NOE for instance).

The other variant, called 1D NOESY [54] or NOSEYPRESAT, is equivalent to the first increment of the NOESY experiment [54] (90°-t_1-90°-t_{mix}-90°-AQ-RD), where t_1 is set to about 3 μs, the mixing time, t_{mix}, to 0.1–0.15 s combined with irradiating the water resonance during both the t_{mix} and the recycle delay (RD). This method works well with systems where the exchange between water and metabolites is either slow or absent, resulting in much better suppression of the residual "hump" from the water signals [11,55]. However, unlike single-pulse version, this method is restricted to the flip angle of 90° and can only be used for quantitative work with an extremely long RD employed. Nevertheless, the FLIPSY (FLIP-angle adjustable one-dimensional NOESY) experiment [55] (θ-t_1-180-t_2-180-AQ-RD) can overcome the quantification problem by using a small flip angle ($\theta \sim$ 10–30°) and short t_1 and t_2 delays (~2 μs). It has to be noted that the water suppression efficiency is inferior to the 1D NOESY method. It is obvious that the above methods have only one suppressed region (or "null point") in the whole spectrum. These irradiation methods can be implemented on any spectrometers.

The other type of water suppression methods have been developed using PFGs in the form of so-called tailored excitation [56,57] or excitation sculpting [58] and therefore requires gradient facilities. Amongst them, WATERGATE (water suppression by gradient-tailored excitation) schemes are widely employed in the form of either three pairs [56] (W3) or five pairs [57] (W5) of symmetric pulses. The latter showed much improved (or narrower) suppression profiles [57]. However, such methods often employ lengthy pulse sequences and cause some phase distortions to multiplets with a large J couplings even with perfectly optimized spectrometers [58]. Furthermore, more than one "null points" are produced [57] and signals close to such points are attenuated. Another selective excitation sequence, WET [59–62], has also been reported, in particular for LC-NMR studies, with capability of suppressing several signals [61]. Whilst these sequences are reasonably efficient, elaborate optimization is often required posing a great hurdle for the non-specialists. On the other hand, a method called double PFG spin-echo (DPFGSE) have been reported [58] to suppress water resonance efficiently without causing any phase distortions and can be implemented in any sequences readily without elaborative optimization [58]. These gradient dependent methods require gradient facilities and often attenuate, to some extent, the broad signals such as those of lipids in plasma and tissues due to T_2 relaxation or J modulations in the spin-echo-based methods.

For all water suppression methods, the metabolite signals close to the "null points" (e.g. water resonance) will also be affected, if not suppressed completely. If these signals are essential for the purpose of studies, they can be recovered with magnetization transfer through scalar or dipolar coupling as in so-called RECUR-NMR methods [63]. RECUR-NMR methods also reduce, to some extent, the phase distortion caused by WATERGATE. From the above discussion, it becomes clear that the methods meet all criteria for an ideal method remains to be developed and in reality, the choice of water suppression method ought to be as simple as possible if the method is sufficient for the purpose of studies.

Assignments of the Metabolite Resonances

The water suppressed ^{1}H NMR spectra of biological samples, such as urine, blood plasma, and tissues, are information-rich but data complex owing to (1) large number of resonances and (2) superposition of the resonances from a multitude of different chemical entities in multiphase compartments. To make meaningful use of such spectra, the first step is often to assign as many resonances as possible. Normally, the assignments of metabolite signals rely on the positions (chemical shifts), multiplicity patterns (spin–spin coupling), and the intensity of the signals. However, extra care has to be taken when assigning the 1D ^{1}H NMR spectra since the NMR parameters can be affected by many factors such as pH, concentration, temperature, ionic strength, and interactions. To overcome the problems of resonance overlapping, 2D NMR experiments are normally employed to spread the resonances into greater space and to establish the atomic connectivity. Amongst them, ^{1}H–^{1}H 2D COSY [64], TOCSY [65], ^{1}H–^{13}C HSQC [66], HMQC [67], and HMBC [68] NMR experiments are useful for routine metabolite identification. Due to complex interactions the metabolites experiencing in the biological samples, "spiking" with the authentic compounds offers a simple but extremely useful way for unambiguous assignment.

In practice, however, the complexity of the spectra of the heterogeneous samples such as blood plasma [2–12,69] and tissues [20–23,70,71] are amplified by the presence of a large number of overlapping resonances resulting from a wide range of molecules, such as proteins, lipids, lipoproteins, and metabolites [2–12,20–23,69–73], which often have different NMR line shapes resulting from the biomolecules with a wide distribution of molecular weights and mobility. Consequently, the predominating peaks arising from the relatively high concentration molecules often obscure some substances at a low concentration. However, these low-concentration molecules can sometimes be extremely important for classifying toxicological or disease processes. For example, in blood plasma, the intense broad lipoprotein resonances often overwhelm the signals from small metabolites; in tissues, the dominant lipid resonances often obscure signals for the low-concentration metabolites. To overcome these problems, the hyphenated HPLC-NMR-MS can be employed to separate each component before spectroscopic detection. One can also use the non-invasive spectral editing methods to separate NMR signals without separating samples.

Spectral Editing in Biological NMR Spectroscopy

A number of NMR spectral editing methods have been developed based on the variation in spin relaxation [11,69], diffusion [74], and spin coupling properties. For molecules experiencing weak interactions, the diffusion rate measured as the apparent diffusion coefficients is inversely correlated with the molecular size. Therefore, larger molecules diffuse slowly whereas small ones diffuse fast (unless they are bound to macromolecules). Thus, the complex NMR spectra of biofluids can be edited by taking advantage of the differences in diffusivity (or size) of molecules. Diffusion-edited NMR spectroscopy can be implemented by inserting a "diffusion filter" to attenuate or even eliminate resonances from the fast-diffusing molecules [74–77] prior to the detection. Some 1D and 2D diffusion-edited NMR methods have been employed to aid the assignments of resonances arising from the lipoproteins [74–76] in human blood plasma.

Spin relaxation properties can also be exploited in spectral editing. For example, "relaxation-filters" can be inserted, before detection, to attenuate or eliminate the resonances selected according to their relaxation times. Such editing methods have been widely used in high-resolution NMR of biopolymers in the solid state [78–83] for many years and have proven useful. Three major spin relaxation phenomena can be encountered in high-resolution NMR of biological samples, spin–lattice relaxation characterized by T_1 and $T_{1\rho}$, and spin–spin relaxation described by T_2. Whilst the three relaxation times are identical for small molecules tumbling rapidly and isotropically, they can be different in multiphase, multicompartment systems, such as biofluids [12] and tissues [23,84].

To use T_1 editing, an inversion-recovery sequence ($180°_x$-τ_1-$90°_x$) is used to prepare spins in such a way that NMR signal intensities are dependent on the length of τ_1 relative to T_1. The 90° pulse can serve as a read-pulse in 1D experiments or the excitation pulse for the 2D experiments. One can purposefully make a choice of τ_1 to have a positive peak ($\tau_1 > T_1{*}\ln 2$), negative peak ($\tau_1 < T_1{*}\ln 2$), or no peak at all ($\tau_1 = T_1{*}\ln 2$). The T_1 editing has also been reported in 1D NMR as a method of solvent suppression [47,48]. Similarly, the magnetization can be prepared using a spin-locking sequence ($90°_x$-$\tau_{\mathrm{SP}y}$) such that resonances with different $T_{1\rho}$ can be separated by choosing an appropriate spin-lock time, τ_{SP}, and spin-lock power [12]. In the case of T_2 editing, the magnetization can be prepared using a spin-echo sequence, typically a CPMG sequence [85], [$90°_x$-(τ_{E}-$180°_y$-τ_{E})$_n$]. By choosing appropriate τ_{E} and n, the signals can be separated according to their T_2 (i.e. inverse of the line width). Generally, the broad NMR signals from macromolecules or bound small molecules are attenuated or even eliminated, leaving the sharper resonances from the mobile small molecules unaffected. The resonances having intermediate T_2 will be attenuated to an intermediate extent.

However, the T_1-, $T_{1\rho}$-, and T_2-edited 1D NMR spectra of biological samples can still be too complex [12], since NMR spectral peaks from the low concentration metabolites can still be severely overshadowed. Consequently, it is necessary to extend the relaxation-editing approach to multidimensional NMR spectra to establish atomic connectivity and to achieve resonance assignments unambiguously. Examples for T_1-, $T_{1\rho}$-, and T_2-edited 2D NMR methods have already been reported in studying blood plasma and biological tissues [12,86–90]. NMR spectra can also be edited according to the multiplicity using J-resolved spectroscopy or the nature of carbons (CH_3, CH_2, CH, or C) by using DEPT [91], INEPT [92] for ^{13}C NMR and MAXY [93–98] for ^{1}H NMR. These spectral editing techniques can be used in conjunction with most of 2D NMR sequences.

Other Useful Techniques

For most heterogeneous biological samples such as cells and tissues, ^{1}H NMR lines are broadened by residual dipolar interactions, chemical shift anisotropy and susceptibility [99,100]. With the magic angle spinning, these line-broadening effects can be eliminated and high-resolution magic-angle spinning NMR (HRMAS) [20,21,101] spectra can be obtained with similar quality to that of the solution state NMR. In addition, gradient is also available at the magic angle, allowing the gradient-enhanced NMR spectroscopy to be carried out effectively as well. However, automation in terms of shimming and sample exchanges is still in their infancy even though some automatic sample exchangers are commercially available. Therefore, throughput of the HRMAS NMR remains low (two to three samples per hour).

In contrast, high throughput facilities for solution state NMR are well developed and can be in the forms of either flow –injection [102] or automatic sample exchanger. Both methods can screen up to 400 samples per day with options of sample recovery. For flow NMR, the samples are handled with a liquid handler and a sample transfer system together with a flow NMR probe. The whole process can be automatically executed including sample preparation, delivering samples to the detection cells, matching and tuning of probe, pulse length calibration, shimming, data acquisition, and processing. The commercial flow probes include normal 5 mm probe which can handle 300–500 μl samples and micro-flow probes such as micro-capillary probes [103,104] that can handle samples with a volume as small as 3 μl. Automatic sample exchangers can also be used to handle samples in NMR tubes and, in this case, an exchanger, a lot of spinners, and NMR tubes are required, even though there is no need for a liquid handler, sample transfer systems, and Flow NMR probes.

NMR techniques are intrinsically insensitive and any attempts to improve the detection sensitivity have to consider ways to reduce noises (or increase signal-to-noise ratio). There are two types of "noises" in NMR spectroscopy, electronic noises, and chemical noises [8]. The chemical noises arise from the signal overlapping in particular in complex mixtures. To reduce the chemical noises, NMR has to be done with higher magnetic field to increase the chemical shift dispersion or with reduced complexity, ideally, in the form of a single compound by using separation techniques. Such separation can be done either separately or by hyphenating with NMR. The possible hyphenation between separation techniques and NMR detection now includes HPLC-NMR [105,106], HPLC-NMR-MS [107–109], HPLC-SPE-NMR-MS [110], CE-NMR or CEC-NMR [111,112], and SFC-NMR [113–115]. In these hyphenations, the purified fractions (peaks) from HPLC, capillary electrophoresis (CE), capillary electrochromatography (CEC), and supercritical fluid chromatography (SFC) can be measured with NMR or/and MS to obtain structural information. In LC-NMR-MS, the whole chromatogram can be detected in on-flow, direct stop-flow, or timed slice modes. One can also store interesting chromatographic peaks into separate loops and then carry out NMR/MS studies by transferring the loop content. Similarly, one also can store these peaks on a solid-phase extraction (SPE) cartridge and then elude the cartridges individually to determine the molecular characteristics of the peaks [110]. The SPE method offers higher detection sensitivity than loops due to much more compact peak elution and a great opportunity to trap the same peak several times to increase concentration of solutes, increasing detection sensitivity drastically. However, appropriate hardware is required and concentration of the solvent impurities will also be increased with multiple trapping. Hyphenated SFC and NMR and CE-NMR are less common but have enormous potentials for future applications.

On the other hand, in order to reduce the electronic noises, one has to reduce the temperature at which the detection electronic devices work. This involves cooling the detection electronics down to about 20K to increase the sensitivity for about fourfolds and such facilities are now available from almost all the major manufacturers. The latest cryogenic probe can also be used as a flow probe (for flow-injection and LC-NMR work) as well as a conventional tube probe. With a cryogenic probe on a moderate (say, 600 MHz) spectrometer, the detection limit can go down to the nanogram level. However, for the cryogenic probes, the radiation damping remains a massive problem especially when dealing with biological samples.

NMR-Based Metabonomics Techniques

The advantages of NMR spectroscopy include (1) detecting all the NMR visible molecules simultaneously, non-invasively, and non-destructively, (2) providing rich molecular information such as structure, dynamics, interactions, pH, and concentrations, and (3) making it possible to do *in vivo*, *in vitro*,*ex vivo*, and *in situ* studies. The molecular information so obtained includes that from both the endogenous and exogenous metabolites related to the human metabolisms. However, thousands of resonance signals so generated, e.g. from ^{1}H NMR of a urine sample, present a challenge to data interpretation. Such challenge is amplified even further by the requirements of multiple parallel sampling. For example, multiple samples are required for both controls and non-control samples in order to obtain statistically meaningful results. In such cases, visualizations of the spectra by conventional techniques (e.g. human naked eyes) are no longer adequate or possible at all for the data analysis. The large density of the NMR spectral data, nevertheless, can be regarded as fingerprints of the biological systems. Then multivariate data analysis can be readily applied on the NMR data to reduce the complexity and to visualize patterns inherent in the data. Such combination provided the basic methodology for the NMR-based metabonomics/metabolomics studies. In fact, the combination of NMR with the multivariate statistical data analysis, such as principal components analysis-and partial least square-based methods [30,116,117], has been extensively applied to study the human inborn errors of metabolism [118,119], the biochemical consequences of genetic strain differences in mice [120,121], and the responses of the biological systems to drugs [23,122] or other xenobiotics [123].

NMR detection strategies for studying the dietary effects on human metabolism are similar to that for drug effects and some results have already been reported using NMR-based metabonomics. For example, an elevation in urinal excretion of TMAO [124] is reported for subjects who consumed fish meals. Zuppi *et al.* [125] reported that the level of lipids and carbohydrates in diet profoundly affects the levels of urinary metabolites such as alanine, lactate, glycine, and hippuric acid. In another case, after 6 weeks of Atkins' diet containing high lipid, protein but no carbohydrate, a male subject showed elevation of citrate and ketobodies (e.g. β-hydroxybutyrate, acetoacetate) and depletion of alanine in his blood plasma compared to the same subject with normal diet. Furthermore, the level of the low-density lipoproteins (or bad cholesterols) was also elevated after Atkins's diet (Y.L. Wang, unpublished results).

The NMR-based metabonomics methods have also been used to monitor the human metabolomic changes following dietary intervention with soy isoflavones [126]. Substantial intersubject variations have been detected in the plasma metabolomes of five subjects [126]. Although the extent of metabolic responses to soy intervention, amongst volunteers, was subject dependent, the nature of such responses were consistent across subjects by showing changes in plasma lipoproteins, amino acids, and carbohydrates [126]. Similar observations were also obtained from a study of the effects of chamomile tea ingestion on human metabolism using metabonomics approach [127]. Clear differentiation between the samples obtained before and after chamomile ingestion was observed based on subtle changes in the spectral signature relating to increased excretion of hippurate, glycine, together with depletion in the levels of urinary creatinine. It was concluded that perturbation of the aromatic species might be indicative of altered intestinal microbial activity. Samples obtained in the 2-week period after daily chamomile ingestion formed an isolated cluster in the discriminant analysis map inferring that the metabolic effects of chamomile ingestion were not reversible during the 2-week post-dosing period. Such studies highlighted the potential for NMR-based metabonomics technology in the assessment of nutritional interventions, and demonstrated the sensitivity of the approach for characterizing subtle metabolomic changes in the presence of a high degree of variation from genetic and environmental sources.

Future Perspectives

It is clear that NMR-based metabonomics will be one of the most important applications of NMR spectroscopy in studies at the interface of chemistry and biology. Increasingly, our understandings to biological systems are required to treat such systems as an integrated entity or to use systems biology approaches. The information in the metabolism level is therefore essential to understand the functional aspects. In nutritional sciences, the NMR-based metabonomics, integrated together with nutrigenomics, nutritranscriptomics, and proteomics, will undoubtedly provides more complete understandings to the specificity of human responses to nutrients and assists the identification of surrogate tissues and biomarkers that can be used to predict a response. In such a revolutionary era, however, the shortcomings of NMR spectroscopy will have to be further addressed. From the hardware aspects, it is predictable that the NMR frequency will move beyond 1 GHz (1000 MHz) to further increase the chemical shift dispersion and to reduce the overlapping (or chemical noises). In addition, detection sensitivity will also be increased by developing the higher field spectrometers perhaps coupled with further reduction of the electronic noises of the detection circuits. For both aspects, the development of high temperature (e.g. liquid nitrogen or even room temperature) superconductors will be extremely helpful since not only the development of magnet production technology will benefit from such materials but also, when such materials are used for the detection circuits, the electronic noises will be drastically reduced. From the spectroscopy point of view, substantial efforts will be needed to overcome the radiation damping effects as the sensitivity increases. The other important area includes developing ultra-rapid methods to record the multidimensional NMR. Some recent reports of ultra-rapid multidimensional NMR spectroscopy are leading toward such progress already [128–135].

High-Resolution NMR of Milk and Milk Proteins

Josefina Belloque
Instituto de Fermentaciones Industriales, Consejo Superior de Investigaciones Cientficas (C.S.I.C.),
Juan de la Cierva 3, 28006 Madrid Spain

General Remarks

Milk contains basically water, carbohydrates, fat, proteins, and salts, in the form of a solution, a colloidal dispersion and an emulsion (Figure 1). There are excellent books that cover most aspects of milk and milk components [1,2]. High-resolution NMR has been applied to milk, and such studies include quali- and quantitative chemical analysis, the identification of isolated compounds, the *in vivo* monitoring of dairy bacterial metabolism, relaxometry studies, and structural studies of milk components, particularly proteins [3,4]. Initially, milk should be an ideal food product for NMR analysis because it is liquid. However, there are several considerations that have to be taken into account:

1. The presence of compounds in uneven proportions causes significant overlapping or masking of resonances. To solve this problem some components can be removed: fat can be removed by centrifugation in cold conditions, caseins can be precipitated by acidification to pH 4.6, both fat and caseins can be simultaneously removed by ultracentrifugation, whey proteins can be fractionated by ultrafiltration, and lactose can be partially removed by ethanol precipitation. Regular laboratory methods are found in specialized scientific publications, and official standard methods can be obtained from the web page of the International Dairy Federation (http://www.fil-idf.org).
2. The differences in size and mobility of milk components (Figure 1) leads to a wide range of relaxation times and mixed resonance line widths. Fat globules and casein micelles are large aggregates of variable sizes, with very low mobility compared with small soluble components, free in solvent, such as lactose. If better signal and resolution of the aggregated components is needed, and structural information is not required, it is convenient to disaggregate these large structures. For instance, since casein micelles are held together by calcium phosphate, and orthophosphate is partially in the form of insoluble calcium salts, chelation or removal of calcium, with EDTA or CHELEX resin, disaggregates both of them.
3. The natural composition changes significantly among species but, within the same species, there are also significant differences related to factors such as the breed, geographical location, stage of lactation, and even individuals. Bovine raw milk of a great mix of cows is available from dairy farms. Processed milk, purchased in supermarkets, comes from mixed milk, and has usually been subjected to a standardization process. However, differences can still be found among milks from different countries, farms, or milking seasons.
4. The different processing steps that milk undergoes along the processing chain leads to changes in composition and physico-chemical properties, for instance:

   - Storage: proteolysis, lipolysis, and other enzymatic reactions change the composition.
   - Heating: protein unfolding and aggregation, changes in phosphate distribution, and formation of products derived from the Maillard reaction. These alterations occur to different degrees as a function of the type and intensity of process (e.g. pasteurization, sterilization, UHT, drying).
   - Homogenization: Disruption of large structures, micelles and fat globules, into smaller ones, due to the pressure treatment.

NMR Spectra of Milk

Water, lactose, and wide lipid signals dominate the ^{1}H- and ^{13}C-spectra of whole milk, and little attention has been paid to these types of spectra. Recently, Hu and cols. [5] have applied 1D and field gradient HSQC and HMBC experiments to whole milk and milk extracts, and have assigned the observable resonances (Figure 2).

On the other hand, ^{31}P-spectra of milk are very clean (Figure 3) and the resonances assignments are available [3]. ^{31}P-NMR has the capability to distinguish among different forms of phosphate present naturally in milk (orthophosphate, casein SerP, phosphorylated carbohydrates, phosphoglycerydes, creatine-P, nucleotides), as well as diphosphates, added as stabilizers. Many of the phosphorylated compounds visible in the spectrum are

found in the serum, while most SerP, a significant proportion of phosphate, and diphosphate additives, are present in the micellar phase. ^{31}P-NMR spectra has allowed to analyse the distribution of phosphates between the micellar and the soluble phases, the evaluation of differences among species and during lactation, and has revealed new enzymatic reactions induced by pseudomonas. Quantitative analysis by ^{31}P-NMR is a good alternative to the classical spectrophotometric method, which is tedious and poorly informative. However, quantitation can be tricky, since the relaxation of the different compounds, even when disaggregated, can differ largely. For instance, in a 400 MHz spectrometer, ^{31}P spectra of a homogeneous sample, obtained from milk after fat and calcium removal, shows T_1 values of ~2 and ~12 s for casein SerP and orthophosphate, respectively. The use of the relative area to an internal standard can provide quantitative results, provided that full relaxation between transients is achieved,

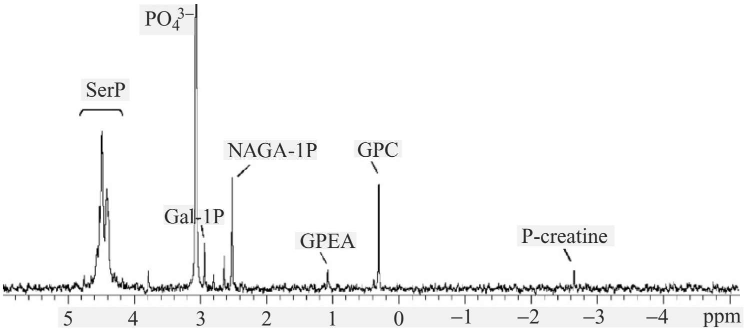

Fig. 3. ^{31}P-NMR spectrum of non-fat milk, pre-treated with CHELEX, at pH 9.5. SerP: casein phosphoserine, PO$_4^{3-}$: orthophosphate, Gal-1P: galactose-1-phosphate, NAGA-1P: N-acetylglucosamine-1-phosphate, GPEA: glycerophosphoethanolamine, GPC: glycerophosphocholine, P-creatine: phosphocreatine.

which may require a long time. If a shorter pulse (e.g. 45°) is used, relaxation is faster, thus shortening the experiment time. If the samples are homogeneous and relaxation times do not vary among samples, a 90° pulse and a short delay time (i.e. partial relaxation) can be used, obtaining reproducible spectra with good S/N (Figure 3). ^{31}P-NMR has also widely been applied to the study of the structure of caseins and casein micelles (see below).

In addition to proteins, the milk fat has become one of the most interesting fractions to study in milk. Quali- and quantitative NMR analysis of lipid components is being applied to develop methods for authentication of dairy products. The lipid analysis can discriminate among species [6], but also among different types of feeding and/or geographic origin [7], since the feeding of an animal modifies the milk fat composition. ^{13}C- is used to analyse the distribution of mono-, di- and unsaturated fatty acids, as well as the positional isomers of fatty acids in triacylglycerols. These compounds are fractionated from milk and dissolved in an organic solvent, usually $CDCl_3$. ^{31}P-NMR is used for the analysis of phospholipids, previously extracted from the fat globule membrane, and prepared in solvents such as dimethylformamide-triethylamine-guanidinum hydrochloride.

NMR Studies of Milk Proteins

The structure and structural changes of milk proteins have been a major research subject in the dairy field. First of all, the structure of milk is closely related to the structure of the casein micelles, which still remains a matter of controversy, although most accepted models agree that κ-casein is located on the surface of the micelle. Second, many milk proteins are allergens, and this activity is closely related to their structure and conformational stability. Third, the physiological and biological activities of peptides derived from milk proteins, that depend on the peptide structure, are a current matter of study. Fourth, the structural changes induced to milk proteins are related to their functional properties (e.g. gelling, foaming, emulsifying, thickening capabilities), that are used to improve dairy and non-dairy products. The 3D structure of milk proteins and peptides have been elucidated by NMR, X-ray diffraction and theoretical modelling, and have provided the basis for the study of induced structural changes. Whey proteins that are soluble and with well-defined structures, have been subjected to considerable research by NMR compared to caseins.

Caseins

They are difficult to study since their native form is the micelle. There is evidence to support that caseins are rheomorphic, i.e. they do not have a defined structure, and some authors have even further suggested that they are in an open/unfolded state [2,8]. Caseins are multiphosphorylated proteins that contribute to the solubilization and transport of calcium and phosphate, due to their ability to interact with calcium phosphate, through SerP residues, clustered in limited regions of their polypeptide chain. Phosphopeptides carrying these SerP residues are studied because they also bind calcium phosphate and are easier to study. NMR and structure models have been reported for phosphopeptides, such as β-CN f(1–25), α_{s2}CN f(2–20), casein macropeptide (κ-CN f(106–169) and, the most recent one, α_{s1}-CN f(59–79) [9].

Casein Micelles

Calcium phosphate, particularly the micellar calcium phosphate (MCP), plays an essential role in the stabilization of micelles, by cross-linking SerP residues of caseins, but at least part of the calcium phosphate is in equilibrium with serum (SCP). When casein micelles are subjected to ^{31}P-NMR, the observable resonances belong to casein SerP signals and the phosphate present in the micelle. Using liquid-state NMR, casein SerP appears as a broad peak providing little information, unless the micelles are disaggregated by calcium chelation. The use of solid-state magic angle spinning (MAS)-NMR provides higher resolution. ^{31}P single-pulse- and cross-polarization MAS NMR have been applied to casein micelles and milk powder. Using model compounds, and with the aid of simulation software, this technique has shown that phosphate is in the form of hydroxyapatite (HAP), has allowed the identification of mobile and immobile forms of HAP, and has made possible to identify Ca^{2+} binding SerP sites from different caseins [10].

Whey Proteins

Opposite to caseins, these are globular proteins that are soluble in the milk serum. The major proteins are β-lactoglobulin (BLG) and α-lactalbumin (ALA), although other proteins, such as BSA, lactoferrin, immunoglobulins and lysozime, are present in minor quantities. Even though many studies have been done with whey bovine proteins, the only structure that has been elucidated by NMR is that of BLG. This protein is easy to purify, it has a MW of 18 KDa, and gives reasonably sharp NMR signals, especially at pH 2–3 since, under these conditions, it is a monomer, and very stable. The structure has been solved by both X-ray crystallography and NMR (Protein DataBase (PDB) ID 1CJ5), and complete ^{1}H- and ^{13}C and ^{15}N assignments are available. The structure of bovine ALA was obtained from X-ray diffraction (PDB ID 1F6S), although ^{1}H, ^{13}C and ^{15}N NMR assignments are available from the BioMagRes data Bank (BMRB ID 4811 and 4332). Similarly, the structure of bovine lactoferrin comes from X-ray diffraction (PDB ID 1BLF). In some cases, such as BSA, lysozyme and immunoglobulin, crystal structures are available for other species different than bovine (e.g. human serum albumin (PDB ID 1BM0), or hen egg lysozyme (PDB ID 193L). Crystal structures can be very useful for partial NMR assignments of bovine whey proteins.

Peptides

Peptides present in milk are the result of proteolysis of caseins or whey proteins by enzymes, either indigenous in milk or from microorganisms. While proteolysis is, in general, detrimental to milk, it enhances the quality of some dairy products, particularly fermented milks and cheese. In the last years there has been an increased interest in the identification of milk peptides with antimicrobial, immunomodulant, ACE-inhibiting and other biological activities that can be used to improve the quality of fermented dairy products. NMR can contribute to the evaluation of the structure-function relationship. For instance, lactoferricin is a peptide derived from lactoferrin that has higher antimicrobial properties than its precursor. While this peptide has a helix shape in the native protein (PDB ID 1BLF), NMR studies have shown that, in solution, it has a hairpin conformation (PDB ID 1LFC), which is more effective for microbial membrane permeabilization.

Milk Protein Structural Changes

Because of the nature of caseins, structural changes studies have been limited to relaxation and diffusion measurements. However, whey proteins and, above all, BLG, has been subjected to detailed structural studies, analysing the influence of denaturing agents, heating, high pressure, lactosylation, site-directed mutagenesis, and ligand binding on its structure and/or stability [11].

One of the most interesting areas has been to elucidate the unfolding pathways of the protein under physical treatments. The knowledge of the unfolded intermediates helps to understand the nature of the interactions of the protein with other proteins, water and co-solutes. In the last years, there has been increasing evidence to support that protein folding is a hierarchical process that starts with the building of robust regions and allow the correct folding of the rest of the protein [12]. In the same manner, the unfolding of the protein is a stepwise process. In BLG, it can be observed that particularly robust regions, that seem to be the initiation-folding site, are the most resistant to unfolding [11]. ^{1}H-NMR coupled with deuterium exchange give very useful and detailed information about the unfolding process, by perturbing the protein, and observing the disappearance of backbone NH resonances. If the structure of the protein is known and the ^{1}H resonances are assigned, the unfolding process of precise regions of the protein can be followed by using 2D spectra (Figure 4). The effect of heat, cold and high pressures on BLG has been studied this way [13–16]. Some NMR probes allow performing experiments *in situ*, which provides the advantage of observing the real unfolding mechanism, avoiding the refolding of the protein and the re-equilibration of the system. However, if this is not available, an off-line scheme can be used, capturing different intermediate unfolded states by their degree of deuterium substitution (Figure 4). The recent progress on NMR techniques and the interest of researchers in the folding/unfolding processes have led to the development of methods that allow 2D spectra acquisition in real time.

Checking whether the structure is refolded after the physical treatment or, on the contrary, whether it shows changes from the original form, can be done by comparing the spectra taken before and after the treatment. If relaxation or diffusion parameters are measured before and after processing, information about aggregation can also be obtained.

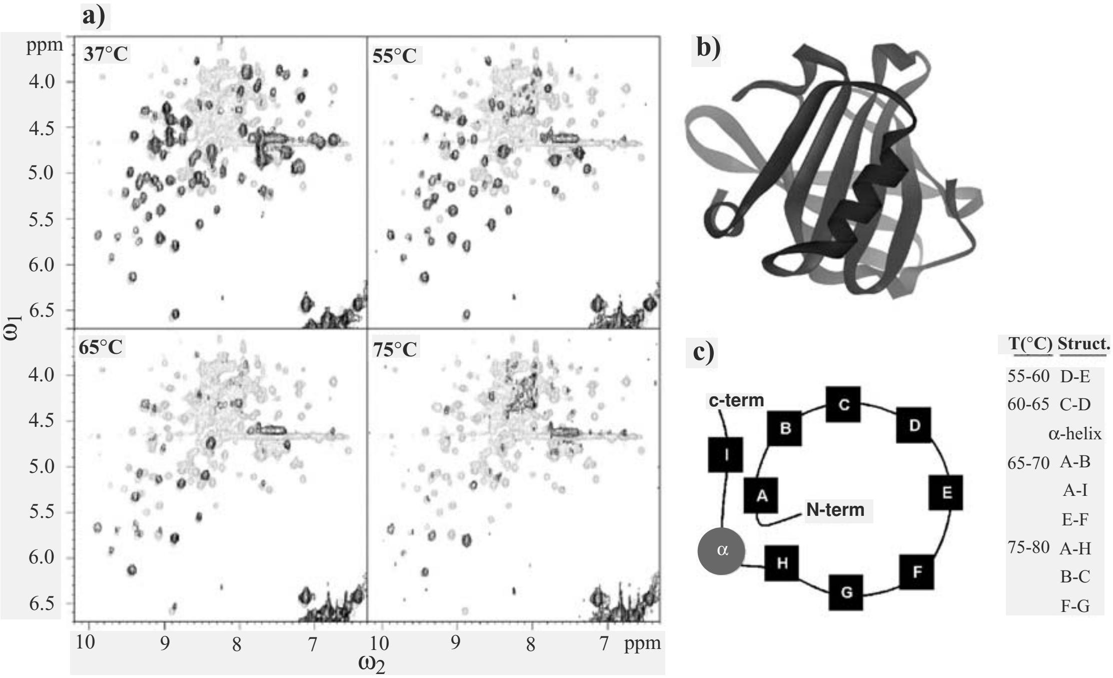

Fig. 4. Effect of heat on BLG. (a) Fingerprint region (NH-Hα) of TOCSY spectra of BLG heated at different temperatures in a D_2O solution. Grey contours are from a non-heated non-deuterium-exchanged BLG reference sample. Reproduced from [13]. (b) 3D structure of BLG. (c) Organization of β-strands (A-I) and the α-helix of BLG, and structural interactions that are lost at different temperatures [13].

High-Resolution ^{13}C Nuclear Magnetic Resonance in the Study of Oils

Maria Antonietta Brescia and Antonio Sacco
Dipartimento di Chimica, Università di Bari, via Orabona 4, 70126 Bari, Italy

Introduction

High-resolution ^{13}C NMR spectroscopy has been widely used in lipid and vegetable oil analysis [1,2]. This is due to the electronic configuration of ^{13}C nucleus, that makes the chemical shift spread over a wide range of frequencies (200 ppm), permitting a minor overlapping of the signals compared to proton spectra, and, consequently, the acquisition of structural information. The most important advantage of ^{13}C NMR spectroscopy is the possibility to determine the positional distribution of the acyl chains on the glycerol moiety. This determination cannot be done with ^{1}H NMR spectra due to the strong overlap of the peaks.

However, a limitation connected with the use of ^{13}C spectroscopy for the analysis of oils is due to low natural abundance of ^{13}C and small gyromagnetic ratio that results in its peculiar low sensitivity. As a consequence, longer analytical time is required for acquisition and only major components, like triacylglycerides can be analyzed and quantified. Quantitative information from ^{13}C NMR spectra can be acquired if resonances are not affected by the effect of nuclear Overhauser enhancement (NOE) that occurs during proton decoupling of ^{13}C, through the mechanism of dipole–dipole relaxation. NOE can be suppressed by using the inverse-gated proton-decoupled sequence, which gates the decoupler only for the acquisition time.

Analysis of the different regions of the ^{13}C NMR spectrum and/or the entire spectrum can provide useful insight on oil composition, enabling quality and authenticity controls.

Quantitative Determination of the Oils Major Components

Fatty Acids

The ^{13}C NMR spectrum of a virgin olive oil, dissolved in $CDCl_3$, is shown in Figure 1. Four signal regions can be recognized due to different types of carbons of triacylglycerides. The assignments were performed by comparing the signals of the ^{13}C spectrum with the chemical shift of standard glycerides. This procedure is generally followed [3–5] even though it has been recently demonstrated that a slight chemical shift of the signals in the ^{13}C NMR spectra of oils is a function of their concentration, especially in the carbonyl region [6].

Table 1 illustrates some case studies based on analytical applications of ^{13}C NMR spectroscopy. A quantitative determination of MUFA, linoleic, and linolenic acids of various vegetable oils from the resonances present in the methyl and methylene regions (14–35 ppm) of the ^{13}C NMR spectrum [7]was proposed. It was found that the optimization of the recovery delay was necessary in order to get data in agreement with those obtained by the classical gas chromatography method, in particular for the linoleic acid determination. It resulted that a total experimental time of 30 min per sample was required.

The areas of signals resonating in this region were also used for the determination of iodine value of palm oil [8].

An alternative method for the quantification of the major fatty acids (saturated, oleic, and linoleic) based on the analysis of the signals due to carbonyl and ethylenic carbons, resonating in the 195–105 ppm region was proposed for Greek olive oils [9]. This quantification procedure required the presence of an internal reference (pyrazine). The overlap of peaks in the carbonyl region was reduced applying a Lorentz Gaussian enhanced filter function to the FID and a peak deconvolution procedure to allow a precise integration. This methodology was extended investigating mixtures of virgin olive oils and seed oils. In this case, the quantitative analysis was performed only on signals resonating in the olefinic region, due to the minor overlapping presented [10]. A linear increase of linoleic acids contents was observed with increasing addition of seed oils to olive oils. This evidence allowed to construct reference curves, proposed as a diagnostic tool for the estimation of olive oil adulteration.

The adulteration of olive oil with soybean oil having high linoleic acid content was also examined by ^{13}C NMR distortionless enhancement by polarization transfer (DEPT). This technique employs a polarization transfer able to enhance signal intensities [11], and shorten the experimental times required when compared to ^{13}C NMR spectra. The signals of unsaturated carbons of

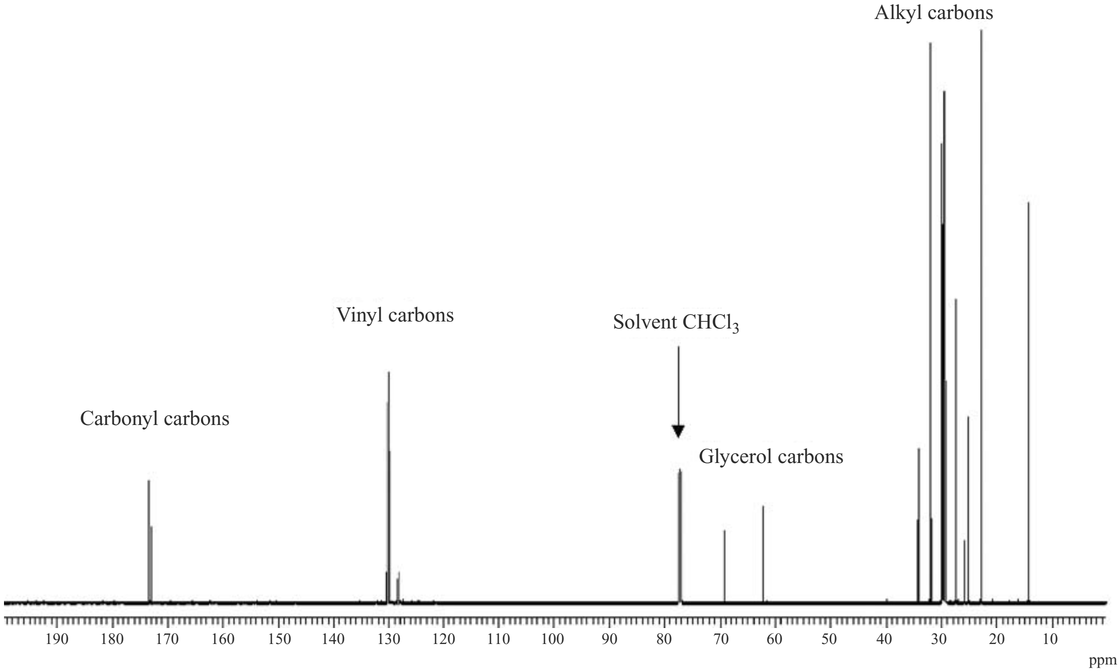

Fig. 1. ^{13}C NMR 500 MHz spectral pattern of an olive oil.

oleyl, linoleyl, and linolenyl chains, observed in the 132–127 ppm region, were found to give two resonances for each carbon signal, depending on the chain position on the glycerol backbone. Integrals of these resonances were used to calculate the calibration curves based on a linear relationship between resonance intensities and soybean concentration in olive oil.

The methylene, olefinic, and carbonyl regions in the ^{13}C NMR spectra were considered to obtain quantitative information about the fatty acid distribution of fish oils [12]. The addition of paramagnetic compounds to the analyzed samples was provided in order to decrease the experimental time for performing quantitative measurements.

Qualitative and quantitative determination of fatty acids in vegetable seeds is necessary to assess their value. Magic angle spinning ^{13}C NMR technique has shown to be very attractive in this case because it is a non-destructive

Table 1: Quantitative ^{13}C NMR determinations on oils

Samples	Parameters	Analyzed spectral region	Reference
Canola seeds	Fatty acids	29–20 ppm	12
Fish oils	Fatty acids	Entire spectrum	10
Fish oils	Fatty acids and positional distributions	178–172 and 75–50 ppm	25
Mixtures of olive and seed oils	Unsaturated fatty acids	130–127 ppm	9, 32
Olive oils	Free fatty acids and partial aylglycerols	176–173 and 75–60 ppm	16
Olive oils	Diglycerides	75–60 ppm	17
Palm oils	Iodine value	30–24 ppm	7
Palm oils	Free fatty acids and partial acylglycerols	174–172, 75–60, and 30–20 ppm	18
Vegetable oils	Unsaturated fatty acids	36–14 ppm	6
Vegetable oils	Fatty acids and positional distributions	173–127 ppm	8, 19–20, 22–24
Vegetable seeds	Unsaturated fatty acids	130–127 ppm	11

method, being applied directly on the seed, and because it permits to obtain a spectral resolution that approached that of liquid oils. However, it is worth to consider that for the analysis of seeds having a low oil content (like corn and rape seeds) or a complex unsaturated fatty acid composition, DEPT technique was necessary to increase the sensitivity [13]. From the analysis of the methylene region of canola seed oil spectrum, it was possible to detect trans olefins in oils [14] because allylic methylenes adjacent to cis double bonds are shifted by 5 ppm to frequency lower than that of trans isomer. This determination is advantageous respect to the classical chromatographic method, because it detects all trans isomers simultaneously, while in a chromatogram different isomers give rise to different small signals that are not accurately measurable. The detection of trans fatty acids can be extremely helpful to reveal the addition of refined oils to virgin olive oils. In fact, oil refining processes (bleaching and/or deodorizing) are carried out at high temperatures that favor the isomerization of oleic acid (cis) to elaidinic (trans). This acid is absent in virgin olive oils, while its content in olive and olive-pomace oils varies from 0.1 to 0.6%, therefore its presence in olive oil can be considered an index of adulteration [15]. The detection of the amount of trans and cis fatty acids is also important for the quality control of hydrogenated vegetable oils and to determine the effect of the experimental conditions of the hydrogenation process in double bonds isomerization and migration. Gunstone [16] and Miyake and Yokomizo [17] obtained important results on the position and configuration of double bonds by investigating the olefinic region of the ^{13}C spectrum.

Glycerol Esters

Glycerol can form mono-, di-, and triacylglycerols, resonating in the spectral region from 60 to 72 ppm (Figure 2). The symmetrical esters (2-monoacyl, 1,3-diacyl, and triacyl) give only two signals at 1:2 intensity ratio, while the asymmetrical esters give three separate signals of equal intensity. Assignments of standard glycerides were obtained using DEPT experiments [18]. The total amount of diacylglycerols and the ratio between 1,2 and 1,3-diacylglycerols can be evaluated in terms of molar ratios (%) through the analysis of the peaks intensities:

$$R1 = 100 \times \mathrm{DG}/(\mathrm{DG} + \mathrm{TG})$$

$$R2 = 1{,}2\text{-DG}/1{,}3\text{-DG}$$

$$R3 = \mathrm{MG} \times 100/(\mathrm{MG} + \mathrm{DG} + \mathrm{TG})$$

In the above-reported relationships, DG represents the sum of the intensities of the resonances due to carbons of 1,2- and 1,3-diacylglycerides; TG represents the sum of the intensities of carbons of triacylglycerides; MG indicates the intensities of signals due to α-monoglycerides (69.9 and 63.1) and β-monoglycerides (61.02 and 72.2) (signals not present in the spectrum shown in Figure 2). The spectrum must be acquired using appropriate relaxation delays and pulse widths in order to carry out the quantification procedure, since full recovery of magnetization between subsequent pulses is necessary.

This determinations can be useful to detect the freshness of the oils and to reveal the presence of partially neutralized oils to olive oils that are given out as "virgin". Diacylglycerols (mainly 1,2) can come either from incomplete triacylglycerols biosynthesis or from limited lipase action on triacylglycerols and their content, indicated by $R1$, should not exceed 2–3% in virgin olive oil. The glycerol content increases with olive oil acidity. Large amounts of diacylglycerols (mainly 1,3-diacylglycerols) are found in neutralized olive oils, produced from a starting material with a high level of free fatty acids and in oils obtained from overripe olives or after several months of oil storage due to lipolysis and 1,2- and 1,3-isomerization. In both the cases, $R2$ is always lower than 1. A quantitative ^{13}C NMR study carried out on olive oil showed that significant differences in diacylglycerols content occurred among cultivars [19], probably due to its relation with maturation stage. In fact, it was observed that lower total diacylglycerol content is characteristic of late maturing cultivars, whereas early maturing fruits produce higher levels of total diacylglycerides.

The determination of mono- and diacylglycerol content is also important, since they are commonly used as emulsifiers in the food industry. For this reason, the quantitative analysis of these compounds was performed on palm oil [20]. Since glycerol carbons are near the T_1 minimum for dipole–dipole relaxation mechanism, spectra were acquired at low magnetic fields (300 MHz) and at an elevated temperature (50 ˚C) to obtain narrow signals.

Fatty Acids Positional Distribution

In the low-field region of the spectrum, carbonyl carbons of the triacylglycerides resonate. Oil samples have two sets of carbonyl signals: the first, centered at ~173.2 ppm, includes the fatty acids esterified at 1,3-glycerol positions (α), while the second, centered at ~172.8 ppm, is due to fatty acids bonded to the 2-glycerol position (β). In olive oil, four signals were observed in the first group due to saturated (S), eicosenoic (E), oleic (O), polyunsaturated fatty acids (L), while in the second group there are two signals, respectively due to oleic and polyunsaturated acids (Figure 3). The analysis of this region enables the

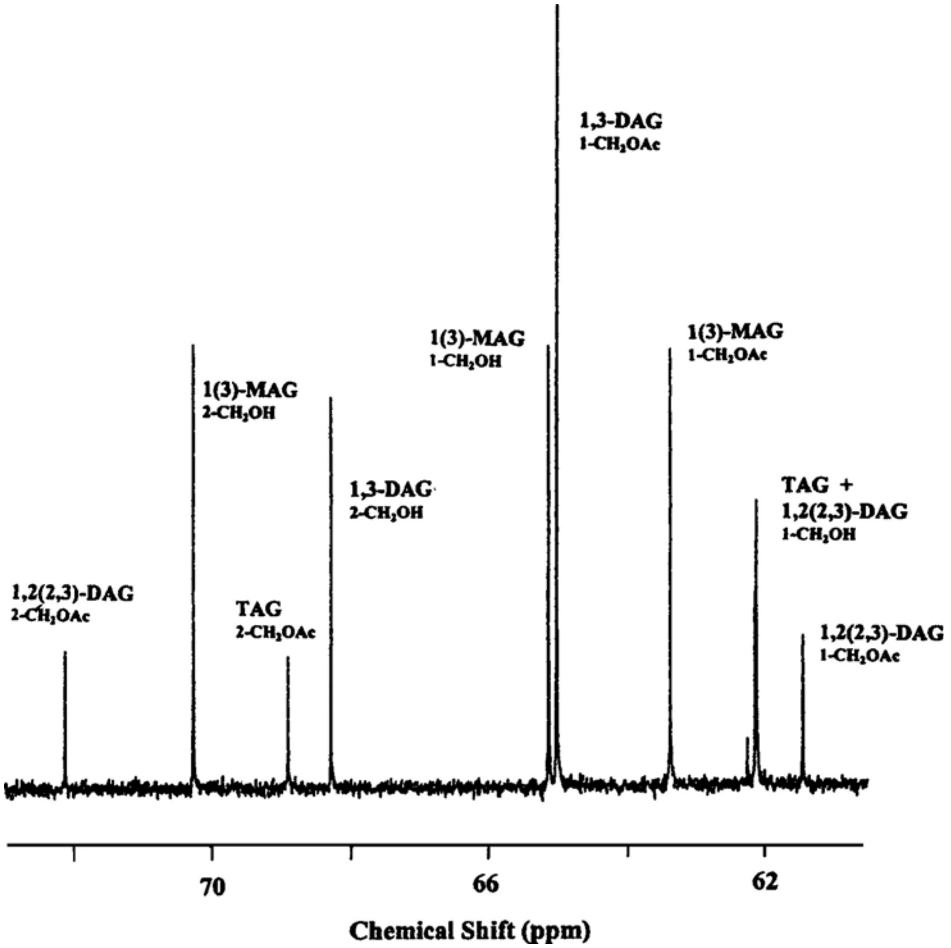

Fig. 2. The glycerol carbon region 60–72 ppm of the ^{13}C spectrum of a standard mixture of glycerides at different esterification degree. The resonances of glycerol carbons are labeled as $-CH_2OAc$ and $-CH_2OH$ in correspondence of an acylated and a non-acylated alcoholic group of the glycerol molecule (from Ref. [2]).

detection of addition of synthetic esterified oils, considered non-edible by the European Union, to virgin olive oils. Esterified oils show a random distribution of saturated fatty acids, leading the 15% of saturated acids in the 2-glycerol position. The biosynthesis of triacylglycerols in the vegetable oils leads to the preferential esterification of unsaturated fatty acids in the 2-glycerol position; therefore, the amount of oleic and linoleic acids in this position represents the 98–99% of the total fatty acid content. As a consequence, if the saturated fatty acids exceed 1.5% in this position, the analyzed oil contains a certain amount of esterified oils. The EU official analytical procedure for the analysis of esterified oils mixed with olive oils is based on an enzymatic method requiring several steps, while NMR making use of ^{13}C resonances yields immediate results, operating directly on the oil samples. In fact, in the carbonyl region of the ^{13}C NMR spectrum of virgin olive oil only one resonance is observed for the 2-glycerol position, corresponding to the unsaturated fatty acids, while in the same spectral region an esterified oil shows a minor peak due to saturated acids. This signal was quantified by means of a curve resolution program, enabling the detection of a 10% addition of esterified oils to olive oil [21].

The areas of the signals resonating in the carbonyl region of the spectrum were used to perform a regiospecific

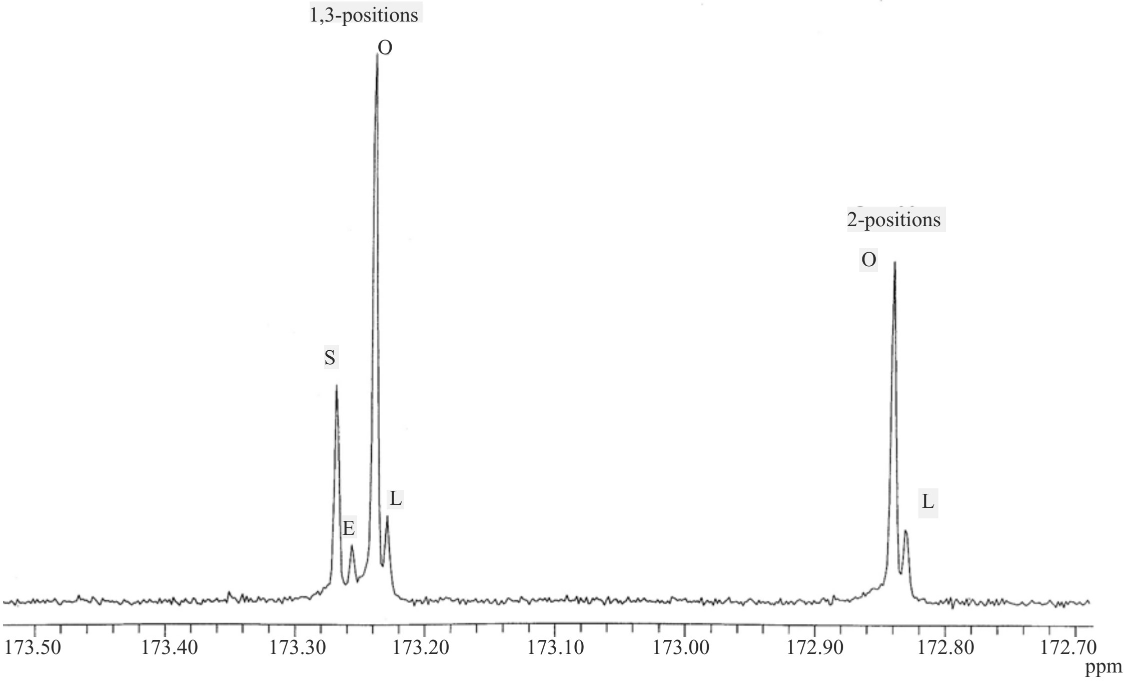

Fig. 3. 500 MHz ^{13}C NMR spectrum of the carbonyl region of an olive oil.

analysis of triacylglycerides of Italian monovarietal olive oils, calculating the distribution of saturated, oleyl, and linoleyl chains between 1,3 and 2 positions of glycerol [22]. Using the same approach, the fatty acid composition and distribution in triacylglycerols of other vegetable oils was determined [23–25].

The examination of acyl positional distribution in canola and other non-edible vegetable oils is more complex than for olive oil, due to the presence of eicosenoic and erucic acids, which signals result overlapping to those of linoleic acid in the carbonyl region. For this reason, the analysis of the olefinic region of the spectra was also necessary to obtain a qualitative and quantitative evaluation of these acids [26].

The study of the carbonyl region was also performed on the ^{13}C NMR spectra of fish oils revealing that glycerol β-position is esterified preferentially by docosahexaenoic acid [12].

In the ^{13}C NMR spectrum of an oil with high content of free fatty acids, the signals of free COOH groups appear at 176–178 ppm. The determination of free acidity can be easily performed by comparing the intensity of this signal to the sum of free and esterified carbonyl groups. This method was applied to quantify free fatty acids in olive oils [18] and in fish lipids [27]. Quantification of free fatty acids in palm oils was performed from the C3 peak of free fatty acids resonating in the region of aliphatic carbons [20].

Minor Oil Components

Among minor olive oil components, phenolic compounds play an important role in the sensory characteristics and in the oxidation stability of virgin olive oil (see Section 2.4 of "^{1}H NMR of oils"). In particular, it has been demonstrated that the esters of tyrosol (Ty) and hydroxytyrosol (OHTy) with elenolic acid contribute to the sensory characteristics of the oil, being responsible of the pungent taste, while OHTy and its derivatives are correlated with oil resistance to oxidation [14]. ^{13}C NMR spectroscopy of the polar fraction extracted from virgin olive oils permits to calculate the ratio of free and esterified Ty + OHTy comparing the intensities of C1 carbon of free Ty + OHTy (64.5 ppm) with the C1 signal of the corresponding esterified compounds (66.8 ppm).

The molar ratio between total (free and esterified) OHTy and Ty can be calculated by comparing the intensities of aromatic signals at 121.3 and 116.1 ppm and provides a useful parameter for oil stability.

^{13}C NMR Spectroscopy As a Discriminating for the Varietal, Geographical, and Botanical Origin of Vegetable Oils

Since olive oil is a product of high nutritional and commercial value, its adulteration with different quality and origin oils represents a big temptation. A rapid screening method is therefore requested to detect oil adulteration. Recently, methods based on ^{13}C NMR spectroscopy have been considered advantageous in this field because of compositional and structural information contained in the NMR signals. The proposed methods provide models which are obtained applying statistical methods of multivariate analysis to spectroscopic measurement of representative sets of samples.

Principal component analysis, principal component regression, and partial least squares were applied to 35 signals areas from the ^{13}C NMR spectra of six olive oil cultivars sampled in different Italian regions with variable selection methods of Fisher ratio and the ratio of inner variance to outer variance [28]. The classification of the oils by variety was found to be more successful than classification by region of origin. In order to improve the geographical origin discrimination, the potential of DEPT sequence was also investigated, since it permits to obtain better S/N ratio of ^{13}C NMR spectra. This approach was applied to olive oils coming from 13 Italian PDO areas [29] located in different regions, and to olive oils coming from three close PDO areas in Apulia region (Southern Italy) [30]. The acquisition and processing conditions were optimized in order to perform accurate and reproducible measurements. Multivariate statistical analysis was applied to the intensities of selected peaks present in the ^{13}C NMR spectra and permitted to distinguish the analyzed oils according to their origin. In both studies the cultivar factor seemed very important, since classification worked well especially when oils of different PDO where obtained from olives of different cultivars.

Cultivars differentiation of virgin olive oils coming from different PDO areas in Apulia region, was also explored with classical chromatographic analyses (fatty acid, sterol, and triacylglyceride composition) and with ^{13}C NMR spectroscopy, that was used for comparative purposes to official methods. Therefore, classical and NMR parameters were separately evaluated but the same statistical approach was used for both data sets. As far as NMR data are concerned, normalized heights of signals present in the ^{13}C NMR spectrum, selected with analysis of variance, were used as variables for statistical elaboration [31]. The models obtained from the application of discriminant analysis to the data sets of chromatographic and ^{13}C NMR results were found to be in a good agreement, being statistically similar. This study confirmed that ^{13}C NMR spectra contain the information about acyl composition and positional distribution of glycerol moiety; since for the analytical data, fatty acids and triacylglycerols were the most responsible for distinguishing oils' cultivars, and all the selected peaks for ^{13}C NMR were relevant. This technique could therefore be effectively used for classifying cultivars.

A combined ^{13}C NMR and GC approach was also successfully used to determine the cultivar effect on fatty acid composition of monovarietal Sicilian olive oils [32].

Some authors studied the potential of ^{13}C NMR analysis to distinguish oils from different cultivars, geographical and botanical origins, as well as mixtures of olive oils from different geographical origins and of hazelnut oil in olive oil [33]. The intensities of peaks most effective in the discrimination of the different types of oil were selected as variables by stepwise discriminant analysis (SDA). The difference between virgin olive oils and vegetable oils having a high content of linoleic and oleic acid was obtained. In addition, the statistical method classified, with 97% of classification ability, hazelnut oil samples and mixtures of hazelnut oil in olive oil.

^{13}C NMR of Olive Oil Minor Compounds to Determine Oil Authenticity

^{13}C NMR spectroscopy cannot be directly used for the analysis of minor compounds due to its low sensitivity. Nevertheless, the information acquired by ^{13}C NMR in the analysis of triacylglyceridic composition of oils have prompted some authors [34] to explore the unsaponifiable matter of virgin and refined olive and pomace oils, after previous separation from triacylglycerides by treatment with a potassium hydroxide solution. The low-field region of the spectra contained signals that were assigned to squalene that was the major component of the unsaponifiable matter of virgin olive oil and was present, in lower quantity, also in refined olive oils and in refined olive-pomace oils. Other signals were assigned to sterols, β-sitosterol, triterpenic, and long-chain monounsaturated alcohols. The heights of these peaks were evaluated by means of SDA permitting to achieve a discrimination between the different types of investigated oils.

However, the use of unsaponifiable matter requires a time-consuming preparation and does not hold information about triacylglycerols and other saponifiable components, which can also be related to oil quality. To overcome this limitation, a chromatographic method was used to isolate an oil fraction containing 15% of triacylglycerols and 85% of polar compounds [35]. ^{13}C NMR spectra of this fraction were obtained from 109 vegetable oils of different grade and various botanical and geographical origin. Moreover, mixtures of virgin olive oils from different geographical regions were analyzed. Spectra were similar to those obtained for olive oils but contained the double number of signals, since minor compounds like diacylglycerols, monoacylglycerols, sterols, and fatty alcohols were visible. The information contained in the spectra was employed to classify olive oils by using SDA and variable selection.

^{13}C NMR spectra of oil fractions obtained with the same method for 66 vegetable oils were also analyzed to evaluate the potential use of these fractions in predicting oil stabilities. A 0.99 correlation index was found by stepwise linear regression analysis between oil stability, determined by Rancimat method, and the heights of several signals present in the ^{13}C NMR spectra [36]. The statistical method selected the signals more correlated to oil stability. These signals were associated to fatty acid composition and to the presence of minor compounds with antioxidant characteristics.

High-Resolution ^{1}H Nuclear Magnetic Resonance in the Study of Oils

Maria Antonietta Brescia and Antonio Sacco
Dipartimento di Chimica, Università di Bari, via Orabona 4, 70126 Bari, Italy

Introduction

High-resolution NMR plays an important role in oil analysis. This is firstly due to the absence of sample pretreatment, since oils are simply added to a deuterated solvent before analysis. ^{1}H NMR studies of oils have increased because of the great amount of information that high field NMR instruments can provide with a single experiment and in a very short time. This entry is mainly focused on the qualitative and quantitative information that can be obtained from the oils ^{1}H NMR spectra regarding major and minor components. Some of the most interesting implications in the control of quality and authenticity will be also discussed.

Triglycerides

A typical ^{1}H NMR spectrum of an olive oil is reported in Figure 1. It shows 10 signals of significant intensity due to protons of triglycerides—the main oil components. These signals are also present in the spectra of other vegetable oils, but their shapes and intensities are different due to different fatty acid composition. These signals do not allow the complete discrimination of single fatty acid components, unlike the traditional gas chromatographic method, considering their overlapping in the spectral area of interest. Anyway, they can be used for various useful applications. For example, the oil unsaturation degree can be calculated by determining olefinic protons, resonating at 5.29 ppm (signal A in the spectrum), relative to the number of glyceride methylene protons (signal B in the spectrum) [1]. This parameter is an important indicator of the development of rancidity and was employed to monitor the lipid oxidation process in vegetable oils [2].

The traditional determination of the unsaturation degree of an oil consists in the quantitative reaction of iodine to fatty acids double bonds, giving as a result the iodine value (IV). It can be obtained directly from the NMR spectrum by means of the following equation:

$$\begin{aligned}\mathrm{IV} = {} & 253.8[(A - B/4)/2 + (E/4 + C/2)]/2/100 \cdot \\ & \text{average molecular weight,}\end{aligned}$$

where 253.8 is the molecular weight of iodine, and the average molecular weight of the considered oil is obtained as follows:

$$\begin{aligned}&\text{average molecular weight}\\ &\quad = 15.034(G + H)/3 + 14.026(C + D + E + F + I)/2\\ &\qquad + 173.100B/4 + 26.016(A - B/4)/2,\end{aligned}$$

where A–I are the integrals of the signals present in the spectrum in Figure 1. The IV was determined for several vegetable oils and coincided with that obtained by the conventional method [3].

The measurement of the ratio of olefinic to aliphatic protons was proposed to follow the oxidative deterioration of fish oils [4], since the common peroxide value is not easily measurable due to the high content of unstable polyunsaturated acids. A good correlation between the determined NMR index and peroxide value was also verified.

From the integrals of the signals A–I, the quantification of classes of fatty acids (saturated, monounsaturated, linoleic, and linolenic acids) [5] can also be carried out (Table 1). These data are well correlated with those obtained with the official chromatographic method, although they are less detailed, but these determinations are sufficient for preliminary quality and authenticity evaluations.

Recently, other procedures based on ^{1}H NMR spectra have been proposed for the quantification of fatty acids in prepared triacylglycerols mixtures [6] and in mixtures of methyl esters and triacylglycerols [7].

The methyl group of linolenic acid (signal G in Figure 1) can be used to quantify this acid but, in corn and olive oil, this signal is quite small, therefore accurate quantification through the formula given in Table 1 is precluded. A more suitable quantification method is based on the comparison of signal G and the nearby ^{13}C satellites of signal H, whose amount is exactly 0.57% of the intensity of signal H. This parameter is important because it permits to detect the adulteration of olive oil with seed oils as soybean and rapeseed oils, since they have a different linolenic acid content. Signal G can also be used to obtain a global measure of the ω-3 polyunsaturated fatty acids

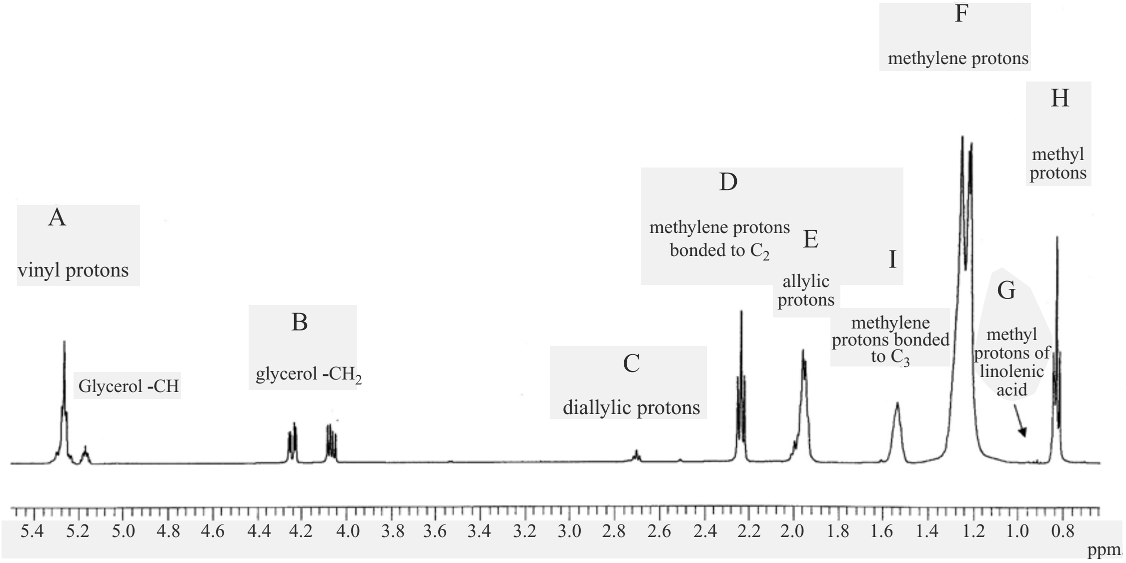

Fig. 1. ^{1}H NMR 500 MHz spectrum of an olive oil.

in fish oils [8]. In order to reduce errors in the quantitative determination, careful attention must be paid to avoid oxidative deterioration of sample oil, because oxidized oils may give signals interfering with measurements. Oils from 24 samples of raw, cooked, and canned albacore tuna were quantified and compared.

Since vegetable oils contain various proportions of saturated, oleic, and polyunsaturated acyl groups, the resulting signals have different chemical shifts and shapes depending on these proportions. A careful observation of the shape and number of peaks of each signal present in the spectra allows to find significant differences between vegetable oils of different composition [9,10]. For example, sunflower oil can be easily distinguished from olive oil due to its high linoleic acid content that is particularly evident in the intensity of the signal resonating at 2.76 ppm. Protons of linoleic acid give visible signals at 0.89 ppm, and at 2.06 ppm, due, respectively, to the terminal methyl group and to allylic protons of linoleic acid. A careful observation of the spectra can be also useful to distinguish oils of similar composition, such as olive and hazelnut oils. In fact, the presence of a very small proportion of linolenic acid in olive oil (∼1%) permits to distinguish it from hazelnut oil, whose amount of linolenic acid is much lower (∼0.1%). Moreover, the difference in saturated acids, higher in olive than in hazelnut oil, is evident also observing the shape of the signal due to methylene protons, that is formed by three signals, resonating at slightly different chemical shifts, due to saturated, oleic, and linoleic acids. These slight differences in unsaturated and polyunsaturated fatty acids content between olive and hazelnut oil become less remarkable when a real adulteration problem is concerned, and mixtures of hazelnut and olive oil have to be detected. In this case, pure and adulterated samples cannot be distinguished by a visual inspection of the spectra. To solve this problem, a multivariate statistical method was developed and evaluated first on a big number of pure and adulterated samples [11]. The integrals of peaks resonating at 5.29, 2.76, and 1.6 ppm were chosen as variables for statistical analysis, since they reflect, respectively, the amount of unsaturated, polyunsaturated fatty acids, and the total content of fatty acids. Moreover, the ratio of linolenic respect to linoleic acid and the ratio of linolenic to all other fatty acids were determined calculating ratios of suitable signal heights. Discriminant analysis was applied to these

Table 1: Calculations of fatty acid composition of oils by signal intensities in the ^{1}H NMR spectrum

Fatty acids (%)	Formula
Linolenic acid	$100[G/(G+H)]$
Linoleic acid	$100(3C-4G)/2(G+H)$
Unsaturated acids	$100(E/2D)$
MUFA	$100\{E/2D-[G(G+H)]-[(3C-4G)/2(G+H)]\}$
Saturated acids	$100[H/(G+H)-E/2D]$

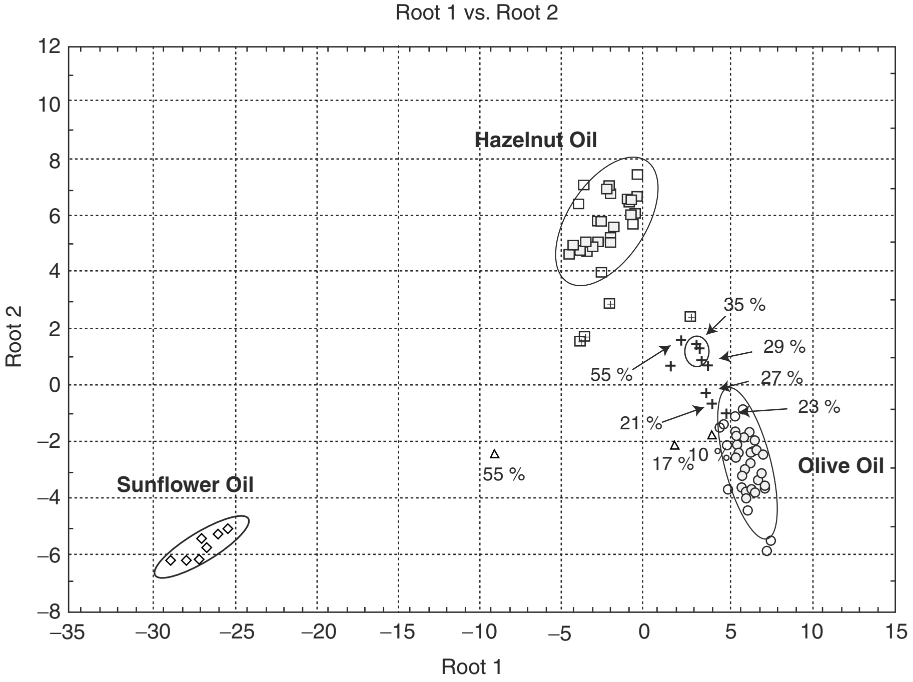

Fig. 2. Plot of discriminant functions determined by ^{1}H NMR parameters. Circles: olive oils; squares: hazelnut oils; rhombus: sunflower oils; crosses: mixtures (m/m%) of olive oil and sunflower oil; triangles: mixtures of olive oil and hazelnut oil. The ellipses display the 95% confidence range for each group of oils. The big cross indicates one olive oil which was repeated four times (from Ref. [11]).

variables permitting the detection of mixtures at a minimum level of 25% hazelnut oil (Figure 2).

Some analytical methods for the detection of mixtures of hazelnut oil in olive oil are based on the observation of the differences in δ and γ tocopherol and in β/δ tocopherol ratio [12], that are normally higher in hazelnut oil, and on LC/GC analysis of the esterified sterolic fraction [13]. These methods reveal the addictions of 5–10% of hazelnut oil, but need long times of sample preparation. ^{1}H NMR spectroscopy can be interesting as a screening method, because it allows much shorter times for sample preparation and analysis.

A statistical approach was also applied to the analysis of 13 types of vegetable oils and mixtures of virgin olive oil with seed oils (corn, sunflower, and soybean oil) in an attempt to establish the lowest possible detection level of adulteration. In this case, it was necessary to combine several oil compositional parameters obtained by two NMR approaches. 1,2-diglycerides, 1,3-dyglicerides, and sterols were determined by analysis of ^{31}P NMR spectra after derivatization of diglycerides with 2-chloro-4,4,5,5-tetramethyl dioxaphospholane. On the same phosphitylated samples, ^{1}H NMR spectra were carried out and fatty acids were quantified [14]. With this method, it was possible to detect olive oil adulteration at 5%.

The analysis of the ^{1}H NMR spectrum of fish oils permits the quantitative determination of docosahexaenoic acid (DHA), whose positive influence on human health has been emphasized. Its content depends on the fish species, on age, on storage and processing, due to the oxidative deterioration of the highly unsaturated lipids. Due to their proximity to a double bond, methylene C2 protons of DHA resonate downfield to C2 signals of other fatty acids. It was thus possible to determine the DHA content in mg/g in fish oils by comparing the signal areas of the C2 protons of DHA with those of other fatty acids, in the presence of an internal standard solution of ethylene glycol dimethyl ether and 1,4-dioxane [15].

Minor Compounds

Phenolic Compounds

Phenolic compounds play an important role in the nutritional characteristics and oxidation stability of edible vegetable oils. The majority of seed oils contains only traces of phenolic compounds, while virgin olive oil is particularly rich in these antioxidants. Moreover, these compounds contribute in a characteristic way to oil sensory qualities, since they are responsible for its bitter and pungent flavor. The bitter taste is particularly related to the presence of oleuropein glucoside and its aglycon. The content of phenolic compounds in olive oils is heavily affected by the variety, origin, and maturity degree of olives [16]. Phenyl acids and phenyl alcohols (like tyrosol and hydroxytyrosol) have been found prevalently in olives [17], but are also present in olive oil. The prevalent phenolic constituents of olive oil are secoiridoid derivatives, such as the dialdehydic form of the elenolic acid linked to hydroxytyrosol or to tyrosol (ligstroside) and the elenolic acid linked to hydroxytyrosol (oleuropein aglycon). Their structure has been identified using NMR [18], after extraction in absolute methanol and separation by HPLC. Other compounds detected in olive oil phenolic fraction, whose structure was elucidated with NMR, are demethyl-oleuropein, glucosides of hydroxytyrosol [19] and also two soluble lignans—pinoresinol and its derivative, 1-acetoxypinoresinol [20].

Aldehydes and Volatile Compounds

The aldehydic compounds are important in the evaluation of oil quality for two reasons: first of all they permit to follow the oils oxidative processes; secondly, due to their volatility, they play an important role in the sensory attributes of olive oils.

The first ^{1}H NMR studies regarding oxidation processes of edible oils have been conducted on pure triacylglycerols, like trilinolein, trilinolenin, and triolein. When these model systems were brought to 40 °C in presence of pure oxygen, they formed principally *mono*-hydroperoxides, together with *bis*-hydroperoxides and *tris*-hydroperoxides [21,22] that produce a characteristic signal at 8–8.9 ppm, due to the hydroperoxide group. Other authors [23,24] have directly monitored by ^{1}H NMR spectroscopy the deterioration process of edible oils submitted to thermal stressing, in order to study the nature and levels of potentially toxic products, which were produced during heating at frying temperature. They detected the presence of signals due to hydroperoxides and saturated, *mono*-unsaturated, *di*-unsaturated, and hydroxy *mono*-unsaturated aldehydes. While saturated and *mono*-unsaturated aldehydes were present in various vegetable oils, the last two were also detected in oils containing a high quantity of polyunsaturated fatty acids (as linseed oil). From these studies, it was concluded that the oxidation process occurs in two stages. In the first stage of thermal oxidation, the fatty acids take oxygen-forming hydroperoxides. When the hydroperoxide concentration reaches a certain level, and when the thermal process is intensified, second oxidation occurs with the formation of aldehydic compounds that are responsible of the undesirable rancid flavor. These aldehydes can be easily detected in the low-field region of the ^{1}H NMR spectrum [25] and can be used to follow the oxidation process of an oil and to evaluate its oxidative stability.

The composition of volatiles plays an important role in defining the sensory quality of virgin olive oils. Positive (green-fruity odor, etc.) and negative attributes (bitter tasting, etc.) have been correlated with the presence of aldehydes, alcohols, polyphenols, terpenes, and acetic acid. The very low concentration of these compounds in virgin olive oil makes possible their direct determination only by high field (500–600 MHz) ^{1}H NMR [26]. In order to observe these polar minor compounds, they should be soluble in the used solvent. For this reason, a trace of DMSO-d_6 is added to chloroform-d in the NMR tube. Moreover, a high number of scans (4000) is a necessary acquisition parameter to obtain these minor compounds with appreciable intensity (Figure 3).

Sterols

The signal due to methyl CH_3 in position 18 of the sterols resonates between 0.6 and 0.7 ppm. The signal due to methyl 18 signal of β-sitosterol, resonating at 0.62 ppm, has been clearly identified in virgin and refined olive oils. Its intensity can be compared with the resonance of ^{13}C satellites of the methyl group of fatty acids, permitting the quantification of β-sitosterol [5], that can be useful to distinguish seed and pomace oils from olive oils, since the former have shown a higher amount of β-sitosterol and other sterolic compounds.

Signals due to stigmasterol [26] and to cyclo-arthenol [27] have been also detected in olive oils.

Diglycerides

Diglyceride content and the ratio of 1,2-diglycerides and 1,3-dyglicerides represent an important index of olive oil quality and freshness. The quantitative evaluation of these compounds can be performed with medium field ^{1}H NMR (200–400 MHz) after oil derivatization with trichloroacetyl isocyanate that reacts with hydroxyl groups of diglycerides leading to the quantitative formation of trichloroacetyl carbamates [28]. After derivatization the CH_2 and CH glycerol resonances of 1,2-diacylglycerides are well resolved from the triacylglyceride multiplets, therefore an integration of the relative signal intensities is possible, permitting to evaluate the amounts of 1,2- and 1,3-diglycerides. In addition, the diglyceride proton is converted by derivatization in

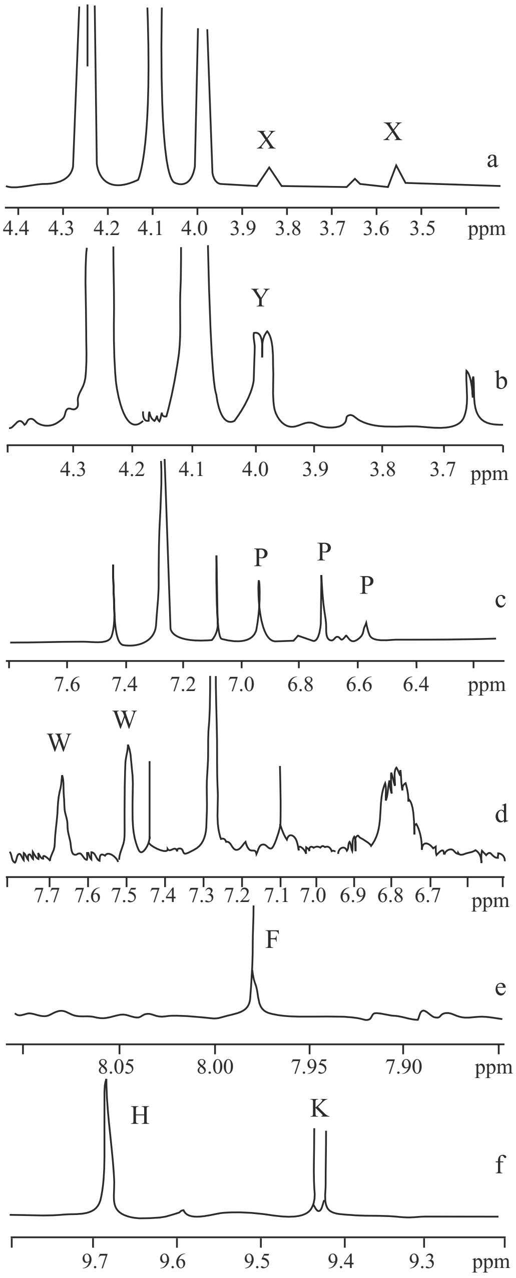

Fig. 3. ^{1}H NMR spectrum of olive oil. (a) X are the characteristic resonances of a bitter oil; (b) Y of a vinegary tasting oil; (c) and (d) P and W are soluble phenols; (e) F is formaldehyde present in pungent oils; (f) K and H are aldehydes in green-fruity olive oils (from Ref. [26]).

the NH proton, that resonates at 8.4 ppm and it can be integrated to give a quantitative measure of the free hydroxyl groups. The results obtained by this method agree with those obtained with ^{13}C NMR approach (see Section “Minor oil components” in “^{13}C NMR of oils”). Anyway, the same information can be achieved with 600 MHz ^{1}H NMR, since resonances of glyceryls protons of 1,2-diglycerides and 1,3-dyglicerides can be detected without the need of derivatization [5]. The same signals were also easily monitorable in the ^{1}H NMR spectra of encapsulated marine oil supplements [29].

Use of ^{1}H NMR Spectroscopy to Characterize Olive Oil Geographical Origin

Extra virgin olive oil is very valuable among edible oils due to its high nutritional value. Its characteristics are determined by a series of factors: nature of the soil, climate, variety of the plant, cultivation, and extraction techniques. In order to protect producers of high quality olive oils and ensure consumer awareness of product quality, European Community legislation has introduced the Protected Designation of Origin (PDO) mark that allows the labeling of virgin olive oils with the names of the areas where they are produced. This certification increases the oil value. Several studies, based on the combination of ^{1}H NMR data and multivariate statistical analysis, have been performed for the systematic characterization of olive oils composition. One of the first works was carried out on 55 olive oils coming from four Italian regions [30]. The samples were dissolved in a mixture of 0.7 ml of chloroform-*d* and 20 μl of DMSO-d_6 and the spectra were run on a 600 MHz spectrometer. The heights of 30 resonances present in the spectra were measured and normalized to the height of the signal due to the methylene resonance at 1.26 ppm, to give an index proportional to the molar ratio between each compound and the total amount of fatty acids. Afterwards, a variable selection method permitted to identify peaks which showed significant variations for oils of different geographical origins, that are due to β-sitosterol, saturated and unsaturated aldehydes, and volatile compounds. A cluster analysis was applied to the selected resonances permitting to discriminate the oils in relation to their geographical origin. This procedure demonstrated its reliability when applied on an enlarged data set formed by 216 oils collected in 3 years from different Italian regions, using the same set of selected resonances [31] (Table 2).

The question of geographical identification becomes more interesting when it regards small production areas, where high quality products are often obtained. Moreover, often there are several PDO oils in one region, produced in areas not far from each other, as it happens in some Italian regions, like Apulia and Tuscany, where four and three PDO were, respectively, designated for olive oil. For this

Table 2: Chemical shift assignment of the selected resonances used for geographical origin discrimination of olive oils (according to Ref. [31])

δ (ppm)	Group	Compound
9.70	−CHO	Hexanal
9.61	−CHO	Unsaturated aldehyde
9.54	−CHO	Unsaturated aldehyde
9.45	−CHO	*Trans*-2 hexenal
8.00	−CH	Formaldehyde
4.88	Nd	Cycloarthenol
4.65	Nd	Terpene
4.63	Nd	Terpene
4.53	Nd	Terpene
1.62	$-CH_3$	Squalene
0.62	$-CH_3$	β-sitosterol

reason, the same previously described statistical approach was used to discriminate 42 extra virgin olive oils from three different zones in Tuscany [32]. Several hierarchical clustering procedures and discriminant analysis were applied on the signal intensities confirming the potential of ^{1}H NMR in the differentiation of PDO oils. It was also interesting to notice that when oils differed in geographical origin and in cultivar, a better separation of the oils resulted, indicating that both cultivar and geographical origin contributed to the differentiation of oils.

A different approach consisted in the application of ^{1}H NMR to the phenolic extracts of olive oil samples coming from three close and restricted geographic areas. The peak intensities were determined and signals due to aldehydic, vinyl, and aromatic protons of the phenolic compounds were selected for the statistical analysis according to their capability of discriminating the origin of the samples. Discriminant analysis was applied to the selected intensities of the NMR signals [33] and permitted to separate the oils according to their geographical origin obtaining a predictive capacity of 88%.

Introduction

Applications of high resolution deuterium-NMR in organic and bioorganic chemistry have regularly expanded in the last decades, accompanying the development of high field spectrometers which are required to overcome, at least in part, the severe drawbacks resulting from the nuclear properties of deuterium. In the technological conditions of the seventies both the small gyromagnetic ratio (4.107×10^7 rad/s/T), responsible for poor intrinsic sensitivity (9.6×10^{-3} with respect to ^1H), and the very low natural abundance of deuterium (1.5×10^{-4}) were serious impediments to the study of natural abundance deuterium spectra. Fortunately, the predominance of quadrupolar relaxation avoids perturbations in signal intensities due to nuclear Overhauser effects. Since 1980, more than 300 articles have been published in the field of high resolution ^2H-NMR and, in this number, about 200 are concerned with quantitative determinations of isotope ratios, for which we have proposed the terminology SNIF-NMR (site-specific natural isotope fractionation studied by nuclear magnetic resonance). Both the first paper dealing with the NMR determination of non-random distributions of deuterium and the corresponding patent concerning applications appeared in 1981 [1,2].

Isotopic Abundances and Isotopic Ratios

In a closed system at equilibrium (chemical, plant, animal) the distribution of the different isotopes of a given atom may be described by overall and specific parameters which must satisfy mass and isotopic balance.

For a given atom, such as carbon or hydrogen, having both a heavy and a light stable isotope, the *isotopic abundance*, A, is the ratio of the number of heavy isotopes, H, to the number of heavy and light, L, isotopes:

$$A = H/(H + L) \tag{1}$$

The *isotope ratio*, R, is the ratio of the numbers of heavy and light isotopes:

$$R = H/L \tag{2}$$

A and R are related by the simple relations:

$$A = R/(R + 1) \tag{3a}$$

$$R = A/(1 - A) \tag{3b}$$

In principle, a given molecular species is composed of a large number of isotopomers containing one or several isotopes. Thus, for a given chemical species $C_xH_yO_z$, the theoretical number of isotopomers, N, is:

$$N = (XH_3 + 1)^a(XH_2 + 1)^b(XH_1 + 1)^c(2^x)(3^z) \tag{4}$$

where a, b, and c are the numbers of XH_3, XH_2, and XH_1 groups contributing respectively to 4, 3, and 2 isotopomeric possibilities. For example, vanillin, $C_8H_8O_3$, has 884,736 isotopomers.

In the case of hydrogen, owing to the low natural abundance of the deuterium isotope, the presence of bi-deuterated (and *a fortiori* multi-deuterated) molecules may be neglected at the usual precision of the NMR determinations and only mono-deuterated isotopomers are generally considered. In these conditions, the A and R values are equal. However, in the case of carbon for instance the A and R parameters should not be confused and bi-labeled molecules may no longer be ignored.

It may also be convenient to express the isotopic content in terms of the relative parameter, δ, commonly used in isotope ratio mass spectrometry (IRMS). The isotopic deviation, expressed in ‰, refers the isotopic content of the considered sample or molecule, i, to that of an international reference, ref:

$$\delta_i = 1000(R_i - R_{\text{ref}})/R_{\text{ref}} \tag{5}$$

The reference is a compound carefully calibrated by interlaboratory campaigns of measurements conducted by international organizations: IAEA (Vienna), IRMM (Geel), NIST (Washington, DC). The certified values of the isotopic ratio and isotopic abundance of the Vienna-Standard Mean Ocean Water (V-SMOW) [3] are 155.76 and 155.74 ppm, respectively. A secondary reference, the Standard Light Antarctic Precipitation (SLAP), exhibiting an isotope ratio of 89.0 ppm, is also available from IAEA in Vienna.

Graham A. Webb (ed.), Modern Magnetic Resonance, 1651–1658.
© 2008 *Springer.*

The site-specific isotope ratio, R_i, of a given molecular site, i, has been defined in the same way [4]:

$$(D/H)_i = D_i/H_i \tag{6}$$

where D_i is the number of deuterium atoms at site i. Since the presence of bi-deuterated molecules can usually be neglected D_i represents the number of isotopomers mono-deuterated at site i. H_i, the total number of hydrogen atoms of type i, is equal to $P_i N_H$ where P_i is the number of equivalent positions at site i and N_H the number of fully protonated molecules. The ^{2}H-NMR investigation of SNIF is presently the only way to access directly and simultaneously to hydrogen isotope ratios, $(D/H)_i$, associated with different positions, i, in a given molecule.

It is also convenient to define a relative parameter, $R_{i/j}$:

$$R_{i/j} = F_j S_i/S_j \tag{7}$$

where S is the intensity of signal i or j. $R_{i/j}$ represents the number of heavy isotopes at site i in a situation where site j is arbitrarily given its stoichiometric number of atoms, F_j. In principle, S is the area of the NMR signal. However, $R_{i/j}$ may be semi-empirically defined on the basis of signal heights which are usually measured with better precision than signal areas. Obviously, when computed from signal heights, the $R_{i/j}$ parameters measured in different samples of a given molecular species may be safely compared only on condition that constant transverse relaxation times are maintained by strictly identical preparation of the samples. In the case of ethanol, for instance, the line widths of the methyl and methylene deuterium signals being nearly equal, the ratio of signal heights is close to the ratio of signal area. When the methylene site, $i \equiv \mathrm{II}$, is compared to the methyl site, $j \equiv \mathrm{I}$, characterized by the stoichiometric number of hydrogens $F_{\mathrm{I}} = 3$, the value of $R_{\mathrm{II/I}}$ usually differs strongly from the statistical value 2 which would correspond to a random distribution of the deuterium atoms. Values of $R_{\mathrm{II/I}}$ higher than 2.7 are determined for instance in ethanol samples resulting from the fermentation of beet sugar.

Isotopic Fractionation

As discussed in Part 2, isotopic fractionation may occur at many steps of the elaboration of a product as a result of thermodynamic or kinetic isotope effects. The site-specific isotopic ratios of a molecule are therefore governed by the isotope contents in the precursor sites of the starting materials and by the subsequent individual fractionating events.

The Mass and Isotopic Balance

In a physical, chemical, or biochemical transformation the parameters of the starting and resulting compounds are connected by mass and isotopic balance relationships. Considering a complete transformation of a given compound, S, into two products P and Q, with mole fractions x and (1 - x), the mass and isotope balance requires that the isotopic abundances are related by:

$$A_S = xA_P + (1-x)A_Q \tag{8}$$

Denoting α_P and α_Q the fractionation factors of P and Q, the disproportionation of isotopes from S to P and Q is written:

$$A_S = \alpha_P A_P = \alpha_Q A_Q \tag{9}$$

More generally the overall isotopic abundances, A_S and A_Q of initial, S, and final, Q, states composed, respectively of $i = 1$ to n and $j = 1$ to m components are:

$$A_S = A_1x_1 + A_2x_2 + \ldots + A_ix_i + \ldots + A_nx_n \tag{10a}$$

$$A_Q = A_1x_1 + A_2x_2 + \ldots + A_jx_j + \ldots + A_mx_m \tag{10b}$$

Obviously, in a closed system where the S components have been completely transformed into Q: $A_Q = A_S$

Site-Specific Hydrogen Fractionation

If the deuterium isotope was randomly distributed within a given molecule, S, containing P hydrogen atoms, the molar fraction of isotopomer i would be equal to the statistical value $F_i = P_i/P$ where P_i denotes the number of equivalent hydrogen positions at site i. In fact, we have shown that most molecules exhibit strong deviations with respect to a statistical distribution of deuterium [1] and that the true molar fractions of the mono-deuterated isotopomers, denoted f_i, can be directly determined by quantitative ^{2}H-NMR. For a molecule with n different sites, the site-specific isotope ratio, R_i, is related to the overall isotope ratio, R, by:

$$R_i = f_i R/F_i \tag{11a}$$

$$R = \Sigma_i^n F_i R_i \tag{11b}$$

If we consider again the complete transformation of a set of starting materials, S, containing n sites, into products, Q, the deuterium content, R_j^Q, in every site, j, of an end product, Q, can be computed with a good approximation, from the deuterium contents, R_i^S, in the different sites, i, of the starting molecules [5]:

$$R_j^{\mathrm{Q}} = \sum\nolimits_i^n a_{ji} R_i^{\mathrm{S}} \tag{12a}$$

or, in matrix notation:

$$\mathbf{R}^{\mathrm{Q}} = [\mathrm{A}]\mathbf{R}^{\mathrm{S}} \tag{12b}$$

where $\mathbf{R}^{\mathrm{Q}}$ and $\mathbf{R}^{\mathrm{S}}$ are the column vectors of the deuterium contents in the end and starting molecules respectively and [A] is the matrix of the transfer coefficients, $a_{ji,}$ which connect selectively every site j of an end product to every site i of the reactants. These redistribution coefficients are powerful sources of mechanistic information (cf. Part 2). In particular, the a_{ji} value enables to determine whether a given hydrogen j of a reaction product is connected or not to hydrogen at position i of a starting compound. Intermolecular hydrogen exchanges occurring in the course of the reaction pathway for instance are thus detected [5].

Isotopic Fractionation in the Preparation of the Sample

Thermodynamic and kinetic isotope effects associated with physical transformations (cf. Part 2) have important repercussions on the reliability of the experimental isotopic parameters. Usually, a compound extracted from a chemical or natural medium has been subjected to various technological or chemical treatments, each of them being likely to be responsible for isotope effects. Consequently, the SNIF values measured on the extracted product may be considered as representative of the true isotopic parameters of the molecule only on condition that the compound has been completely recovered and that no hydrogen exchange with the medium has occurred [6]. In comparative studies of a given molecular species incompletely extractable from different materials it is therefore necessary either to elaborate a non-fractionating analytical chain or to define standardized analytical procedures in which isotopic fractionation is strictly controlled. In the last case, fractionation effects may be considered as reproducible and the experimental isotope ratios may be safely discussed on a relative basis.

Quantitative Deuterium-NMR

Experimental Parameters

Firstly it should be emphasized that, in a given magnetic field, the chemical shift discrimination expressed in frequency units is 6.5 times lower in ^{2}H-NMR as compared to proton NMR. With a spectrometer characterized by a proton nominal frequency of 400 MHz, for example, deuterium-NMR has therefore a resolution potential somewhat analogous to that of ^{1}H-NMR at 60 MHz. Consequently, in order to optimize peak separation it is advantageous to resort to high field equipments (11.4 T spectrometers are currently used). Neglecting small intrinsic isotope shifts, the deuterium chemical shifts expressed in ppm are identical to the corresponding proton chemical shifts. This property is very useful for assigning deuterium signals. However, differences in solvent shifts affecting the ^{1}H and ^{2}H spectra must be avoided or taken into account. In a first step, a complete analysis of the proton spectrum has therefore to be achieved by exploiting, if necessary, all resources of available one- and two-dimensional NMR sequences.

As previously noted, the relaxation of the deuterium nuclei (spin 1) is dominated by the relatively efficient quadrupolar mechanism. Consequently, nuclear Overhauser effects, which are mainly due to dipolar relaxation components, may usually be neglected. This property has important repercussions on the technical conditions of spectrum acquisition and on the methods of quantitative analysis. In particular, it is not necessary to resort to time-consuming gated decoupling sequences aimed to eliminate Overhauser enhancements. For simple organic molecules reorienting relatively rapidly, the quadrupolar longitudinal, T_1, and transversal, T_2, relaxation times are equal and relatively short. Short relaxation times are favorable from the sensitivity point of view since they authorize fast signal accumulation. However line widths increase when T_2 decreases. Fortunately, in the case of deuterium, the quadrupolar coupling constant is relatively small and the relaxation times of small molecules are frequently higher than 0.1 s. These values are convenient for efficient accumulation of signals with moderate line widths. For example, in the case of ethanol, accumulation of 90° pulses with an acquisition time At equal to 6.8 s fits conveniently the condition At $>6\ T_1$ required to recover at least 99.8% of the magnetization of the methyl isotopomer characterized by a relaxation time T_1 equal to 1 s. To recover the same proportion of the methylene isotopomer ($T_1 = 1.25$ s) an acquisition time $A_{\mathrm{t}} = 7$ s would be required. Moreover, the signal is sampled finely enough to ensure correct curve fitting. In order to minimize random fluctuations due to short-term instabilities of the spectrometer, each spectrum recorded with a given number of scans, N_{S}, is repeated N_{E} times, leading to a duration $N_{\mathrm{S}} \times N_{\mathrm{E}} \times A_{\mathrm{t}}$ of the experiment. For ethanol or vanillin studied at 11.75 T (500 MHz ^{1}H spectrometer) in a 10 mm OD cell with an acquisition time of 6.8 s, 2.4 and 5.8 h, respectively, are needed. At 7.05 T (300 MHz ^{1}H spectrometer) and in the same conditions the experimental times are, respectively, equal to 9.7 and 23.2 h. In order to weaken these drastic conditions the acquisition time for ethanol can be reduced from 6.8 to 3.4 s but at the price of a small decrease of the internal repeatability. As in most linear analytical techniques, the standard deviation of a series of measurements decreases with the number of repetitions, and obviously the precision increases with the signal-to-noise ratio.

From these properties, it is clear that the method is subjected to severe limitations when the compound to be investigated is available only in small quantity (<0.5 g) or when it is insufficiently soluble. In addition, since line widths increase rapidly when the size of the molecule increases, the spectra of large slowly reorienting molecules are hardly exploitable.

Signal Processing

Random and systematic errors occurring in quantitative treatments of NMR spectra have been fully documented [7–11]. They are attributed to instrumental instabilities, baseline distortions, phase corrections, imperfect algorithms for integrals estimation, etc. In particular, the manual phasing and fitting steps are responsible for operator dependent errors. Processing in the time domain was claimed to obviate artifacts arising after Fourier transformation. In this respect, interesting performances are exhibited by methods such as linear prediction and singular value decomposition which require no prior knowledge on behalf of the user [12,13]. However, in our case it is preferable to work in the frequency domain which offers the possibility of estimating the curve-fitting quality for every resonance. Quantitative analysis of deuterium spectra is fundamentally improved by a dedicated algorithm based on complex least-squares analysis of the NMR signal [14]. In the absence of truncation of the free induction decay, for reasonable values of the signal-to-noise ratio (>20), and in the hypothesis of Gaussian noise, this algorithm was theoretically proved to ensure optimum precision compared to all other exact and differentiable algorithms. The data are modeled as a sum of Gaussian noise, unphased Lorenztians, and zero-, first-, and second-order baseline distortions. The method, which is well suited for quantitative determination of spectra containing a limited number of signals (<30), rigorously manages all experimental parameters: frequencies, damping factors, intensities, phases, acquisition delay (described by specific intensity and phase parameters). The iteration time depends only on the number of signals since the number of sampling addresses is nearly the same whatever the molecule studied. In the pioneering times of bench top computers, 3 s were needed to compute a 10-signal spectrum but iteration is now instantaneous. Therefore, quantitative determination can be rapidly achieved in fully automatized conditions.

For identical acquisition conditions, the standard deviation, σ, on signal intensity computed from the complex least-squares treatment, is inversely proportional to the signal-to-noise ratio:

$$\mathrm{Log}(\sigma) = -\mathrm{Log}(S/N) + \mathrm{Cst} \tag{13}$$

A 10-fold increase in the signal-to-noise ratio increases the precision in the same proportion, but obviously at the price of a much longer acquisition time.

As illustrated in Figure 1, complex spectral residuals can be derived from a comparison of the real and simulated spectra. These residuals enable systematic components to be sorted out, such as isotopic satellite lines, and spectral distortions with respect to the Lorentzian model [14,15]. It was shown in particular that these distortions are mainly spectrometer dependent.

Referencing of Isotopic Parameters

For a given molecular species, the isotopic profile expressed in terms of molar fractions, f_i, of the different isotopomers is frequently sufficient for discriminating samples from different origins (cf. Part 3). Consequently, many problems can be solved without the need for isotopic referencing.

More generally, absolute values of the site-specific isotope ratios, $(D/H)_i$, of a compound, S, can be obtained either by using an intra- or intermolecular reference of known isotope content or by measuring independently the overall average isotope ratio of the compound, $(D/H)_{\mathrm{S}}$, by resorting to IRMS.

Referencing by Means of a Working Standard

This approach makes use of a working standard, WS, the $(D/H)_{\mathrm{WS}}$ value of which has been previously determined on the V-SMOW/SLAP scale. The working standard may be either weighed and dissolved into the sample or introduced into a hermetic cell coaxial to the sample cell [16].

In these methods the intensity, $I_{i\mathrm{S}}$, of the i signal in compound S is compared to that of the reference signal, I_{WS}:

$$(D/H)_{i\mathrm{S}} = (D/H)_{\mathrm{WS}}(I_{i\mathrm{S}}P_{\mathrm{WS}}N_{\mathrm{WS}})/(I_{\mathrm{WS}}P_{i\mathrm{S}}N_{\mathrm{S}}) \tag{14}$$

where P_{S} and P_{WS} are the stoichiometric numbers of hydrogen atoms in sites i and WS, and N_{S} and N_{WS} are the numbers of fully protonated molecules of S and WS in the active volume of the coil. When the coaxial arrangement is used, the isotope content in V-SMOW can also be referred to that of WS by using the same cell.

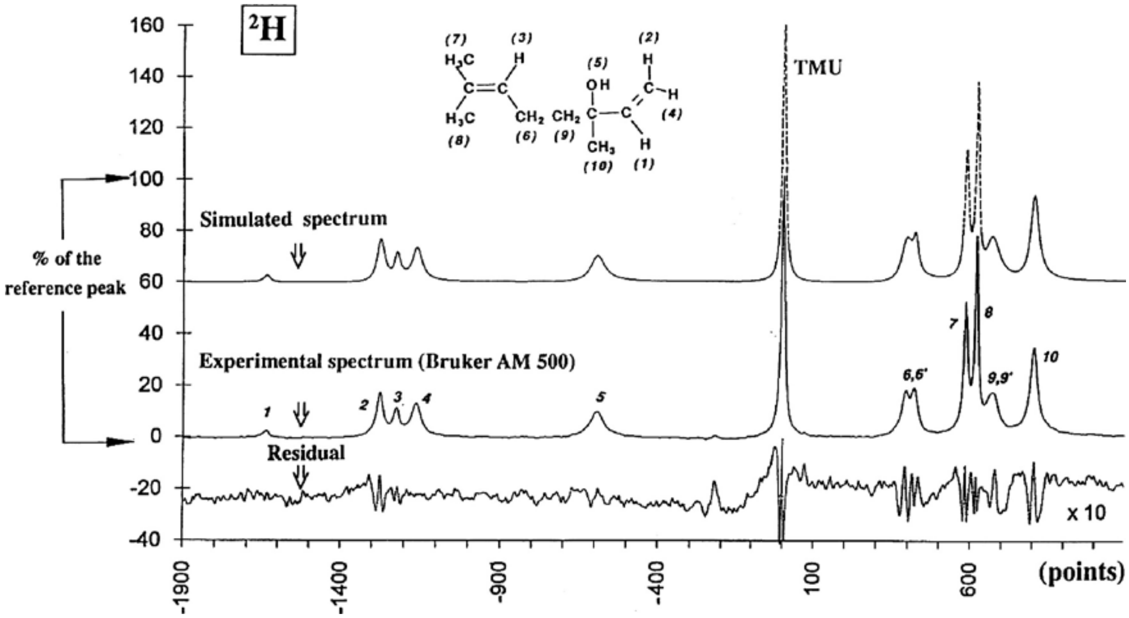

Fig. 1. Complex least-squares curve-fitting of the ^{2}H-NMR spectrum of linalool. The experimental spectrum has been obtained at 76.8 MHz with an AMX Bruker spectrometer equipped with the SNIF-NMR concept system [14]. The residual is represented on a 10 times expanded intensity scale. The isotopic reference is tetramethylurea.

It is necessary to select and calibrate carefully the working standard WS. Its NMR signals should not interfere with those of the target molecule and its volatility, chemical inertness, and solubility should be suitable. Moreover, its relaxation properties should conveniently fit those of the substrate. In this respect, *N*,*N* tetramethylurea, $[(CH_3)_2N]_2CO$ (TMU), was adopted in the study of ethanol used as a probe for investigating thousands of wines and fruit samples [17](Part 4). Samples of TMU with certified values of $(D/H)_{WS}$ are delivered by the Joint Research Centre of the E.U. at Geel, Belgium.

The error on $(D/H)_i$ depends on the quality of integration of the *i* and WS signals and on errors on the weights of S and WS. For simple mobile molecules, the cumulated relative error on mass and ^{2}H intensity, which is generally lower than 0.3×10^{-3}, induces an uncertainty of about 0.3 ppm on $(D/H)_i$. This value is in good agreement with results obtained in several interlaboratory comparison studies [18,19]. Equation (13) does not necessarily imply that the substrate S is chemically pure. If the amount of impurities can be determined with sufficient accuracy, by gas chromatography or proton NMR for instance, the corresponding purity ratio of S is then introduced into Equation (14).

SNIF-NMR has been fully investigated in terms of precision and accuracy. Precision is usually defined as repeatability, *r* (short-term repetition of measurements in the same laboratory, with the same instrument, by the same operator), and reproducibility, *R* (long interval of time between a series of repetitions involving different operators, different instruments, and different laboratories). Statistical expressions of *r* and *R* are derived from the notions of within, S_r^2, and between, S_L^2, variances of series of measurements [20,21]. Denoting *p* the number of laboratories (i) participating in the ring test and *n* the number of repetitions leading to an analytical result (in the case of SNIF-NMR, $n = N_E$ the number of replications of spectra for a given sample), S_r^2, S_R^2, and S_L^2 are given by:

$$S_r^2 = (1/p)\Sigma_1{}^p S_i^2 \tag{15}$$

$$S_L^2 = [1/(p-1)]\Sigma_1{}^p (x_i - X)^2 - S_r^2/n \tag{16}$$

$$S_R^2 = S_r^2 + S_L^2 \tag{17}$$

where x_i and S_i^2 are the mean and the standard deviation of the intensities resulting from *n* replications of spectra and *X* is the general mean.

The repeatability and reproducibility are:

$$r = 2.83\, S_r \text{ and } R = 2.83 S_R \tag{18}$$

The precision and accuracy performance has been reviewed in 1988 [17] but progress in instrumentation and data treatment in the last 15 years has helped to improve the quality of the determinations. In the case of ethanol, the presentation to the Office International de la Vigne et du Vin (OIV) of an up-to-dated version [22] of the UE regulation concerning the application of SNIF-NMR to wine analysis has brought to light the latest performance of the method for the measurement of $(D/H)_{\mathrm{I}}$ (I corresponds to CH_2DCH_2OH): $S_r = 0.29$ ppm, $S_R = 0.43$ ppm. For other types of products, r and R decrease with the size of the molecular probe. In the case of vanillin extracted from vanilla beans, S_r varies from 1 to 2% in relative values depending on the nature of the isotopomer.

Referencing by Combined Use of SNIF-NMR and Isotope Ratio Mass Spectrometry

This approach may be considered as a pseudo hyphenated technique since it uses IRMS to complement SNIF-NMR spectroscopy, according to the relationship:

$$(D/H)_{i\mathrm{S}} = (D/H)_{\mathrm{S}} f_{i\mathrm{S}}/F_{i\mathrm{S}} \tag{19}$$

where $f_{i\mathrm{S}}$ and $F_{i\mathrm{S}}$ are, respectively, the real and statistical molar ratio of isotopomer i and $(D/H)_{\mathrm{S}}$ is the overall isotope ratio of the substrate, S.

$f_{i\mathrm{S}}$ is determined by ^{2}H-NMR, in the absence of additional standard, and $(D/H)_{\mathrm{S}}$ is measured independently by IRMS. In this technique, which requires previous burning of the sample, only the overall isotope ratio of the molecule is directly accessible.

When large series of products involving the same molecular probe have to be studied, Equation (14) is certainly the best choice since it adapts satisfactorily to full automation. However, it should be emphasized that using internal referencing may induce serious biases when the aim is to compare deuterium contents in different chemical species. In this situation, the most accurate method to obtain site-specific isotope ratios is frequently to resort to Equation (19). However, this approach requires that both NMR and mass equipments are available.

Electronical Referencing

Finally, it is possible to refer the isotope ratio of an unknown product to that of a signal electronically generated [23]. The idea of the ERETIC$^{\mathrm{TM}}$ (ERETIC is a trademark of Bruker, France) method is to use as a reference, a pseudo-FID synthesized by an electronic device and transmitted inside the NMR probe during the reception of the NMR signal. If this electronic signal has the same shape and the same frequency as a FID, an additional peak is produced in the spectrum after Fourier transformation. Since all the parameters of this reference peak (half-height, magnitude, chemical shift, and phase) can be freely chosen from the spectrometer console, signal overlap, saturation of the receptor, and other drawbacks encountered with addition of referencing standards are avoided. Furthermore, the ERETIC signal has no T_1 relaxation time and does not introduce a limitation in experiment duration.

The ERETIC signal is obtained by multiplication of a sinusoidal signal (high frequency component) and an exponentially decreasing signal (low frequency component). The high frequency component is provided by one of the channels of the NMR spectrometer. It is derived just before the amplification stage. Most modern NMR spectrometers are equipped with hardware able to synthesize RF shaped pulses. An exponential shape can therefore be numerically defined and used as the low frequency component. In heteronuclear experiments with proton decoupling, as it is the case for isotopic NMR, the pseudo-FID can be transmitted through the proton coil, which is not tuned at the operating frequency (here the deuterium frequency) and acts therefore as a broadband antenna for the ERETIC signal. Because this coil is also used for decoupling, the ERETIC signal has to be mixed with the proton irradiation by an RF coupler placed just before the probe. There is no need for an additional electronic device to apply the method [24].

In the case of isotopic analyses, the intensity, $I_{i\mathrm{S}}$, of signal i in compound S is compared to the intensity, $I_{j\mathrm{C}}$, of site j in the spectrum of a calibration compound, C, run separately. The ERETIC signal is used to compensate for the variation of intensity that arises between the two experiments. By analogy with Equation (14):

$$(D/H)_{i\mathrm{S}} = (D/H)_{j\mathrm{C}}(I_{i\mathrm{S}} P_{j\mathrm{C}} N_{\mathrm{C}} I_{\mathrm{eS}})/(I_{j\mathrm{C}} P_{i\mathrm{S}} N_{\mathrm{S}} I_{\mathrm{ec}}) \tag{20}$$

where I_{eS} and I_{eC} are the intensities of the ERETIC signal measured on the spectra of compounds S and C, respectively. Ideally, the calibration molecule is the same as the studied molecule.

It must be noted that the ERETIC method uses a calibration compound located in a different tube from that of the sample measured. If the gravimetric method is employed to determine the ratio $N_{\mathrm{C}}/N_{\mathrm{S},}$ the volumes of the two samples have to be taken into account. Since it is technically difficult to measure the total volumes with the precision required, the relative concentrations may be more efficiently measured by ^{1}H-NMR [25,26]. Because the active volume is fully occupied by the sample, the ERETIC method is favorable from the sensitivity point of view. In the case of ethanol for instance, removing TMU from the sample improves the signal-to-noise ratio by a factor 1.6. With other molecules higher improvements may be obtained, in particular when solvent is needed to improve miscibility of the sample with the chemical reference.

It should be noted that reduced repetition times may be used. When the compound investigated and the calibration sample are identical in composition and concentration the relaxation times T_1 are the same. Therefore, partial saturation has the same magnitude and spectral distortions are identical for the two spectra. Consequently, it is not necessary to choose a repetition time, T_R higher than $6T_1$. For example, with $T_R = 1.5T_1$, the signal-to-noise ratio remains close to that obtained with $T_R = 6T_1$ and the same number of repetitions. Distortions are observed but differences between the D/H values are small.

Since the ERETIC method achieves quantification with the help of a reference which is not a real NMR signal, the limitations of the method are rather different from those of classical methods. The signal is transmitted by a broadband antenna to avoid quality factor variations. The method is therefore independent of coil variations both during emission, because the reference signal is transmitted by an additional probe, and during reception, because the reference and sample signals are collected from the same probe. The reference being stable in time, the calibration step does not need to be performed at every quantitative acquisition

Carbon SNIF-NMR

Although both the intrinsic sensitivity and the natural abundance of carbon-13 are much higher than those of deuterium the SNIF-NMR method is better suited to the determination of hydrogen isotope ratios than to that of carbon isotope ratios. This behavior is largely due to differences in the relaxation properties of the nuclei on one hand, and to differences in the extent of natural isotopic dispersions on the other hand. Whereas the fast quadrupolar relaxation of deuterium permits relatively short repetition times to be selected, signal accumulation in quantitative conditions is much less efficient in the case of carbon, which frequently exhibits relatively long relaxation times. Moreover, in the presence of broadband decoupling, dipolar contributions to the relaxation of ^{13}C are responsible for variable signal enhancements due to Nuclear Overhauser Effects. Consequently, long and precise sequences of NOE suppression must be carefully implemented [27,28]. In addition, whereas the large mass difference exhibited by the isotopes of hydrogen is associated with a wide range of hydrogen isotope ratios, the isotopic parameters of carbon vary in a relatively small range. In ‰ units [Equation (5)], the carbon isotopic range covers less than 40‰ as compared to about 500‰ in the case of hydrogen. Very high levels of relative experimental accuracy are therefore required in carbon SNIF-NMR.

Traditionally, carbon isotope ratios are measured by IRMS. However, since the compound must be combusted previously into carbon dioxide and water, the isotope ratio measured on CO_2 is an average over all carbon atoms of the sample. Site-specific values can be determined by IRMS but at the price of tedious degradations of the molecule aimed to isolate specific positions. In spite of its lower sensitivity, carbon SNIF-NMR provides a unique tool for directly comparing isotope contents at different molecular positions in a one-pot experiment. Thanks to continuous improvements in the technological performances, many instabilities, due in particular to filtering and field drifts can be eliminated.

Moreover, the reproducibility is improved by a rigorous complex least-squares treatment of the signal [14]. As mentioned above, this algorithm avoids, in particular, operator dependent errors associated with phase and baseline adjustment procedures.

The general principles discussed in the case of hydrogen (“Isotopic Abundances and Isotopic Ratios” section) also apply to carbon. However, since the natural abundance of carbon-13 (about 1.1%) is no longer negligible at the required precision of the measurements, the isotope ratio, R, may not be simply assimilated to the isotopic abundance, A.

On a relative basis, the site-specific abundances, A_i, can be calculated from the molar fractions, f_i, of the ^{13}C isotopomers mono-labeled at position i, and from the overall isotopic abundance, A_T, determined by IRMS, by means of Equation (20) [analogous to Equation (11)]:

$$A_i = A_T f_i / F_i \tag{21}$$

where F_i are the statistical molar fractions, which would characterize a random distribution of ^{13}C. The actual molar fractions, f_i, are determined from the signal area, S_i, of the mono-labeled isotopomers:

$$f_i = S_i / \Sigma_i S_i \tag{22}$$

This equation assumes, as a reasonable approximation, that the relative isotopic abundances of the bi-labeled species are analogous to those of the mono-labeled ones.

When integrating the signals of the mono-labeled isotopomers it is necessary to take into account possible contributions of the bi-labeled species. The corresponding satellite lines, situated at positions depending on the ^{13}C–^{13}C coupling constants and on small isotope effects, can be independently observed in INADEQUATE experiments. In glycerol, for instance [29], the molecule contains magnetically equivalent carbon atoms at positions 1, 3. In such a case, it is also necessary to correct the measured area, $S_{1,3}$, for the contribution of the degenerate single signal pertaining to the isotopomer bi-labeled at positions 1 and 3.

It has been checked that satisfactory repeatability and reproducibility performances of the SNIF-NMR analytical chain can be reached [28,29]. Results obtained on glycerol in particular are consistent with values derived from IRMS measurements carried out on derivatives of the same sample prepared by appropriate degradation reactions [29]. For a given molecular species it is now possible, once the experimental parameters have been optimized and standardized, to compare the carbon SNIF-NMR profiles of samples from different origins. Thus, the carbon fingerprint of glycerol originating from maize, olive, grape, or fossil sources are significantly different.

Introduction

Isotope labeling is a privileged source of information on chemical and biochemical mechanisms. In this context, the SNIF-NMR approach, which quantifies non-random distributions of isotopes at the natural abundance level, can be considered as a labeling method devoid of the need for isotopic enrichment [1]. Consequently, in its fields of application, it benefits from specific advantages with respect to conventional labeling methods. In particular, it avoids time-consuming syntheses of selectively labeled precursors, enables all monolabeled isotopomers of a molecular species to be simultaneously compared in identical experimental conditions, and provides a unique strategy for investigating mechanistic pathways taking place in unperturbed conditions. The main limitations are due to the rather poor sensitivity and chemical shift resolution of ^{2}H-NMR (cf. Part 1), which preclude observation of complex metabolites present in very diluted media or available only at the submilligram level.

From a theoretical point of view, fractionation of isotopes occurring in the course of physical, chemical, or biochemical transformations is the result of kinetic and thermodynamic isotope effects. Consequently, in the case of a natural product, the hydrogen and carbon isotopic NMR profiles are expected to reflect the successive isotope effects which have actively presided to the elaboration of the molecule, starting from its ultimate parent precursors, water and carbon anhydride.

Influence of Phase Transitions and Transport Phenomena on the Isotopic Parameters

Phase transition phenomena are generally accompanied by fractionation of isotopes. An equilibrium liquid–vapor isotope effect, EIE, is defined as the quotient of the isotope ratios in the vapor state, R_V, and in the liquid state, R_L.

$$\alpha_e = R_V/R_L \tag{1}$$

In the case of water for instance, the vapor state at equilibrium is slightly depleted in deuterium with respect to the liquid state, and the value of the thermodynamic liquid/vapor isotope effect, α_e, is about 0.974 [2,3]. In general, the isotopic composition of environmental water is the result of many kinetic and thermodynamic isotope effects associated with evaporation and condensation events. In such transformations, the isotopic ratios follow simple kinetic equations of the Rayleigh type:

$$(R/R_0) = (N/N_0)^{(\alpha-1)} \tag{2}$$

where R_0 and R are the isotope ratios of the substrate at the beginning and at a given stage of the transformation and N/N_0 is the degree of conversion of the substrate. The nature of the fractionation factor, α, depends on the kind of transformation considered and may represent either thermodynamic, kinetic, or mixed mechanisms.

Since fractionation effects associated with phase transitions and transport phenomena depend on environmental parameters, the isotopic NMR profile is expected to reflect the climatic conditions that have prevailed during the period of plant growing. A first climatic influence is introduced by meteoric water used by the plant for its photosynthesis. In this respect, it has been shown by isotope ratio mass spectrometry that the deuterium and oxygen-18 contents of meteoric water are related by the so-called Craig equation [4]:

$$\delta^2\mathrm{H_w} = 8.08\delta^{18}\mathrm{O_w} + 9.57 \tag{3}$$

whose slope and intercept depend slightly on the geographical situation. A relationship of type 3 stands also for water accumulated in fruits but the slope is generally smaller.

The climatic dependency is transferred to leaves and then to sugars, cellulose, and other metabolites. Thus, the deuterium content of water of fruit berries is related to the climate of the region of production:

$$\text{Meteoric water}: \Delta\delta D_W(‰) = 0.086\,\Delta T - 0.0017\Delta P, \tag{4}$$

$$\text{Wine water}: \Delta\delta D_W(‰) = 0.20\,\Delta T - 0.0047\,\Delta P, \tag{5}$$

Graham A. Webb (ed.), Modern Magnetic Resonance, 1659–1667.
© 2008 *Springer.*

where $\Delta\delta D_W$ represents the change in deuterium content as a function of changes in temperature, T(°C), and precipitation, P (mm). For example, the difference in the deuterium contents of wine water in Vienna, Austria ($T = 10.3\,^\circ$C and $P = 612$ mm) and in Porto Allegre, Brazil ($T = 20.1\,^\circ$C and $P = 1212$ mm) is equal to 4.3‰ whereas the corresponding difference for meteoric water is equal to only 1.8‰. This behavior expresses the isotopic fractionation efficiency of leaves in vine.

Simultaneous Determination of Site-Specific Thermodynamic Isotope Effects

Since thermodynamic isotope fractionation effects in exchanging systems are important sources of information on chemical and biochemical mechanisms [5–8], many theoretical and experimental methods [9–12], including NMR chemical shift measurements [13–15], have been devoted to the investigation of these parameters. In contrast to most experimental procedures, which require the use of labeled compounds and only provide indirect access to equilibrium isotope effects, the SNIF-NMR method enables thermodynamic isotope effects at different molecular sites to be directly compared in many kinds of exchange equilibria [16,17].

Liquid–Vapor Fractionation Effects

The isotopomers of a given molecule may be affected differently by the liquid–vapor isotope effect defined in Equation (1). The site-specific values of α_e can be simultaneously measured by NMR through dedicated distillation experiments [16]. This one-pot determination is well suited to accurate comparisons of isotopomers. Thus, the results of distillation experiments, performed on alcohols, in technical conditions involving very high reflux and slow product rate, can be analyzed according to the Rayleigh-type model. For every isotopomer, the isotope ratios of the remaining material (L) and distillate (D) are expressed, as a function of the fraction of the transformation, ρ, by the following relationships:

$$R_L = R_S(1-\rho)^{\alpha-1} \tag{6a}$$

$$R_D = R_S(1/\rho)[1(1-\rho)^{\alpha}], \tag{6b}$$

where R_S is the isotope ratio of the starting material.

For a given site, the unit fractionation factor, α, depends on the constant number of theoretical plates of the distillation column and on the specific thermodynamic isotope effect, α_e. The accuracy of the determination is improved by performing a series of separate distillations stopped at different fractions of transformation, ρ. The unit fractionation factors can then be computed from nonlinear regression analyses carried out on the whole curves defined by Equations (6a) and (6b). However, since the intercept of the R_D curve at $\rho = 0$ verifies Equation (7), a first approximation of α can be rapidly deduced from a single experiment carried out for a value of ρ as low as possible [16,18].

$$\alpha = (R_D/R_S)_{\rho\to 0} \tag{7}$$

Some examples of results obtained on alcohols are given in Table 1.

Table 1: Site-specific unit fractionation factors, α, and thermodynamic isotope effects, α_e, for liquid–vapor phase transition of methanol and ethanol. The ^{13}C parameters are determined by isotope ratio mass spectrometry (IRMS) on the same distillate samples as those used in the hydrogen SNIF-NMR measurements

Molecule	T(K)	Factors	^{13}C (IRMS)	CH_2D	CHD	OD
CH_3OH	338	α	1.0020	1.0150		0.820
		α_e	1.00023	1.0017		0.977
CH_3CH_2OH	351	α	1.0035	1.0230	1.0180	0.819
		α_e	1.00043	1.0032	1.0024	0.975

Note: CH_2D denotes the CH_2DOH and CH_2DCH_2OH isotopomers, CHD the CH_3CHDOH isotopomer, and OD the CH_3OD and CH_3CH_2OD isotopomers.

It is interesting to note that the $\alpha_e(^{13}C)$, $\alpha_e(CH_2D)$, and α_e(CHD) values are higher than unity. This means that, in these cases, the heaviest isotopomers are more volatile than the lightest ones. This behavior differs from that of water and of the hydroxylic isotopomers which are usually characterized by α_e values [19] significantly smaller than unity, a situation corresponding to higher preference of the light isopomer for the vapor state.

These phase transition effects may be responsible for important isotopic fractionation in the preparation of samples. Thus, the site-specific isotope ratios measured on samples obtained by distillation depend on the rate of extraction. In case of insufficient recovery, the carbon-bound hydrogen atoms of alcohols for instance are significantly enriched in deuterium with respect to the starting material. Conversely, the occurrence of fractionation effects at phase transitions may be exploited to get information on rates of evaporation or concentration and more generally on technological treatments undergone by a given sample (cf. Part 4).

Isotope Effects in Chemically Exchanging Systems

Hydrogen exchange processes involving, in particular, water and exchangeable groups, such as OH, NH, SH, etc., are common in chemical and biological media and many experimental and theoretical methods have been devoted to the study of equilibrium isotope partitioning in such systems. In principle, at natural isotopic abundance, all isotopomers in an exchanging system at equilibrium, at given temperature and pressure values, can be simultaneously quantified by NMR [17]

$$\mathrm{AH}_i + \mathrm{BD}_j \xrightleftharpoons{} \mathrm{AD}_i + \mathrm{BH}_j (K).$$

Thus, when atoms i and j, pertaining, respectively, to species A and B containing P_i^{A} and P_j^{B} hydrogen atoms, exchange slowly on the NMR time scale, the thermodynamic isotope fractionation factor, α^*, corresponding to the equilibrium constant K, can be measured:

$$\alpha^* = (D/H)_i^{\mathrm{A}}/(D/H)_j^{\mathrm{B}} = K P_j^{\mathrm{B}}/P_i^{\mathrm{A}}, \tag{8}$$

where α^* is simply computed from the area of signals i and j in the deuterium spectrum and from the mole fractions of compounds A and B. Thus, in aqueous solutions of alcohols, deviations with respect to a statistical partitioning of deuterium between water and alcoholic hydroxyl groups are detected. It is directly shown, for instance, that deuterium exhibits a higher affinity for the hydroxyl bond of propanol or butanol than for water. Multiple hydrogen isotope partitioning can even be investigated in ternary mixtures.

Determination of Thermodynamic Isotope Effects in Tautomeric Equilibria

The SNIF-NMR method is particularly suited to the simultaneous determination of primary and secondary thermodynamic isotope effects in tautomeric equilibria [20]. Others methods [5] must usually face the complexity of multi-isotopomeric mixtures associated with the use of labeled substrates or deuterium enriched media and a limited number of exchanging systems is accessible to the existing techniques. In the keto–enol tautomeric exchange of acetylacetone for instance, several isotopomeric equilibria are simultaneously involved at natural isotopic abundance (Figure 1) and NMR can directly determine a set of four thermodynamic fractionation factors.

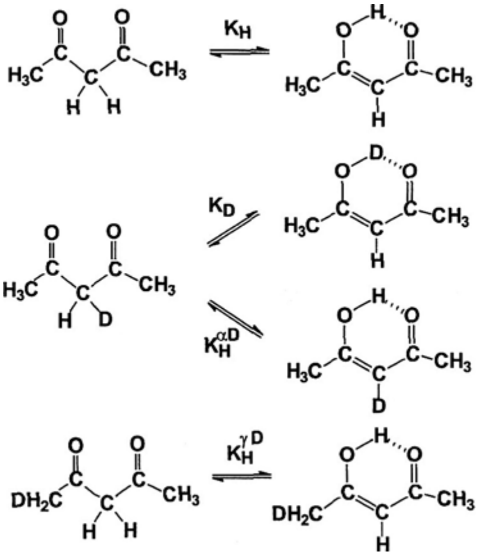

Fig. 1. Multi-isotopomeric exchanges simultaneously accessible in a SNIF-NMR investigation of acetylacetone tautomerism. In addition, a fast equilibrium (with respect to the NMR time scale) involves the two equivalent forms of the enol structure.

Thus, the fractionation factor $\alpha(=\mathrm{CH}^{\mathrm{e}}/\mathrm{OH}^{\mathrm{e}})$ relating the =CH and OH sites of the equivalent rapidly exchanging enol species is simply derived from the sole ^{2}H-NMR spectrum. More generally, a combination of ^{2}H- and ^{1}H-NMR experiments is used to determine the isotopic parameters that relate keto and enol tautomers in β-diketones. Thus the fractionation factor, $\alpha(\mathrm{CH}_2^{\mathrm{k}}/\mathrm{OH}^{\mathrm{e}})$, relating the hydroxyl group of the enol form and the methylene group of the keto form is

$$\alpha(\mathrm{CH}_2^{\mathrm{k}}/\mathrm{OH}^{\mathrm{e}}) = K_{\mathrm{H}}/2K_D^{\alpha\mathrm{H}} = S_{\mathrm{CHD}}^{k}(1-a)/2aS_{\mathrm{OD}}^{\mathrm{e}}, \tag{9}$$

where S_{CHD} and S_{OD} are the area of the keto CHD and enol OD signals measured on the deuterium spectrum and a is the molar fraction of the keto form determined on the proton spectrum. The measured primary equilibrium isotope effects illustrate a preference of deuterium for the methylene fragment of the keto form, with respect to both the hydroxylic or ethylenic positions of the enol tautomer. For instance, values $\alpha(\mathrm{CH}_2^{\mathrm{k}}/\mathrm{OH}^{\mathrm{e}}) = 1.09$ and $\alpha(\mathrm{CH}_2^{\mathrm{k}}/\mathrm{CH}^{\mathrm{e}}{=}) = 1.02$ are determined in acetylacetone. Secondary thermodynamic isotope parameters characterizing partner sites not directly involved in the exchange process (Figure 1) can also be simultaneously estimated.

Determination of Kinetic Isotope Effects

In the case of hydrogen, kinetic isotope effects (KIEs) are frequently the source of high values of the fractionation factors. This behavior results from the large difference in mass of the isotopes, which is itself responsible for significant differences in vibrational motions and in zero-point vibrational energies. KIEs are currently exploited to gain information on the mechanism of chemical or biochemical reactions and in particular to investigate the structure of transition states [8,21–25]. In conventional kinetic methods, determination of the KIE values requires the synthesis of selectively labeled reactants, which are then investigated in independent kinetic experiments. SNIF-NMR, which avoids the recourse to tedious labeling, enables primary and secondary KIEs at the different molecular positions to be compared in a one-pot experiment. Moreover, since the tracer is present in very small quantity in the substrate, the so-called Melander's kinetic equations become simpler [22].

The D/H ratios associated with the different isotopomers of a substrate, A, or of the reaction product, Y, can be expressed in terms of the primary and secondary KIEs, by taking into account the dilute isotopic conditions of the SNIF-NMR experiment and the type of the reaction [26]. For instance, in a closed system and in the absence of intramolecular competition, when a hydrogen atom AH is transferred to a product YH, the isotope ratios of the remaining reactant, R_A, and of the product, R_Y, depend on the primary isotope effect, $k_H/k_D = 1/\beta$ according to Equations (10a) and (10b) (Figure 2):

$$R_A = R_{0A}(1-\rho)^{(\beta-1)}, \qquad (10a)$$

$$R_Y = R_{0A}[1-(1-\rho)^{\beta}]/\rho, \qquad (10b)$$

where R_{0A} is the initial isotopic ratio and ρ is the degree of completion of the reaction.

It should be emphasized that, in this simple case, extrapolation of the kinetic Equation (10b) to $\rho = 0$, gives directly access to the KIE value.

$$\beta = k_D/k_H = 1/\mathrm{KIE} = (R_Y/R_{0A})_{\rho\to 0}. \qquad (11)$$

In addition, Equation (10a) shows that the ratio R_A/R_{0A} increases or decreases very rapidly in the vicinity of $\rho =$ 1. This means that the isotope ratio of the remaining reactant may differ strongly from that of the starting material at a high degree of completion. Then, R_A becomes very sensitive to the value of the KIE. This behavior can be exploited for improving the accuracy of the KIE determination [26–28].

If the site of reaction in AH is situated in a position α to the investigated bond the isotopic ratios depend on a secondary kinetic isotopic effect $k_H/k_H^{\alpha} = 1/\gamma$ and the same equations apply where β is replaced by γ.

Kinetic equations can be derived in the same way for more complex reactions, involving for instance hydrogen abstraction from a set of equivalent hydrogen atoms [26]. Thanks to the natural presence of tracer amounts of all types of monodeuterated isotopomers several primary and secondary isotope effects are simultaneously accessible from such equations. Some examples of the use of SNIF-NMR to determine KIE values and to elucidate chemical reaction mechanisms can be found in references [27–34].

Specific Connections Between SNIF Parameters of Reactants and Products

The sensitivity of site-specific isotope ratios to active equilibrium and KIEs intervening at various steps of product elaboration make them attractive sources of information on the mechanistic history of biological or chemical syntheses.

Isotope Effects and Affiliation Coefficients

It should be emphasized that high values of hydrogen primary KIEs are not necessarily accompanied by strong fractionation factors. In a simple open system where compound, S, present in unlimited quantity, is transformed into product Q, the values of the isotope ratios, $(D/H)_j^Q$ and $(D/H)_i^S$, are constantly related by the KIE proportionality coefficient. In contrast, in a closed system where S is totally transformed into Q, all deuterium and protium atoms, i, of the starting material are finally recovered in the product and the isotope ratios of Q and S are equal, whatever the value of the KIE. More generally, the influence of the KIE on the isotopic parameters depends on the rate of the transformation according to kinetic equations dictated by the mechanistic pathway.

As discussed in Part 1 (Equation 12), at the end of a transformation, the set of isotope contents in reaction products can be related to the initial set of isotope contents in reactants by a matrix of coefficients, [A], which describes the overall redistribution of the deuterium atoms governed by the reaction pathway [35]. A coefficient, a_{ji}, represents the individual degree of connection of a given site, j, in any product molecule, Q, to a specific site, i, of a starting material, S. Thus, whatever the complexity of the considered reaction, the SNIF parameters of the Q and S molecules provide a global isotopic balance representing the whole set of successive and competive reaction steps.

The SNIF-NMR profile of natural products is generally the result of complex chains of reactions. Many steps of the *in vivo* reactions are kinetically invisible because, in the absence of branching, they may be considered as taking place in closed systems and are devoid of isotopic fractionation whatever the values of possible KIEs. The final NMR profile is therefore conditioned by the genealogy of the atoms and is mainly governed by the site-specific isotope contents of the precursors, including water, and by the sole active fractionation effects introduced at isotopically sensitive branching points.

Determination of the Isotopic Redistribution Coefficients

For a given transformation, the a_{ji} coefficients can be determined by submitting starting materials characterized

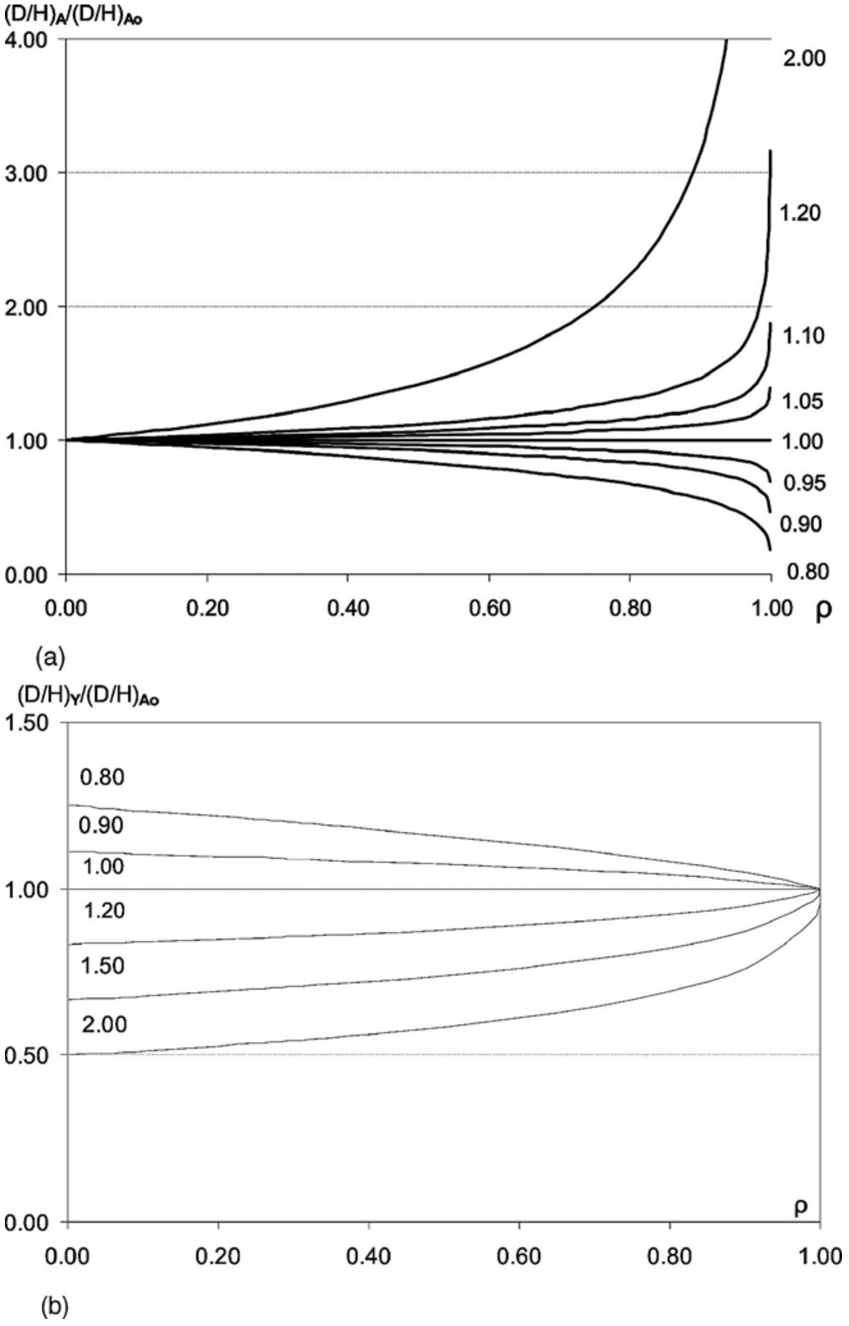

Fig. 2. Evolution of the isotope ratios, $(D/H)_A$ (Part a) and $(D/H)_Y$ (Part b) of reactant, A, and product, Y, as a function of the fraction of reaction, ρ, in a simple closed system where AH is transformed into YH with different values of the kinetic isotope effect k_H/k_D. The isotope ratios of A and Y are referred to $(D/H)_{A0}$ the isotope ratio of the starting reactant at $\rho = 0$. The region close to $\rho = 1$ corresponds to conditions of improved sensitivity for the determination of the KIE.

by different values of their SNIF parameters to a series of experiments carried out in strictly standardized conditions. When natural precursors with different isotopic NMR profiles are not available, molecules selectively labeled in deuterium at a level of enrichment close to natural abundance may be used.

Complete redistribution matrices can only be obtained when all deuterium signals of reactants and products are separated and correctly identified and quantified. Therefore, a limitation of the method is due to the relatively poor resolution potential of ^{2}H-NMR (cf. Part 1, Section "Quantitative deuterium-NMR"). Nevertheless, partial information may be usefully derived from coefficients relating signal clusters including several isotopomers. Moreover, when the spectrum of a molecular species is insufficiently resolved, it is often possible to synthesize derivatives exhibiting more exploitable NMR spectra. Care must obviously be taken in such derivatization procedures to preserve the initial isotopic values of the investigated molecule. This approach will be illustrated in the following section.

Elaboration of SNIF-NMR Probes: From Carbohydrates to Ethanol and Glycerol

Since glucose is a key compound in the biosynthesis of natural products, particular efforts have been devoted to the determination of its SNIF parameters and to the investigation of its glycolytic products.

Isotopic Parameters of Glucose and Photosynthetic Pathways

Due in particular to the presence of several hydroxyl groups engaged in exchange processes and hydrogen bonding, the glucose and fructose molecules themselves are not suitable NMR probes. Consequently, it has been necessary to synthesize derivatives exhibiting better-resolved spectra. Several glucose derivatives, such as 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose, which are easily prepared, enable glucose isotopic profiles to be rapidly compared [36], but a better discriminating potential is reached by 3,6-anhydro-1,2-*O*-isopropylidene-α-D-glucofuranose prepared in good yield through three chemical steps [37]. Experimental conditions of the derivatizations were defined which minimize fractionation effects by maximizing the yields of the successive steps. However, since the transformation cannot be complete, the experimental procedures must be standardized in order to obtain isotopic parameters analyzable at least on a relative basis. Using this strategy, it could be shown that, despite the various exchange phenomena that occur in the course of photosynthetic pathways, deuterium is far from being randomly distributed in glucose [38]. Moreover, different SNIF-NMR profiles are exhibited by carbohydrates extracted from plants with different photosynthetic metabolism: C3, C4, or CAM. Even within a given metabolic family, physiological features of the plant introduce specific isotopic signatures. Taking into account the pivotal role of carbohydrates in natural biosyntheses, the NMR parameters may provide important sources of basic information in phytochemical studies.

From Carbohydrates to Ethanol: Hydrogen Isotope Redistribution in the Fermentation Reaction

When large numbers of samples have to be investigated the described strategy for isotopic characterization of glucose or fructose is excessively time consuming. Moreover, structurally different carbohydrate molecules cannot be directly compared. Fortunately, a common derivative, ethanol, well suited to ^{2}H-NMR (cf. Part 1, Section "Referencing of isotopic parameters") and easily obtained through fermentation experiments, could be proposed as a very sensitive probe, representative of sugars. Although the number of hydrogen sites in ethanol is strongly reduced with respect to the seven diastereotopic carbon-bound hydrogen positions of glucose, it was tempting to investigate to which extent, and in which conditions, isotopic properties of carbohydrates are transferred to glycolytic products and in particular to ethanol. Most investigations of glycolytic pathways have involved labeling experiments using either tritium or deuterium and a number of KIEs have been estimated for isolated enzymatic steps [39–42]. However, only a few of these KIEs are expected to participate actively in the resulting fractionation effects. Model fermentation experiments have been conducted in order to determine the a_{ji} coefficients characterizing the connection of specific hydrogen atoms in the products, ethanol and water, to their parent hydrogen atoms in the starting materials, glucose and water. For a given site j in the products, Equation (12) in Part 1 may be re-written as a function of the isotope ratio of a given site $i = k$ in a reactant, S, as:

$$(D/H)^{\mathrm{Q}}_j = a_{jk}(D/H)^{\mathrm{S}}_k + \textstyle\sum_{i\neq k} a_{ji}(D/H)^{\mathrm{S}}_i \qquad (12)$$

Values of the a_{ji} coefficients which relate sites $j = \mathrm{I}$ (methyl) and $j = \mathrm{II}$ (methylene) of ethanol to carbon-bound hydrogen sites i of glucose and to water are given in Table 2. Obviously, the complementary term of Equation (12), $C_i = \sum_{i\neq k} a_{ji}(D/H)^{\mathrm{S}}_i$, depends on the origin of the fermented carbohydrate and on the isotope ratio of the aqueous medium. The reported values hold for experiments carried out with maize samples and Nantes tap water.

Table 2: Isotopic redistribution coefficients, a_{ji}, relating reactants (water, W, and sites 1–6 of glucose) and products (water, W, and sites I—methyl and II—methylene of ethanol) in a fermentation reaction carried out with maize glucose and tap water [43].The coefficients a_{I3}, a_{I4}, a_{I5}, a_{II1}, a_{II2}, a_{II3}, a_{II5}, and a_{II6} are close to zero and a small connection between site II of ethanol and site 4 of glucose is detected. Slightly different values have been measured in other series of experiments [44–46]

a_{I1} C_1	a_{I2} C_2	a_{I6} C_6	a_{IW} C_W^{I}	a_{IIW} C_W^{II}
0.12112	0.08113	0.30114	0.2181	0.738

The a_{ji} values predicted for a situation where hydrogen i of glucose would be preserved from any kind of exchange with the medium in the course of the reaction pathway and would end at position j of the product are: $a_{Ii} = 1/6$ for the methyl site and $a_{IIi} = 1/4$ for the methylene site. Consequently, a first conclusion drawn from the results in Table 2 is that the methyl group of ethanol exhibits, a strong connection with the two hydrogen atoms at site 6, and a less tight connection with hydrogen at sites 1 and 2, of glucose, a moderate connection with water and no connection with sites 4 and 5 of glucose. In contrast, the methylenic hydrogen atoms are mainly derived from water and are only very slightly connected with site 4 of glucose. The deviations of a_{I1} and a_{I2} with respect to the theoretical value 1/6 are indicative of intermolecular hydrogen exchanges which can be further analyzed in mechanistic terms [43].

On the basis of this NMR isotopic strategy, it becomes possible to examine whether natural or experimental factors exert a significant influence on the mechanistic pathway. Thus, experiments performed with different yeasts, different concentrations of carbohydrates, and different yields of the transformation have demonstrated a remarkable mechanistic stability of the chain of reactions [44]. Although glycolysis is associated with overall fractionation effects that may exceed 40 ppm, the considered factors are responsible for variations limited to a few ppm. Similarly, it could be shown that, in spite of their strong influence on the rate of bioconversion, changes in the composition (natural or "synthetic") of the fermentation medium, exert only small effects, which can be interpreted, on the redistribution matrix and on the final isotopic values [45].

From Carbohydrates to Glycerol

Another example, the biosynthesis of glycerol through yeast fermentation of glucose, illustrates different kinds of information possibly derived from isotopic redistribution matrices [46]. Under its triacetate form, glycerol exhibits three ^{2}H-NMR signals stereochemically assigned in Figure 3.

The theoretical a_{ji} values corresponding to full hydrogen transfer from i to j are equal to 0.25. Through comparison with this limit, it is concluded that the experimental coefficients $a_{1A} \sim 0$, $a_{2A} = 0.16$, $a_{6A} = 0.23$, $a_{1B} = 0.22$, $a_{2B} \sim 0$, $a_{6B} = 0.22$, characterize high levels of intramolecular transfer from hydrogen atoms 6 pro-R and 2 of glucose to 3 pro-R of glycerol and from 6 pro-S and 1 of glucose to 3 pro-S of glycerol. Moreover, these results contain information on the *relative rates of certain reaction steps* and on the *stereospecificity of reaction*. Indeed the isotopic behavior is only compatible with a reversible isomerization of the triose phosphate intermediates, glyceraldehyde 3-phosphate and dihydroacetone phosphate (DHAP), and with a reduction of DHAP into glycerol slower than the isomerization step. In the reverse situation values of $a_{6(\text{pro-R})A}$ and $a_{6(\text{pro-S})B}$ equal to zero would be expected. In addition, values $a_{A2} \neq 0$ and $a_{B2} = 0$ are only compatible with a reduction of DHAP into glycerol operating through the *si*-face. A non-stereospecific reduction would require $a_{A2} \neq 0$ and $a_{B2} \neq 0$, whereas a reduction through the *re*-face would be characterized by $a_{A2} = 0$ and $a_{B2} \neq 0$. The method therefore provides attractive alternatives to experiments conducted with enriched materials [47].

When interpreting redistribution coefficients a_{ji} smaller than the theoretical value, it should be kept in mind that the percentage of deuterium transferred from i to j should not be assimilated to the percentage of transferred hydrogen unless active KIE can be excluded.

Access to Mechanistic Information on Enantiotopic Hydrogen Sites

Thanks to the diastereotopic character of geminal hydrogen atoms resulting from chirality, NMR is able to provide additional information about stereospecific mechanisms involving methylenic fragments. Thus, differences in isotope contents at the geminal positions of a methylene group indicate that stereospecificity has been preserved along the biosynthetic pathways. For instance, unequal *D/H* values have been determined at methylenic sites of D- and L-aspartic acids from biochemical origin, whereas equal values are exhibited by a D sample produced by chemical synthesis [48]. The method can be applied to the investigation of methylene groups in achiral molecules on condition that a suitable chiral derivative is synthesized by reacting the sample with an optically pure reactant capable of generating sufficient chemical shift discrimination. Thus, the genealogy of the pro-R and pro-S methylenic hydrogen atoms of ethanol can be separately

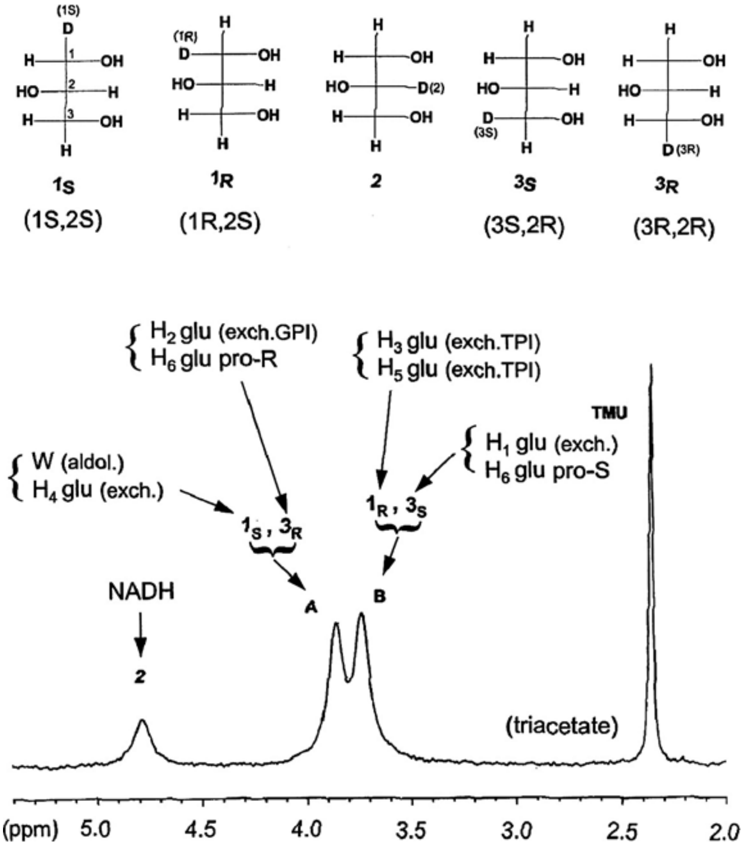

Fig. 3. ^{2}H-NMR spectrum (76.8 MHz) of the triacetate derivative of glycerol. The signals are stereochemically assigned to the monodeuterated isotopomers observable at natural abundance. TMU is the signal of tetramethylurea used as working standard. The described affiliation of the isotopomers to the glucose precursor has been deduced from the isotopic redistribution matrix [45]. Partial or total contributions of hydrogen atoms from the aqueous medium are mentioned. (glu = glucose, exch = exchange, GPI = glucose phosphate isomerization step, TPI = triosephosphate isomerization step, W = water, aldol = aldolization step).

investigated by reacting ethanol with L(–)-mandelic acid [49]. The enantiomeric resolution of the monodeuterated isotopomers thus achieved in optically active ethylmandelate can be used, in particular, to investigate yeast mediated stereospecific exchange of the pro-R hydrogen with water. Other illustrative examples in the field of terpenes will be discussed in Part 3.

SNIF-NMR—Part 3: From Mechanistic Affiliation to Origin Inference

Introduction

In contrast to many other analytical parameters, which are mostly exploited on semi-empirical bases, the SNIF-NMR parameters rest on the well-established theoretical principles of isotope fractionation (Parts 1 and 2). Having shown how the isotopic ratios of end products can be quantitatively related to those of their starting materials, we shall illustrate now how isotopic profiles of natural or chemical products can be interpreted in terms of the mechanistic routes of their elaboration. On this basis, it will be shown that the NMR method provides a very powerful tool for inferring the origin of molecules in terms of different properties of the precursors such as—the natural or chemical nature, the type of plant, the region of plant growing, possibly the year of production, the technological treatments, etc.

SNIF Parameters as Witnesses of Individual Mechanistic Routes of Atoms

We have seen in Part 2 that model experiments conducted on a given chemical or biochemical reaction, enable the set of isotopic connections between individual atoms in starting materials and in products to be elucidated and quantified. The measured isotopic transfer coefficients describe, individually, the overall fate of every atom in the transformation, whatever its complexity. This experimental strategy is not always practicable but, fortunately, many mechanistic features of biosyntheses can be simply elucidated, from analyses of isotopic parameters carried out on appropriate selections of samples from known origin. Thanks to studies devoted to the isotopic characterization of carbohydrates and to the determination of the connectivity scheme in glycolytic reactions (Part 2), it is even possible to trace back the affiliation of many plant metabolites to their ultimate glucose precursor.

From a general point of view, since many kinetic isotope effects operating at various steps of a complex conversion are devoid of fractionating effects on the final products, the SNIF-NMR method is not expected fully to replace separate investigations of isolated reaction steps using selectively labeled precursors. However, in contrast to conventional experiments carried out in strongly deuterium-enriched media, where metabolic switching may occur, the NMR investigation, which operates at tracer isotopic abundance, faithfully describes the overall unperturbed metabolic pathway.

The typical example of monoterpene biosynthesis illustrates the potential of a SNIF analysis based on the sole end products to induce many properties of the biosynthetic pathway and in particular to eliminate incompatible mechanistic hypotheses. Isotopic distribution in natural terpenes is the result of complex chains of reactions starting from carbohydrates. In principle, the monoterpene isotopic profile, illustrated in Table 1, is related to that of geranyl diphosphate (GPP), which is generally considered as the common intermediate precursor [1]. In order to facilitate comparisons within the terpene family, the hydrogen atoms are numbered in Figure 1 according to mechanistic correspondences with the GPP precursor established, for every monoterpenic species, in the course of several decades of thorough biochemical studies [2–4].

Inasmuch as they exhibit consistent behavior when based on the retained schemes of hydrogen connections, the NMR results provide further checks for the whole set of biochemical pathways leading from GPP to the different terpenes.

The NMR approach, already applied in the 1980s, showed that α-pinene exhibits surprisingly large deviations with respect to a statistical distribution of deuterium and that exploitable differences exist in the isotope contents of enantiomers extracted from a given type of plant [5]. These results were incompatible with the mevalonate mechanism, universally admitted at that time for explaining GPP biosynthesis in plants. In particular, a strong deuterium depletion at site ex-2, associated with a much higher isotope ratio at site ex-6 (Table 1), could not be reconciled with the mevalonate mechanism in which both atoms would have the same origin. Unfortunately, at that time, specialists in the field of terpene chemistry suspected the reliability of the new isotopic approach rather than the accepted pathway [6]. The incompatibility of the

$N = 5$	8.8	6.8	3.9	6.1	4.7	6.7	6.4	4.2

α-pinene	C1	C1′	C2	C4	C5	C5′	C6	C8 (C9)	C9 (C8)	C10
1*R*,5*R* (+)	153.3	149.1	40.8	124.2	165.5	148.1	140.1	110.6	91.6	115.8
$N = 4$	2.3	4.6	4.1	10.4	6.5	4.9	6.5	2.9	4.1	1.7
1*S*,5*S* (−)	159.1	151	37.7	93.3	162.9	157.3	152.9	111.9	90.5	119.5
$N = 4$	3.3	4	7.7	1.2	7.9	7	5.1	3.8	4.8	5.9

The GPP numbering of the carbon-bound hydrogen atoms is specified in Figure 1. Geraniol has been extracted from plants with either C3 or C4 metabolism. Samples of α-pinene with strong and opposite enantiomeric enrichments have been investigated. Standard deviations are computed from determinations performed on N samples [10].

NMR results with the mevalonate pathway was recognized later on [7,8] when a new mechanism [9] was proposed for explaining terpenoid biosyntheses. The whole set of specific isotope ratios determined in a large selection of monoterpenes from different plant origins was fully analyzed recently [10], in light of the newly proposed DOXP pathway, which is no longer based on mevalonic acid but on glyceraldehyde 3-phosphate (G3P) and pyruvate precursors [11,12]. Several striking mechanistic properties may be deduced from the overall isotopic scheme. Thus, the remarkable consistency of the NMR isotopic profiles within the monoterpene family supports the existence of a common mechanistic origin and provides unambiguous one-pot checks for the stereochemical schemes of affiliation illustrated in Figure 1 on the examples of geraniol and pinene. The NMR results reveal that the type of photosynthetic metabolism, C3 or C4, exerts a significant influence on the isotopic parameters (Table 1). This behavior may be attributed to the possibility of direct or indirect origin of dimethylallyl diphosphate (DMAPP), one of the two building blocks of GPP. The isotopic profile suggests that, in C3 plants, both isopentenyl diphosphate (IPP), the other building blocks of GPP, and DMAPP are, in majority, synthesized directly through the DOXP pathway (Figure 2a), whereas GPP of C4 plants is largely synthesized through condensation of IPP with DMAPP resulting from isomerization of IPP (Figure 2b).

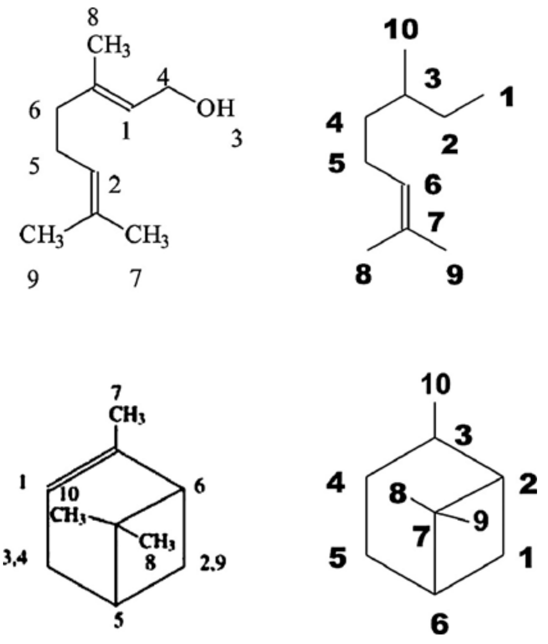

Fig. 1. Mechanistic correspondence between hydrogen positions in the geranyl and pinane skeletons (bold numbers) and corresponding assignments of the ^{2}H-NMR signals. The deuterium isotopomers of geraniol and α-pinene are numbered in the order of decreasing chemical shifts.

On this basis, the NMR method provides unique criteria for estimating the influence of physiological and environmental factors on the relative fluxes of directly and indirectly synthesized DMAPP in unperturbed natural environments. The NMR results also provide an order of magnitude of the kinetic isotope effects accompanying hydride and proton transfers at two steps of the DOXP pathway. Thus, a fractionation factor of the order of 5 with respect to water is determined at position ex-2 of a great variety of samples from the monoterpene family. This factor represents a minimum limit of the kinetic isotope effect accompanying the introduction of a proton

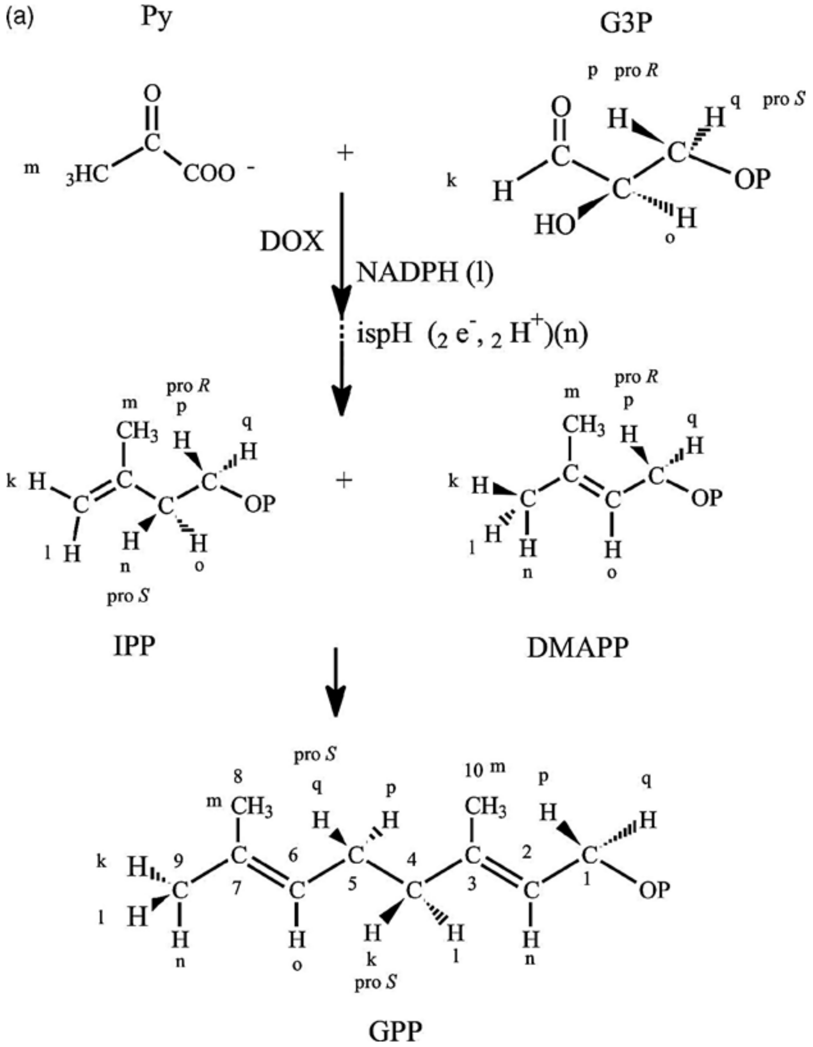

Fig. 2. Hydrogen affiliation of geranyl diphosphate (GPP) to its isopentenyl diphosphate (IPP) and dimethylallyl diphosphate (DMAPP) building blocks and formerly to the pyruvate (Py) and glyceraldehyde phosphate (G3P) precursors [10]. (a) The condensation involves IPP and DMAPP molecules independently biosynthesized through the DOXP pathway. (b) GPP results from condensation of IPP directly produced in the DOXP mechanism and of DMAPP obtained by isomerization of IPP.

(hydrogen denoted n) at a late step [13] of the DOXP sequence of reactions. It provides a reliable criterion for distinguishing the DOXP and mevalonate mechanisms, which may coexist in certain terpenoids [14].

Since transfer coefficients leading from carbohydrates to glycolytic products have been determined (Part 2, Section “Elaboration of SNIF-NMR probes: from carbohydrates to ethanol and glycerol”), it becomes possible to trace back selectively the hydrogen genealogy, going from the considered monoterpene to the key intermediate, GPP, then successively to the condensed couple IPP/DMAPP, then to the DOXP precursor couple pyruvate/G3P, and finally to the carbohydrate precursors (Figure 2).

Interestingly, the methylenic positions, which were enantiotopic in geraniol, become diastereotopic in chiral derivatives, and especially in cyclic monoterpenes. Consequently, they are, in principle, separately observable in the ^{2}H-NMR spectrum (Part 2, Section “Access to

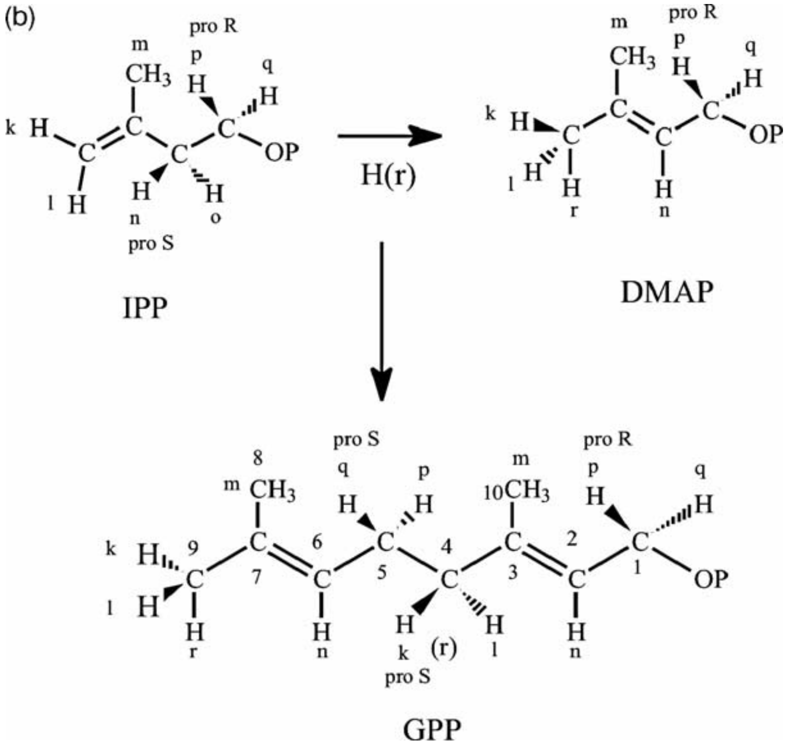

Fig. 2. (*Continued*)

mechanistic information on enantiotopic hydrogen sites"). The isotope contents at these positions may provide additional information [15] on the overall stereospecificity of the chain of reactions leading to GPP and then to terpenes, and, in particular, on the possible occurrence of scrambling steps. Thus, it was shown that all the geminal methylenic sites of GPP, are preserved from racemization. This behavior is demonstrated, for instance, by the existence of different deuterium contents at the diastereotopic methylenic positions ex-5 of optically active pinene samples (Table 1). Similarly, the strong difference in the $(D/H)_{\text{ex-4}}$ values of α-pinenes with opposite chirality proves that the two methylenic hydrogen atoms at site 4 of GPP have been stereospecifically transferred to the terpene. This behavior implies, in addition, that these two ex-4 hydrogen atoms have been stereospecifically introduced into GPP from different precursor atoms (one from the aldehydic site-k of G3P and the other from NADPH in the course of the DOXP pathway). These mechanistic properties provide the basis for an isotopic method of enantiomeric evaluation, applicable when optically pure enantiomers of opposite chirality are available as references. Once the maximum differences in the D/H values of the methylenic positions have been determined on the reference products, the corresponding differences measured on an unknown sample provide attractive criteria for estimating the rate of enantiomeric enrichment [5].

Many natural biosyntheses and biotechnological processes can be investigated in this way. Thus, information was obtained on cofactor recycling in asymmetric biocatalytic reduction of carbonyl compounds mediated by yeasts [16]. The situation is obviously more complicated for minor compounds issued from long biochemical pathways and/or for molecules insufficiently adapted to ^{2}H-NMR quantitative analysis. However, in this case, more exploitable spectra may often be obtained, as illustrated in the case of carbohydrates, through appropriate derivatizations. Thus, although the deuterium spectra of fatty acids suffer from drastic signal overlap, resorting to chemical degradations can individualize specific positions. Interesting information was derived in this way on enzyme mechanisms and in particular on the E-desaturation occurring in capsaicin [17,18].

The examples described above and in Part 2 are illustrative of the potential of isotopic NMR to elucidate different features of mechanistic pathways. They show that, either limited to the sole investigation of end products or possibly reinforced by determinations of isotopic redistribution coefficients through model experiments, the NMR method is particularly helpful (a) for eliminating inconsistent mechanistic hypotheses; (b) for detecting mechanistic changes and quantifying relative fluxes through different pathways; (c) for elucidating individual connections between hydrogen atoms of reactants and products and estimating the percentages of preserved affiliation; (d) for investigating stereochemical pathways in terms of stereospecificity and regioselectivity; (e) for detecting and even quantifying intermolecular exchanges and relative contributions of hydrogen atoms from the medium; (f) for identifying isotopically sensitive branching points; and (g) in certain circumstances, for estimating the value, or at least the order of magnitude, of active kinetic isotope effects.

Undoubtedly, this approach is able to spare considerable experimental time in the numerous labeling strategies usually implemented for elucidating biosynthetic pathways. Moreover, it provides a unique tool (a) for investigating *in vivo* metabolic responses to physiological characteristics of plants and, in particular, for estimating relative fluxes of intermediates in field conditions and for precising the role of different enzymic equipments, and finally for interpreting the influence of environmental factors on biosyntheses in unperturbed natural media. In this respect, natural isotopic abundance avoids the risk, inherent to enriched models, of perturbation of the biochemical pathway due to the effect of KIE in branched reaction steps.

Identification of Starting Materials: The Nature Laboratory

As discussed in Part 2, many mechanistic, physiological, environmental, and technological factors are likely to influence isotopic distribution in plant products. Moreover, hydrogen is reputed to be easily exchanged in the course of biochemical processes. A priori, the specific hydrogen isotope parameters were therefore not granted much future for precisely distinguishing chemically identical molecules biosynthesized in different plant species or grown in different environments. However, in spite of multiple sources of fractionation, the isotopic profile progressively appeared as an extremely powerful tool for precise origin inference. The aptitude of the SNIF-NMR parameters to elucidate the affiliation of a given type of molecule, both in terms of precursor and environment, rests on two important properties of isotope fractionation. Firstly, biosynthetic reactions operating in nature frequently exhibit remarkable mechanistic stability and reproducibility. Moreover, in contrast to many analytical methods, mostly based on hardly predictable compositional parameters [19], the NMR method exploits isotope fractionation effects which can be quantitatively appraised on theoretical bases. Consequently, as checked in the example of the fermentation reaction (Part 2), when a bioconversion is reproduced in strictly identical conditions, isotopic variations measured on products reflect solely differences in the isotopic parameters of their precursors [20].

In nature, a given molecular species is frequently synthesized in different plants species, different plant organs or different environments through the same complex chain of reactions and the kinetically fractionating steps are the same. Thanks to this mechanistic stability the NMR parameters of metabolites may be comparatively analyzed in terms of properties of the precursors. However, in this perspective of origin inference, the example of monoterpene biosynthesis discussed above (Section "SNIF parameters as witnesses of individual mechanistic routes of atoms," Table 1) draws attention on the importance of previously detecting and elucidating all possible changes in the reaction scheme.

The situation is somewhat different for products of animal origin, since the isotope ratios then reflect the diet rather than the animal species [21]. Thus, controlled feeding experiments have shown that lactose from cow's milk can be used for checking the type of diet given to the animal [22]. Similarly, isotope ratios measured on fish lipids are not efficient criteria for characterizing the fish species, a problem that is fairly well resolved by molecular biology, but they are able perfectly to classify wild salmon and salmon farmed in Norway and Scotland for instance [23].

Experimental Strategies for Origin Inference of Products

Taking into account the large price differences often exhibited by raw materials from different origins, it has always been tempting to substitute a cheap counterpart to an expensive molecular species. As illustrated in Part 4, being able to identify the origin of a given molecule is of great economical importance and a number of methodologies have been developed to this aim [19,24]. With the exception of isotope ratio mass spectrometry (IRMS), which measures overall isotope ratios, these methodologies are based on the detection of hardly predictable compositional differences resulting from the presence of molecules (minor components or impurities) structurally different from the adulterated species. When technically applicable, the NMR method of origin inference benefits from remarkable performances in terms of efficiency and reliability. Possibly combined with IRMS, it is often the only tool capable of identifying the origin of a pure molecular species.

Although it can be addressed to any product accessible to ^{2}H-NMR, the method has found a maximum number of applications in the field of food and aromas. In these domains, it has largely contributed to establishing the notion of authentication on quantitative bases.

General Methodology

In practice, many conclusions can be drawn from simple comparison of the $(D/H)_i$ values of the investigated sample with corresponding $(D/H)_i$ values determined, in the same experimental conditions, on samples from known origin. Official and private laboratories currently use this approach for controlling certain types of products (cf. Part 4). To operate in reliable conditions, it requires previous building up of reference databases composed of a great number of samples representing all possible different provenances. In addition, rigorous standardization of the whole experimental procedure is necessary. As a result of equilibrium and kinetic isotope effects accompanying physical treatments such as extraction, distillation, evaporation, etc. (cf. Part 2), isotopic values are likely to be spoilt by undesirable fractionation effects. It is therefore necessary to previously define, for every kind of molecule, standardized experimental conditions that optimize the yields. In a context of international regulation, it is recommended to organize dedicated collaborative studies.

For every type of molecule, this semi-empirical approach of origin inference should be secured by previous determination of the affiliation scheme and appraisal of possible sources of variation in the fractionation effects (cf. Part 2). This basic knowledge is of prime importance—to ensure correct interpretation of certain results, to detect anomalous values, to predict isotopic behavior when appropriate authentic reference samples are missing, and even to build properly a representative data bank.

Statistical Treatments

In order to improve the discriminating performances, numerous samples of a given type of product are usually investigated. Fortunately, integrated analyses of large numbers of data now benefit from computerized statistical methods, such as multidimensional analyses, developed in the course of the last decades. Thus, techniques of principal component analysis, hierarchical classification, or discriminant analysis are crucial help for classifying samples as a function of typical origins. Such statistical treatments of NMR isotopic variables provide interpretable graphical diagrams, which enable an unknown sample to be easily located in the appropriate group (cf. Section "Identification of plant precursors", Figure 4). Integration of multidimensional statistical treatments into automatized SNIF-NMR analytical chains, greatly improves the performance of authentication procedures. The discriminating parameters are retained according to their efficiency for both separating the considered origins and quantifying adulterations involving mixtures of species from different origins.

Natural or Synthetic Origin of Products

With the increasing interest of consumers for the natural status, it is desirable to dispose of methods capable of solving the problem of origin inference both for raw materials and for finished products [25]. In the case of flavors for instance, a distinct labeling may be claimed by food processors when using natural flavors. However, in many cases, the main molecules present in natural compounds can also be produced by chemical synthesis at a much cheaper price. Obviously, when flavors containing synthetic aroma chemicals are sold as natural ones, unfair competition destabilizes the market. Therefore, methods are required for detecting the addition of synthetic molecules to natural compounds. As discussed above, when two chemically identical molecules have been biosynthesized (or synthesized) through different reaction mechanisms, largely different isotopic profiles are expected. Therefore, in many cases, the SNIF-NMR method is particularly efficient for discriminating natural and synthetic origins and quantifying adulterations.

A typical example is that of the vanillin molecule which is nearly one hundred times more expensive when extracted from vanilla beans (4000 ˚ /kg) than when it comes out of the reactor. This gap in price has stimulated, for several decades, considerable research competition in view of alternatively developing and circumventing methods capable of recognizing the natural or synthetic origin of the molecule. Obviously, ^{14}C determination is a good tool for differentiating living pool products from fossil products devoid of radioactivity [26–28]. However, it is easy to "naturalize" synthetic samples through addition of ^{14}C-enriched materials. For a time, hope was placed on IRMS methods based on determination of the overall ^{13}C (and deuterium) content of the molecule [29–31]. Unfortunately, since the ^{13}C/^{12}C ratio of the natural species is higher than that of the synthetic one, the natural value was rapidly simulated through addition to the synthetic (or hemi-synthetic) species of a small quantity of vanillin enriched in ^{13}C on the methoxyl group. In reaction, chemists then developed cutting protocols aimed to isolate the methoxy group in order to detect abnormal enrichment. But since enrichment could also be directed to the carbonyl fragment, decarboxation procedures had to be defined. Finally, the skill of chemists in manipulating ^{13}C contents definitely compromised the chance of IRMS in solving the problem. The ^{2}H-NMR method, which simultaneously observes four isotopomers corresponding to non-exchangeable sites of vanillin, provides a highly discriminant fingerprint [32,33] which needs considerable labeling efforts to be efficiently simulated. Statistical analyses based on the four $(D/H)_i$ variables show that the group of vanillin ex-beans is unambiguously distinguished from synthetic origins [34]. The method enables about 5% addition of vanillin ex-guaiacol in vanillin ex-bean to be detected. Fortunately, research stimulation in this domain is still preserved, since the development of new sources of vanillin [35,36] has renewed the challenge! Whatever their official status, biotechnological vanillin samples obtained from different raw materials through different processes have now to be authenticated with respect to other origins [37].

We shall discuss a second example that of mustard oil. The major component of mustard oil is allyl isothiocyanate. When extracted from mustard seeds, this compound is much more expensive than when prepared by chemical synthesis. Therefore, there is substantial economic interest to reinforce the natural species by its synthetic counterpart. The ^{2}H-NMR signals of the four hydrogen isotopomers of allyl isothiocyanate, $SCN\text{–}CH_2\text{–}CH{=}CH_2$, are relatively thin and well separated [38]. The main difficulty of the experiment is due to the dangerous properties of this substance, which is toxic, flammable, corrosive, and strong lachrymator. Special techniques were therefore adapted to handle the relatively large amounts of sample required by NMR spectroscopy. In particular, Teflon tube liners were placed inside the NMR cell to prevent glass breaking and toxic leakages. Such configuration is detrimental to the shape of the peak but can be compensated for by appropriate signal processing [39]. A principal component analysis performed on the relative parameters R_{ij} (Part 1, Equation 7) shows that the natural samples are clearly distinguished from the synthetic ones. Adulteration of natural samples by the synthetic counterpart is detectable below 10%. Although the overall isotopic deviations, $\delta^{13}C$, $\delta^{15}N$, $\delta^{33}S$, measured by IRMS, are powerless to ensure this distinction, they are helpful, when combined with the NMR results, for improving the discrimination in terms of geographical origin (cf. Section "Climatic Effects and Geographical Origin") of the natural samples (India and Canada).

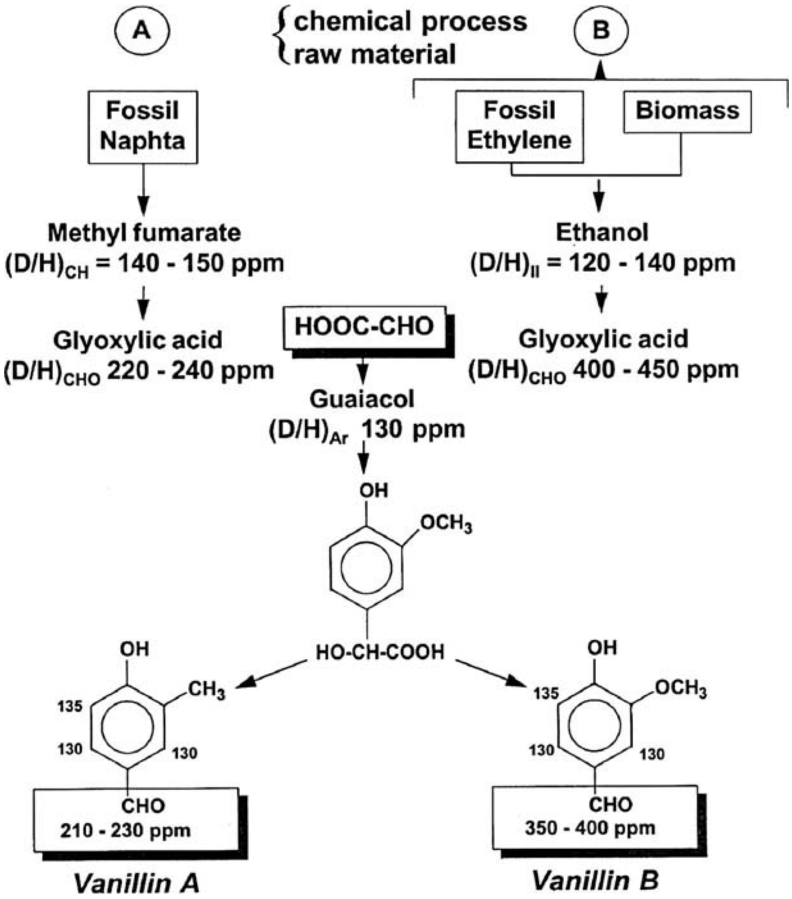
Many other examples demonstrating the potential of the NMR method for ascertaining the genuineness of flavors, perfumes, additives, etc., have been published. The following list, which is not exhaustive, illustrates the variety of molecular structures accessible to the isotopic NMR methodology: benzaldehyde [40,41], *p*-hydroxybenzaldehyde [34], phenylethanol [42], organic acids, in particular acetic acid from vinegar [43–45], esters [45], phenylacetic acids [46], raspberry ketone [47,48], (*R*)-δ-decanolide [49], camphor [50], squalene [51], hexenal and hexanol [52,53], resveratol and rhapontin [54], α-bisabolol [55], aminoacids [56,57], terpenes [58].... Appropriate degradations of the molecule are sometimes carried out in order to enhance the ^{2}H-NMR resolution potential [54]. In certain cases the NMR method is efficiently complemented by IRMS determinations of overall isotope ratios of carbon, hydrogen, oxygen, nitrogen... and hyphenated techniques such as gas chromatography-pyrolysis-IRMS are developed [59].

Characterization of Chemical Processes

Fractionation factors resulting from active kinetic isotope effects taking place in chemical processes may reach very high values and hydrogen isotope ratios of several hundreds of ppm are not rare. Different ^{2}H-NMR profiles are therefore expected for molecules synthesized through different chemical mechanisms and this property can be exploited for identifying chemical processes and therefore for controlling patent utilization.

Returning to the example of vanillin, the NMR method can be extended to the discrimination of synthetic samples produced by different chemical processes [60]. Electrophylic addition in position 4 of the benzene ring of guaiacol, the usual starting material of vanillin synthesis, generally involves formaldehyde or glyoxylic acid reagents. In the case of glyoxylic acid, two main industrial sources are available as shown in Figure 3. In process A, which starts from naphtha and maleic anhydride, glyoxylic acid is formed through a double bond oxidation step, whereas in process B, ionic oxidation of acetaldehyde is involved. In this last case, as in that of the oxidation of toluene into benzaldehyde [41], large fractionation factors due to kinetic isotope effects are expected. Consequently, the two processes may be identified from the well-distinct ranges of D/H values exhibited by the aldehydic hydrogen. More complete analyses of the NMR data provide complementary information on the nature of the raw materials, either biomass or oil, used in the synthesis.

Similarly, synthetic counterparts of benzaldehyde and cinnamaldehyde, the main active molecules of bitter almond and cinnamon oils, can be obtained either by direct oxidation of toluene or by hydrolysis of benzene chloride. These two chemical sources are easily distinguished on the basis of the NMR isotopic values [40,41]. Whereas the combination of primary and secondary kinetic isotope effects accompanying radical transfer in the chlorination of toluene result in fractionation factors <1.2, these factors may be on the order of 5 for proton elimination in the electrophylic oxidation. This behavior is responsible for very large differences in the hydrogen isotope ratio of the aldehydic fragment. Thus, whereas benzaldehyde resulting from hydrolysis of benzal is characterized by $(D/H)_{CHO}$ values of about 165 ppm, values up to



A

Fig. 3. Schematic representations of the two main routes of synthesis of glyoxilic acid. The kinetic isotope effects involved in these reactions lead to very different contents of aldehydic isotopomers [60].

900 ppm are measured in benzaldehyde obtained through oxidation reactions. Thanks to this very large difference, even the overall deuterium content of the molecule determined by IRMS is sufficient for discriminating the two synthetic origins [61]. More generally statistical treatments have been carried out on the molar fractions, f_i, and the relative parameters, R_{ij} (Part 1, Equation 7) measured on 65 samples of benzaldehyde from four different origins: the two synthetic sources, natural benzaldehydes obtained through hydrolysis of amygdalin from bitter almond and kernels (apricots, peaches, plums, cherries, . . .), and semi-synthetic benzaldehyde obtained from cinnamaldehyde ex-cassia or ex-cinnamon through retroaldolization [41]. In the absence of any previous classification, a principal component analysis satisfactorily differentiates these four main origins (Figure 4).

This approach can be applied to both bitter almond oils and cinnamon oils. In the second case, previous derivatization of cinnamaldehyde into benzaldehyde is used for investigating the cinnamaldehyde molecule, which is not a suitable probe for ^{2}H-NMR due to signal overlap, even at high magnetic field.

Identification of Plant Precursors

As compared to the previous problems, which are concerned with the distinction of natural molecules from their synthetic counterparts or with the characterization of different chemical processes, the problem of discriminating molecules elaborated through the same type of biochemical pathway but in different plants species seems

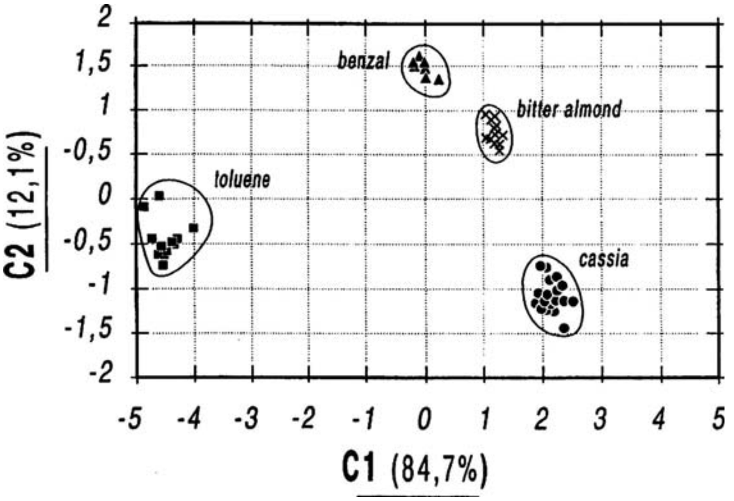

Fig. 4. Representation of benzaldehyde samples from different origins in the plane of the two first components of a principal component analysis based on the hydrogen isotopic variables [41].

less easy to solve. Nevertheless, one of the first papers concerning the method [62] enlightens, on the example of anethole, the capability of the ^{2}H-NMR spectrum to distinguish the three plant origins, fennel, star anise, or green anise [63].

The aptitude of site-specific parameters to discriminate different botanical origins of the precursor is particularly efficient in the case of sugars. Thanks to the reliability of the ethanol probe obtained through controlled fermentation of carbohydrates, many types of vegetal, and even animal species can be distinguished [64]. This strategy enables different chemical structures to be compared: polysaccharides from cereals, tubers, and leguminosae; glucose, fructose, and sucrose from fruits; sucrose from sugar plants; and lactose from milk [65]. Hierarchical clustering, based on hydrogen and carbon isotopic parameters, classifies the different precursor origins according to their degree of mutual dissimilarity. Firstly, sugars of C3 plants are discriminated from those of C4-CAM plants, then citrus are well distinguished from other C3 plants and the CAM pineapple is well identified with respect to the cane and maize C4 plants. Among C3 plants, beet then exhibits a good level of dissimilarity and, although more similar, many other plant species are satisfactorily distinguished [64]. These results provide the basis for the detection of adulteration of fruit juices by addition of exogeneous sugars from beet or cane for instance (cf. Part 4). Interestingly, citrus honey is distinguished, on the same basis, from honey obtained by feeding the bees with sucrose in seasons when they usually collect nectars [66]. A procedure, evaluated in a collaborative study, has also been defined for detecting added sugar in maple syrup [67].

A similar approach can be applied to lactic acid. Thus, the isotopic parameters of $D(-)$ or $L(+)$ enantiomers of lactic acid, produced in fermentation reactions with specific bacteria, are representative of the kind of fermented sugar [68]. As that of the methylene group of ethanol, the ^{2}H content of the CH(OH) group of lactic acid depends on the isotopic composition of the medium in which the fermentation took place.

Unfortunately, some important classes of products, such as lipids, exhibit poorly resolved ^{2}H-NMR spectra. In order to face the investigation of large numbers of samples, extracted from different types of plant or from fish oils, without resorting to time-consuming and fractionating separation and derivatization procedures, analytical strategies appropriate to the direct treatment of mixtures have been developed [69–72]. Thus, when exploited on a statistical basis, average isotopomeric compositions associated with clusters of signals originating from several chemical sites of one or of several fatty acids enable different kinds of plant precursors, in particular olive, to be distinguished. In this respect it should be mentioned that glycerol extracted from lipids also provides information on plant precursors, such as olive and sunflower [73].

Climatic Effects and Geographical Origin

Owing to thermodynamic and kinetic isotope effects associated with phase transition phenomena (Part 2, Section "Influence of phase transitions and transport phenomena on the isotopic parameters"), the hydrogen and oxygen isotope ratios of water are influenced by changes in climatic conditions. These parameters, measured by IRMS, have long been exploited in hydrogeology [74]. More generally, the overall isotope ratios of ice cores and of more or less complex materials such as sediments, wood or cellulose are currently used for paleoclimatic reconstruction [75,76]. However, owing to the complexity of the physicochemical and biochemical sources of isotope fractionation, the interpretation of overall IRMS parameters, which are averages over several molecular sites and, in many cases, over several molecular species, is not straightforward and often remains controversial.

By opening the possibility to investigate individual responses of hydrogen atoms to climatic variations, the SNIF-NMR method significantly decreases the level of complexity of the interpretation [77]. It was shown, for instance, that the ethanol probe obtained by standardized fermentation of fruits, enables successive climatic responses to be decoupled. As deduced from the values of the redistribution coefficients (Part 2, Section "Elaboration of SNIF-NMR probes: from carbohydrates to ethanol and glycerol"), the isotope ratio of the methyl site, $(D/H)_{\mathrm{I}}$, reflects the climatic sensitivity of the carbon-bound hydrogen atoms of sugars, whereas the isotope ratio of the methylene site, $(D/H)_{\mathrm{II}}$, varies with climatic effects on juice water. Consequently, these two parameters are influenced by climatic variations that occur at different periods of plant growth, generally characterized by different evapotranspiration intensities. The aptitude of site specific isotope ratios to convey reliable climatic information has been demonstrated by statistical analyses performed on isotopic variables measured on large numbers of grape (wines) or orange samples collected in different parts of the world. In the absence of previous classification, principal component analyses show that the samples are distributed according to the main climatic features of the regions of production [78,79]. Three main types of climate are roughly distinguished: cold and humid, hot and dry, and temperate. This climatic dependency implies that isotopic parameters can be exploited for inferring the region where the plant precursor has grown. Canonical correlation analyses performed on the basis of typical area of productions illustrate the surprisingly high discriminating potential of the isotopic variables. Not only samples from different countries may generally be identified, but even close regions with relatively similar climate, such as Alsace and the Loire Valley in France, can be distinguished. The performances of geographical inference can still be improved by combining NMR with trace element analysis, which provides soil criteria [80]. For a given plant grown in a given region, the climatic dependency of the isotope ratios may also be exploited for authenticating

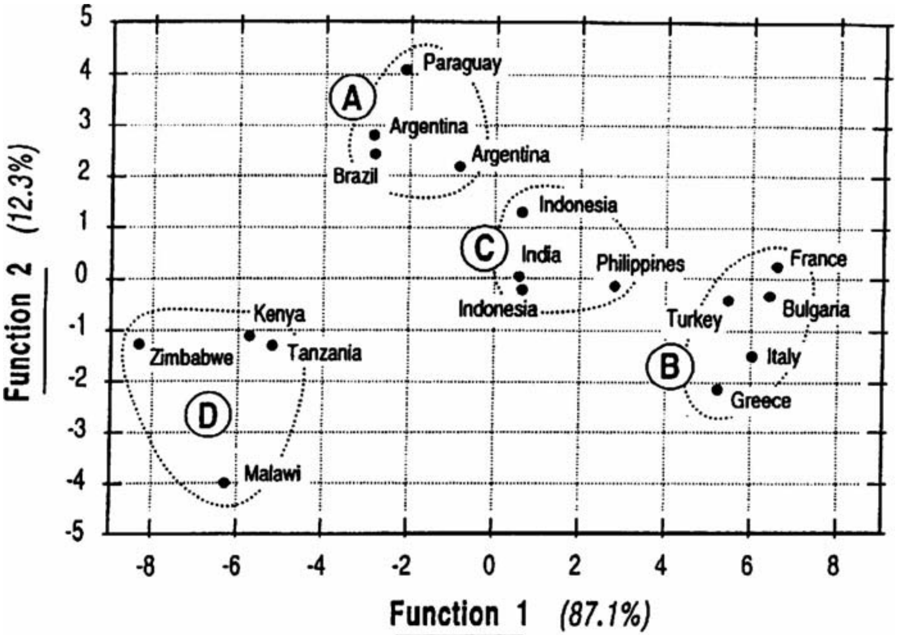

Fig. 5. Representation of nicotine samples extracted from tobacco grown in different countries, in the plane of the two first functions of a discriminant analysis based on site-specific isotope ratios. Four groups of countries characterized by relatively different climatic conditions are distinguished [84].

samples produced in years characterized by significantly different weather [81].

Whereas sugars, investigated through the ethanol probe, are particularly sensitive to climatic variations, the climatic influence is usually more slightly perceived by minor metabolites remote from the initial photosynthetic step. Nevertheless, caffeine from South America for instance can be authenticated with respect to caffeine from Africa [82]. Similarly, the NMR parameters may provide information on the geographical origin of heroin and cocaine [83]. It should also be emphasized that different sites in a given metabolite, do not necessarily exhibit the same sensitivity to climatic variables. In the case of nicotine for example [84], individual molecular sites exhibit different behavior but a canonical correlation analysis based on the site-specific variables enables several production areas of tobacco to be identified (Figure 5).

From a general point of view, it is concluded that different components of a plant and even different sites of a given molecular species may exhibit different isotopic responses to climatic variables. Consequently, care must be taken when interpreting variations in the overall IRMS parameters of complex materials, including cellulose, in terms of climate reconstruction.

SNIF-NMR—Part 4: Applications in an Economic Context: The Example of Wines, Spirits, and Juices

Eric Jamin and Gérard J. Martin
Eurofins Scientific, BP 42301, 44323 Nantes, France

Introduction

The direct access to site-specific natural isotope fractionation opened by the SNIF-NMR method [1,2] was immediately recognized, not only as a source of diversified information in a context of basic research, but also as a powerful technique for controlling the origin of commercial products. The method provides a unique tool for detecting whether a given main component of a food or beverage has been substituted or diluted by addition of a substance with the same molecular formula but from a different chemical, botanical, geographical origin (Part 3, Sections "Natural or Synthetic Origin of Products," "Characterization of Chemical Processes," "Identification of Plant Precursors," and "Climatic Effects and Geographical Origin"). In this respect, it has already largely contributed to establish the notion of *authenticity* of food products on rigorous bases. In order to illustrate the methodologies and performance of SNIF-NMR applied in official and industrial contexts, we have selected two examples of economically important products—wines and juices.

The world wine market has changed drastically in the last 10 years. In Europe—the largest production area—wine production is continually decreasing. Depending on the climatic conditions of the year, the production of the 15 countries of the EU has fallen from nearly 180 million to 155 million hectoliters. It is expected that in 2004 the admission in the EU of six countries whose wine production rose to 6 million hectoliters will just compensate the decrease of production of the 15 former state members. The cause is manifold but, roughly speaking, consumption switches from quantity to quality: for example, the share of quality wines produced in specific regions (QWPSR) which look like the French "Vins d'Appelation d'Origine Contrôlée" (AOC), overall production increases significantly. In France, Italy, and Spain, 46%, 23%, and 31% of the production is made up of QWPSR. However, in emerging Asian markets consumption is growing rapidly, mainly to the advantage of table wines, generally produced locally or imported from neighboring countries. Consequently, there is a greater pressure on the sensory and analytical properties of relatively expensive wines.

Insofar as fruit juices are concerned, the trend towards more quality and less quantity follows that observed for wines. Pure juices are frequently preferred to juices made from concentrates and to nectars, mainly based on the idea that fruit juice is "health in bottle," and in the EU and US, fruit juice markets are of a multi-billion ° magnitude. Orange juices represent more than 60% of the market.

Taking into account this economic context, it is of prime importance to be able to authenticate the origin of marketed products and to detect and estimate possible adulteration.

Current Regulations About Wines and Juices

In order to guarantee the quality of marketed products, very drastic requirements tend to be legally imposed. However, regulations are efficient only inasmuch as rigorous control methods can be implemented [3]. In the case of wines, spirits, and juices, important problems—still challenging in 1980s—are concerned with origin recognition of chemically identical molecules. By offering this possibility, the SNIF-NMR method has entered the field of official regulation and control.

Wines

The Commission of the EU subjects the common market of wines and wine products to very careful attention. The regulation of 1999 [4] resumes and completes regulations of 1987 and 1990 [5]. The principles behind the regulation may be explained in terms of three main vine growing zones A, B, and C (zone C being split into CI, CII, and CIII) rigorously defined according to the minimum alcoholic content of the natural must, *t*% min, the maximum enrichment, *c*% max, and the maximum alcoholic content, *t*% max, of the enriched wine (Table 1).

Men have always had an overactive imagination for transforming grapes into a number of beverages and food. Grape juice can be used as it stands, partly fermented,

Graham A. Webb (ed.), Modern Magnetic Resonance, 1681–1687.
© 2008 *Springer*.

Table 1: Conditions limiting the enrichment of musts in different regions A, B, and C. *t*% and *c*% are expressed in v/v of ethanol in wine and values into brackets correspond to red wines. For example, zone A includes the 15 State Members but France, Greece, Portugal, and Spain, zone B is composed of the Northern and Central France, Austria, and the Baden region in Germany, and zones C include Southern France, Greece, Portugal, and Spain

Area	A	B	CIa	CIb	CII	CIII
t% min	5	6	7.5	8	8.5	9
c% max	3.5 (4.5)	2.5 (3.5)	0 (2)	0 (2)	0	0
t% max	11.5 (12)	12 (12.5)	12.5	12.5	13	13.5

concentrated, rectified (grape sugar), caramelized, and so on. Fermented musts give table wines, quality wines, quality wines “psr” (provenance from specified region), liqueur wines, sparkling wines (aerated, semi-sparkling, etc.), wines lees, grape marc, piquette, wine vinegar, wine of overripe grapes, etc. The authorized oenological practices fill 12 A4 pages, printed in small characters, of the 1999 regulation but insofar as we are concerned with SNIF-NMR, only practices which can be enforced with the help of this technique will be discussed now. First of all, the problem of controlling wine enrichment was of great concern to the EU since the illegal increase of the alcoholic grade of wines by cheapest means, such as addition of sucrose into the fermenting must, is a heavy burden to the European budget. The surplus of wine produced by illegal enrichment should indeed be bought by the European Commission at a price that is significantly higher than that of the corresponding sugar. A second problem, less drastic for the European Treasury but severe for the consumer and the honest wine maker, is the fraud in quality wines “psr”: The geographical origin and the year of production of high priced wines (and spirits) should be ascertained in order not to entail the loss of confidence of the buyer. In the case of sparkling wines, the origin of the carbonic anhydride must be controlled.

Juices

In the European community, the Council directive 2001/112/EC defines several categories of fruit juices and the technology which can be used to produce them. The European industry, within the AIJN code of practice (http://www.aijn.org), provides more detailed guidelines of the expected composition of the most widely consumed fruit juices, including some isotopic parameters. At the world level, common definitions and guideline values of the main parameters are defined by the Codex committee for fruit juices (http://www.codexalimentarius.net). A fruit juice is defined as the fermentable but unfermented product obtained from the edible part of sound and ripe fruits using mechanical or physical means only. Two main categories are defined as follows:

- fruit juice: obtained directly from the fruit (only flavor, pulp, and cells lost during processing may be restored if necessary);
- fruit juice made from concentrate: obtained by replacing in a concentrated fruit juice the water extracted during concentration (plus flavor, pulp, and cells lost during processing).

The addition of sugars to fruit juices (for correcting the sugar/acid ratio) is authorized (except for grape and pear juice) up to 15 g/l, but this must be declared in the ingredients list. The addition of more sugar (up to a maximum of 150 g/l) implies labeling the product as “sweetened” (or “nectar,” when water is also added). The addition of lemon juice is also permitted up to 3 g citric acid per liter, but once again must be mentioned in the ingredients list. Moreover, the addition of both sugar and lemon juice is prohibited. No other ingredient not coming directly from fruit of the same kind is allowed. Especially, the restored flavor, pulp, and cells must be recovered during fruit juice processing.

Ethanol: A Reliable Isotopic NMR Probe for Characterizing Wines, Spirits, and Juices in an Industrial Context

Thanks to its favorable relaxation properties and its well-resolved signals, the ethanol molecule is well adapted to quantitative ^{2}H NMR (Part 2, Section “Elaboration of SNIF-NMR Probes—From Carbohydrates to Ethanol and Glycerol”) and high levels of repeatability and reproducibility are reached in standardized experimental procedures [6].

It is generally not obvious to consider that ethanol is a good probe for authenticating wines and still less evident for juices. In this last case, it is tempting to directly investigate carbohydrate molecules present in the juice. Unfortunately, the ^{2}H NMR spectra of polymeric and even simple carbohydrates are not suitable for estimating site-specific isotope ratios. Although the carbon-bound hydrogen parameters of glucose and fructose are accessible through appropriate chemical derivatizations [7], it is at the price of time-consuming experiments and degraded accuracy incompatible with analytical procedures applicable in an economic context. In contrast, ethanol obtained by fermenting sugars in strictly standardized conditions, provides an attractive probe that enables carbohydrates with

Table 2: Ranges of mean values exhibited by the isotopic ratios of ethanol samples obtained by fermenting different plant sugars, including grape, beet, and cane sugars. The carbon-13 deviation, $\delta^{13}C$ (%) (Part 1, Equation 5) has been measured by IRMS. $(D/H)_I$ (in ppm) is the isotope ratio of the methyl site of ethanol

Plant	$(D/H)_I$	$\delta^{13}C$
Beet	92.7	−26.6
Potato	96.7	−26.5
Red fruits	97.2	−26.6
Barley	98.2	−24.8
Wheat	99.7	−25.8
Apple	100.9	−25.0
Grape	101.8	−26.3
Citrus	105.0	−26.6
Pineapple	108.9	−14.5
Maize	110.7	−10.4
Cane	112.0	−12.2

different molecular structures, including polymers, to be easily compared in very accurate and precise conditions [8].

As discussed in Part 2 (Section "Elaboration of SNIF-NMR Probes—From Carbohydrates to Ethanol and Glycerol"), model fermentation experiments have established the quantitative scheme of site-specific connectivity between glucose and water reactants on one hand and ethanol and water products on the other hand. On this basis, it is concluded that the isotope ratio of the methyl site of ethanol, $(D/H)_I$ (and the overall carbon isotope ratio), reflects properties of sugars and, to a lesser extent, water whereas the methylene isotope ratio, $(D/H)_{II}$, is mainly representative of the aqueous medium. Since the natural abundance isotope ratios of the non-exchangeable hydrogen atoms of sugars depend on metabolic and physiological characteristics of the plant and on the environmental conditions of the photosynthesis [7,9], the isotopic distribution in the alcoholic fermentation products may reflect the origin of the carbohydrate precursors in terms of both plant species and geographical area of production (Part 3, Sections "Identification of Plant Precursors" and "Climatic Effects and Geographical Origin"). Table 2 illustrates several ranges of isotopic values exhibited by ethanol samples obtained through fermentation, in identical conditions, of sugars naturally present in fruit or possibly added to the juice.

Obviously, isotopic values measured on different ethanol samples may be safely interpreted in terms of properties of the sugar precursors only on condition that all mechanistic aspects of the fermentation reaction remain constant. In the case of wines, the fermentation parameters may significantly vary with the type of grapes and with oenological practices. Possible influence of the type of yeast strains and of changes in the composition of the medium had therefore to be investigated [10–12]. Only minor changes were observed in the percentages of intra- and inter-molecular transfer of hydrogen to the methyl site of ethanol as a function of the nature of the yeasts. More generally, a remarkable stability of the $(D/H)_I$ parameter was demonstrated. However, several factors responsible for marginal perturbations of the isotopic results were identified, providing helpful criteria for interpreting apparent anomalies observed in certain samples.

Origin Authentication and Data Banks

Aside from the illegal enrichment of must with sucrose, which has a considerable economic importance, other frauds only burden the wine market. For example, usurpation and abuse of origin affect wines from more or less prestigious estates. Apart from some renowned connoisseurs, very few people are able to precisely identify soil and vintage of a given wine and the consumer is forced to rely on the label. In such cases, isotopic analyses are very efficient tools to authenticate the origin of a wine.

According to the general principles described in Part 3 (Section "Climatic Effects and Geographical Origin"), the isotopic parameters of both water and ethanol are related to the humidity and temperature of the growing region of the plant. Therefore, consideration of meteorological data of the region and of the year helps to make a diagnosis. In the case of wine and fruits, the isotopic parameters of ethanol have been shown to respond even to subtle environmental variations and they efficiently characterize the region of production [13,14].

In practice, many types of wines have been investigated [15–21] and private and official data banks have been constructed in order to provide reference values. In the case of European wines, it was decided in 1991 to build an isotopic data bank concerning wines of all the Member States producing wine. At this time, the official laboratories of these States supply the data bank that is maintained in the Joint Research Centre of Ispra (Italy). The files contain several thousand entries for Austrian, French, German, Greek, Italian, Portuguese, Spanish, and even British and Luxembourg wines [22].

No official data are available for fruit juices, but many kinds of juices have now been isotopically characterized [23,24]. Producers organizations and private companies involved in food and beverage controls have collected authentic samples and built up specific data banks [25]. Since 1987, Eurofins laboratories have gathered data on several thousands of fruit samples. These have contributed in establishing some statistically defined confidence ranges for authentic fruits and guideline values for individual fruits included in the AIJN code of practice.

NMR Methodologies in an Official and Economic Context

Analytical requirements are very different for experiments carried out on limited numbers of samples in a research laboratory, and for measurements performed routinely in an economic context. In the second situation, the need for analyzing several thousands of samples a year and combining a variety of instrumental techniques appeals to rather sophisticated laboratory management systems. Moreover, conditions are placed on long-term reproducibility, reliability of the whole analytical chain, rapidity and minimum cost of the determination, and facility of interpretation.

In order to render the NMR method applicable at an industrial scale, much effort has been devoted to the elaboration of appropriate technological environments. Thus, through continuous collaboration between the Bruker firm and Eurofins laboratories in France, dedicated equipments and computerized programs were elaborated, commercialized, and maintained (SNIF-NMR Concept®). In particular, optimized NMR spectrometers have been fitted with specific probes and with fluorine locking devices, since the deuterium canal is used for observation. All parameters of signal adjustment have been released from any operator intervention through the development of a rigorous theoretical algorithm [26] which enables quantitative determinations to be fully automatized (Part 1, Section “Quantitative Deuterium NMR”).

Wines, juices, and even spirits cannot be directly studied as they stand and it is necessary to carry out a series of preliminary treatments. Since the measurements are done with ethanol and water, juices should be fermented in a first step and the resulting fruit wines must then be distilled. As a result of thermodynamic and kinetic isotope effects associated with phase transitions (Part 2, Sections “Simultaneous Determination of Site-specific Thermodynamic Isotope Effects” and “Determination of Kinetic Isotope Effects”), incomplete isolation of ethanol may induce isotopic fractionation of a few tenths of ppm for a yield of about 90%. The most critical point is therefore to extract ethanol from the product investigated with as high yield as possible and with the greatest alcoholic grade. For wines and spirits, a single distillation is sufficient but in any case, isotopic perturbations due to the process must be eliminated. Integrating the NMR detection into an information system, which routinely manages preparation of samples, NMR acquisition procedures, data handling, and diagnosis, optimizes the efficiency of the method. Moreover, detailed protocols have been defined and collaborative studies organized in order to check the accuracy performances.

Determination of Illegal Enrichments

According to the definitions given in Part 1, the isotopic composition of a mixture is a weighted mean of the parameters of the components. It is therefore required to know or to measure the isotopic ratios of the pure components in order to be able to compute the composition of the mixture. The first experimental description of the detection of chaptalization in wines appeared in 1983 [27]. It was published 4 years later as an official method of the “Office International de la Vigne et du Vin” (OIV) [28] and in 1990 it was included in the EU regulation concerning the control of wines [29,30]. If using only SNIF-NMR can determine wine chaptalization, the detection of other frauds is improved when the ^{2}H and ^{18}O isotopic ratios of the water contained in the product are measured. In this respect, although SNIF-NMR can be safely applied in determining the D/H of water, isotope ratio mass spectrometry (IRMS) is routinely preferred for this purpose. The precautions for eliminating adverse isotopic effects have been reviewed [21,29,31].

In the case of fruit juices, the SNIF-NMR and ^{13}C IRMS methods based on the isotopic analysis of ethanol resulting from fermentation have been officially recognized after international collaborative studies (AOAC Official Methods 995.17 and 2004.01, respectively).

The composition of a chaptalized wine or of an enriched juice is easily computed from the isotopic NMR ratio of site I of ethanol, providing that reference data are available. The molar fraction x of a mixture M containing two components A and B is given by Equation (1):

$$x = \left[(D/H)_{\mathrm{I}}^{\mathrm{A}} - (D/H)_{\mathrm{I}}^{\mathrm{M}}\right] \Big/ \left[(D/H)_{\mathrm{I}}^{\mathrm{A}} - (D/H)_{\mathrm{I}}^{\mathrm{B}}\right] \quad (1)$$

M may be either an unknown chaptalized wine or a fermented sugared orange juice for instance. A is the reference wine or juice and B is the sugar (beet or cane sucrose) added to the product [32]. Some more refined fraudsters use a mixture of beet and cane sucrose with the idea of circumventing SNIF-NMR, since it has been shown that an addition of beet sucrose in a must decreases the isotope ratio, $(D/H)_{\mathrm{I}}$, of the methyl site of wine ethanol, whereas addition of cane sucrose increases this parameter (Table 2). However, since two independent parameters can identify a ternary mixture containing grape, beet, and cane ethanol, combining ^{13}C IRMS determinations soon deterred this practice. To solve this system of equations, the knowledge of the isotopic parameters of authentic wines or juices is required. Geographical and annual variations may be taken into account by resorting to the up-to-date databases of authentic samples described in Section "Origin Authentication and Data Banks" [32]. On this basis, authenticity limits are defined as statistical confidence ranges of isotopic parameters, using either univariate or multivariate approaches.

Isotopic Characterization of Concentrated Juices

Commercial fruit juices are often made from concentrate. Similarly, concentrated grape juice may be used in wine production. Since the concentrated juices are prepared through low-temperature evaporation processes, the isotopic data of the final products, commercial juices and wines, depend not only on the botanical and geographical parameters but also on the fractionation factors associated with the physical transformation. Consequently, when isotopic analysis is used for sample authentication, the influence of the technological treatment must be estimated in order to isolate useful information about the original product. Model experiments of low-temperature evaporation processes have been carried out and analyzed [33], according to the principles discussed in Part 2 (Section "Simultaneous Determination of Site-specific Thermodynamic Isotope Effects"), on the basis of Equation (2):

$$R_C/R_S = N_C/N_S^{(\beta_{\text{eff}-1})} \tag{2}$$

where R_S and R_C are the hydrogen (or oxygen) isotope ratio of water in the starting juice and in the remaining concentrate respectively, and N_C/N_S is the molar ratio of residual water. β_{eff} is the effective fractionation factor which fits the kinetic contribution of the evaporation process. This parameter has been determined for ^{2}H and ^{18}O in experiments involving different sugar solutions and juices. At a temperature of 18 °C, the following values have been determined: $\beta_{\text{eff}}(^2\text{H}) = 0.923(\pm 0.003)$ and $\beta_{\text{eff}}(^{18}\text{O}) = 0.991(\pm 0.002)$. These results can be applied in two complementary ways. Firstly, in the case of orange concentrates suspected of containing sucrose, it is possible to infer the δ^2H (or δ^{18}O) value of the natural juice water before concentration from both the Brix value and the δ^2H (or δ^{18}O) value measured on water of the concentrate. The computed isotope contents of the original juice water are then used for evaluating the $(D/H)_I$ value of ethanol which would result from fermentation of the pure juice. These estimated parameters provide improved references for computing the amount of sucrose addition in concentrate and they significantly increase the sensitivity of detection of this practice. Conversely, when R_S is known, Equation (2) may be exploited for estimating the concentration rate. This procedure was successfully applied to the detection of added concentrated must in wine. The values of δ^2H and δ^8O of the wine water are then compared to the values of the same parameters measured in pure grape musts or natural wines from the same region and year.

Multi-component and Multi-isotope Strategies in the Detection of Adulterations

With the combined use of SNIF-NMR and ^{13}C IRMS, most of the economically profitable forms of adulteration, which are concerned with the addition of sugar from cheap sources such as beet, cane, or maize, can be detected. In some instances, however (e.g. when the geographical origin is unknown), it can be difficult to prove adulteration with certainty, and the use of other components as isotopic internal references is a way of improving the detection limits of adulterations. Such multi-component multi-isotope patterns may involve individual sugars [34], sugars and acids [35], or sugars and water [36]. Finally, some fractions like proteins can also be used as "absolute" internal references as they are not concerned by economic adulteration [37].

Thanks to the recent development of preparative HPLC procedures, organic acids can be routinely isolated from any kind of fruit juices and wine. Obviously, this requires complete recovery of each component at all stages of the purification to avoid any isotopic fractionation. Based on numerous results from a wide database of authentic fruits collected around the world, systematic isotopic correlations between individual organic acids or between organic acids and other components have been established. Reproducible relationships are observed for any given fruit species, which can be solely attributed to the metabolism of the fruit and remain independent from its geographical origin. The use of internal referencing based on such multi-component patterns significantly enhances the sensitivity of both NMR and IRMS isotopic methods for the detection of sophisticated adulterations [37–42].

To illustrate the increasing complexity of some problems, it should be mentioned that refined adulteration practices have been specially developed to bypass the isotopic methods based on sugar analysis via fermented ethanol. Thus, when addition of specifically designed sugar syrups, derived from starch or inulin from C3 plants is suspected, the only way to detect low levels of sugar addition is to use GC analysis of oligosaccharides profiles, which reveal the presence of marker peaks of these industrial syrups. Conversely, this method does not detect raw sucrose addition. Therefore, in order to fully control the absence of sophisticated adulteration of a fruit juice, it may be necessary to combine isotopic and conventional analyses.

Detection of Exogeneous Minor Components

In certain cases, adulteration by exogeneous minor components may also be suspected. Frequently this practice aims to mask illegal dilution or enrichment of the product.

The most abundant acids of fruit products (citric, L-malic, and L-tartaric acids) are solids that are insoluble in most organic solvents, which makes their SNIF-NMR analysis more difficult. Nevertheless, suitable derivatives such as esters provide access to the D/H ratios of non-exchangeable hydrogen atoms. For example the ^{2}H NMR spectrum of triethyl citrate enables the two original methylene sites of citric acid to be conveniently quantified. Looking at the affiliations of carbon and hydrogen atoms along the glycolysis pathway and in the Krebs cycle, it appears that citric acid carbon atoms derive from all glucose carbon atoms and that at least two-thirds of the non-exchangeable methylenic hydrogen atoms come from water of the medium. Since the industrial production of citric acid uses various cheap sugar sources, the ^{13}C deviations cover the whole range of values characterizing C3 and C4 plants. On the other hand, the deuterium enrichment in plant water versus ground water results in a significant shift of the deuterium content of fruit citric acid as compared to its artificial counterpart. Then, the combined use of global $^{13}C/^{12}C$ and site-specific $^{2}H/^{1}H$ ratios satisfactorily discriminates citric acid from fruits such as lemon from all commercial sources.

As a final example, we may consider the case of glycerol, usually produced in significant amounts (3–5%) in fermentation reactions. Its presence in wine has a noticeable influence on the sensory parameters. Forbidden addition of exogeneous glycerol is easily detected by SNIF-NMR since the isotopic profile of glycerol naturally present in wines can be differentiated from that of synthetic glycerol and also from that of glycerol derived from other plants [43,44].

High-Resolution Nuclear Magnetic Resonance Spectroscopy of Wine, Beer, and Spirits

Ana M. Gil and Iola F. Duarte
Department of Chemistry, CICECO, University of Aveiro, 3810-193 Aveiro, Portugal

This text aims at presenting an account of the use of high resolution ^{1}H and ^{13}C Nuclear Magnetic Resonance (NMR) spectroscopy for the direct characterization of the composition of wine, beer, and spirits. This differs from the approach involved in the well established quality control method known as Site-specific Nuclear Isotope Fractionation (SNIF)-NMR, which usually involves ^{2}H observation for the measurement of isotopic ratios and correlation with product origin and which is described in a separate entry of this handbook. The application of high resolution NMR to the complex food mixtures mentioned above aims at detecting as many compounds as possible, including minor components, not only giving a compositional overview of the food, but also allowing the unexpected to be detected in a number of possible situations (biochemical studies, adulterations, contaminations). A vast number of studies have used NMR to identify particular compounds in sample extracts following specific separation and concentration steps. In wine, phenolic compounds are still the class of compounds more extensively studied due to their role in wine characteristics as well as interesting antimicrobial and antioxidant properties. However, the intention of this text is to account preferably for studies involving the direct NMR analysis of whole samples, rather than of their extracts, except where otherwise specified.

Wine has been, by far, the alcoholic beverage to which NMR has been most extensively applied. Direct NMR analysis of wine emerged in the mid 1980s, with the seductive advantages of avoiding lengthy separation and concentration steps prior to analysis of specific compounds or compound families. The first studies involved ^{13}C NMR for determination of several components: diethylene glycol [1], sugars, sugar alcohols and sugar acids [2], and amino acids [3]. However, the relative higher sensitivity and natural abundance of ^{1}H make it a preferred nucleus for practical uses where measurement rapidity is intended. In ^{1}H NMR, efficient suppression of solvent peaks (water and ethanol in the case of alcoholic drinks) is necessary and the significant technological advances in NMR instrumentation and software have played a key role in enabling good quality ^{1}H NMR spectra to be obtained. Comprehensive peak assignment in the ^{1}H NMR spectra of wines requires necessarily the combined use of 1D and 2D NMR experiments such as COrrelation SpectroscopY (COSY), Heteronuclear Single-Quantum Coherence (HSQC), and Heteronuclear Multiple-Bond Correlation (HMBC). Such techniques were used in a study of Slovenian wines, differing in variety, vintage, and geographical area, in tandem with comparison with the ^{1}H and ^{13}C NMR spectra of known compounds [4]. Many amino acids, alcohols and organic acids were detected and some spectral variations were correlated to the variables under study. Subsequent reports describe a similar approach for the identification of amino acids and anthocyanins in wine, compounds which play determinant roles in wine properties and quality [5,6]. Figure 1 shows regions of the ^{1}H and ^{13}C NMR spectra of the wine under study, without the use of suppression for the large signals. The incorporation of a WET (water suppression enhanced through T_1 effects) pulse sequence in the 1D and 2D experiments allowed simultaneous suppression of several large signals (water, ethanol, glycerol, and some unassigned signals) and significant improvement of the spectra. Unambiguous ^{1}H and ^{13}C assignment of many amino acids could then be achieved [5,6], together with that of several anthocyanins [6]. Improvements in NMR peak assignment may still be required, particularly in regions of strong signal overlap (even in 2D spectra) and/or of very low signal to noise ratio. Hyphenated NMR may be of help in future qualitative studies of wine, as shown by preliminary results obtained for a wine phenolic extract sample by the on-line combination of liquid chromatography, NMR, and mass spectrometry (LC-NMR/MS) [7]. This study reports the identification of catechin, epicatechin, *trans*-resveratrol, tyrosol and caffeic acid, compounds which could not be identified using NMR spectroscopy alone. An additional aid for peak assignment comes from Diffusion Ordered SpectroscopY (DOSY). Applied recently to Port wine (Figure 2) [8], DOSY makes use of information on compounds diffusivity, in addition to NMR parameters. Compositional differences between Port wines of different

ages were noted, including a significant decrease of the relative amount of high molecular weight aromatics in the oldest wine.

The possibility of using NMR spectroscopy to differentiate and classify different wine types was firstly explored by combining ^{1}H and ^{13}C NMR with pattern recognition techniques [9]. This approach is indeed necessary if large sample numbers are to be handled. The 1D NMR spectra of 53 German white wines from different regions were recorded and subjected to Principal Component Analysis (PCA). Small variations in peak positions, due to pH, concentration effects, and/or apparatus instabilities, were corrected by a specifically developed algorithm; this resulted in successful sample classification. A subsequent study addressed a set of Slovenian white wines differing in vine variety and geographical origin [6]. Multivariate analysis of some amino acids signals enabled wine varieties to be distinguished and the inclusion in the analysis of signals from glycerol, butylene glycol, and succinic acid allowed separation according to geographical origin. A classification study of Apulian Italian wines [10] involved the comparison of multivariate analysis of ^{1}H NMR spectra with that of data obtained by alternative methods, including high performance ion chromatography (HPIC), high performance ion chromatography exclusion (HPICE), and emission spectrometry. Results enabled wines from different geographical regions to be distinguished with basis on amino acids composition, as viewed by NMR, or on heavy metals composition, as viewed by the alternative methods. A similar approach was applied to a group of wine samples from Southern Italy and Slovenia, showing that the best prediction of the country of origin is achieved by multivariate analysis of the NMR data (Figure 3), rather than of data obtained by HPICE or inductively coupled plasma emission spectroscopy (ICP-OES) [11].

Additional interesting applications of NMR to wine include the elucidation of key metabolic traits of wine bacteria through the *in vivo* NMR analysis of cell suspensions [12] and the development of a method to study full intact wine bottles [13,14]. In the latter case, a new experimental setup was devised in order to use a horizontal bore magnetic resonance imaging magnet of 2.01 T to accommodate a full wine bottle. ^{1}H and ^{13}C NMR spectra were recorded for a selected wine and their use for quantifying acetic acid and detecting complex sugars, phenols, and trace elements was discussed.

The applications of high resolution NMR to beer and spirits are much more limited, compared to wine. One of the first reports of NMR of beer drew attention for the importance of characterizing the carbohydrate fraction of beer and for the complexity of the carbohydrate profile in the ^{1}H NMR spectrum, recorded at 600 MHz [15]. Chromatographic separation of the low molecular weight fraction of beer oligosaccharides was carried out, followed by fraction analysis by 1D and 2D NMR. In tandem with MS spectrometry and HPLC, NMR results enabled the identification of several isomaltooligosaccharides of degree of polymerization (DP) up to 10. More recent reports describe the use of NMR for the characterization of water soluble arabinoxylans from barley and barley malt [16] and a novel flavanol glucoside from barley and malt [17]. Hop bitter acids,

which are important taste and flavor agents in beer, were analyzed by LC-NMR [18]. Several bitter acids such as humulones, isohumulones, dihydroisohumulones, and tetrahydroisohumulones, were successfully identified in hop extracts and their structures characterized by NMR. Particular attention has been given to hop isohumulones in a study which involved HPLC of hop extracts prior to NMR characterization of the fractions [19].

Some accounts of direct NMR analysis of whole beer may also be found. Overall qualitative analysis of beer has been carried out by standard 1D and 2D NMR methods [20], the only sample preparation involved being the ultrasonic degassing of the sample. Figure 4 shows regions of the 2D TOtal SpectroscopY (TOCSY) spectrum of a beer. About 30 compounds could be identified covering a range of chemical families. In subsequent work, use was made of LC-NMR/MS for the detailed characterization of beer aromatic compounds [21] and carbohydrates [22]. In the former case, tyrosol, 2-phenylethanol, and thryptophol could be identified for the first time by direct analysis of beer, whereas, in the latter case, detection of maltooligosaccharides of DP up to 9 was achieved. Figure 5 shows an on-flow NMR chromatogram obtained for beer. Preliminary DOSY results have also shown that the coupling of diffusivity information to NMR

parameters may help significantly in the characterization of beer by NMR [23]. The subject of compound quantification in beer has been tackled very recently and in detail by ^{1}H NMR [24]. Organic acids and amino acids were quantified both by signal integration and by partial least squares (PLS) regression, comparing NMR data with amino acid analysis by HPLC and organic acid analysis by capillary electrophoresis. ^{1}H NMR is shown to be a rapid and satisfactorily accurate method to quantify compounds down to 10 mg/L in concentration. The use of PLS improves accuracy and enables compound quantification using partially overlapped signals. The issue of beer classification was addressed using NMR in tandem with PCA [20,25]. This work has shown that beers differing in types (lager, ale, alcohol-free) may be distinguished with basis on their dextrin content and composition, as well as on aromatic composition.

Reports on NMR of spirits include some accounts of SNIF-NMR analyses for detecting sugar addition in maple syrup [26], authentication of fruit spirits [27], dating of brandies and spirits [28], authentication of tequila [29], together with some studies involving the isolation of specific compounds followed by NMR characterization.

Relaxation Time Methods

NMR Relaxation of Dairy Products

F. Mariette

CEMAGREF, Food Engineering research unit, CS64427, 35044 Rennes Cedex, France

Introduction

The applications of NMR to dairy products are numerous and can be divided into three groups. The first group comprises the use of high-resolution NMR spectroscopy for the molecular study of dairy compounds such as casein and whey protein [1,2]. The second group involves the use of Magnetic resonance imaging applied to dairy processing [3,4], and the third group concerns studies based on NMR relaxation measurements. This chapter will focus only on NMR relaxation applications, including pulsed field gradient NMR for the measurement of molecular diffusion. Relaxation measurements on dairy products have usually been performed at low field and the main aim was to propose a non-destructive technique to determine water or fat content [5] and solid fat content (SFC) [6]. These applications use NMR signal intensity and little attention has been paid to relaxation time values and their significance. We have therefore chosen to review this field of application specifically.

Water Relaxation

All possible water nuclei (^{1}H, ^{2}H, and ^{17}O) have been used in attempts to obtain information about molecular structure and water mobility. The interpretation of relaxation time parameters is quite difficult as relaxation involves several mechanisms such as chemical exchange, cross relaxation and diffusive exchange between different water populations. There has for many years been considerable controversy about the ways to interpret relaxation time parameters, especially the relative importance of chemical exchanges between protein protons and water protons [7] and cross relaxation between the longitudinal magnetization associated with water protons and protein protons [8]. ^{17}O Nuclear Magnetic Relaxation Dispersion (NMRD) studies recently demonstrated that relaxation dispersion is not due to a long-range hydrodynamic effect or to long-lived water molecules on the protein surface, but to small numbers of crystallographic water molecules buried inside the protein and exchanging with bulk water on a submicrosecond time scale [9,10]. ^{2}H dispersion includes an additional contribution from a labile proton, which dominates over the hydration water contribution for ^{1}H relaxation. It is therefore now clear that, in contrast to ^{17}O relaxation, ^{1}H and ^{2}H water relaxation does not provide any information about water mobility [11], and water relaxation measurements cannot be used to obtain detailed information about the protein structure. Nevertheless, water relaxation measurement is a very sensitive way to study the changes in the protein structure induced by chemicals and physical parameters [12]. Several studies have therefore investigated the water-casein interactions in milk and in milk powders [7,13–16]. Others have dealt with isolated milk components such as lactose [17,18], caseins [19,20], caseinate [8,13,17,21–27] bovine serum albumin [28,29–33], β lactoglobulin [34–36], α lactalbumin [34], and whey [17,34]. For example, ^{17}O NMR relaxation measurements have been used to investigate the effects of NaCl, $CaCl_2$, sucrose concentration, temperature, and pH on casein hydration [13,23–26]. Similar variations in water relaxation rate have been observed between ^{17}O and ^{1}H relaxation measurements according to milk pH. The structure of the micellar casein changes when the pH decreases due to release of the calcium–phosphate complex into the soluble phase. Release is maximal at pH 5.3 and both the ^{17}O and ^{1}H water relaxation rates are minimal [13]. For non-casein micelles such as sodium caseinate solution, the dependency of the water relaxation time on pH is negligible compared to variations observed with micellar casein dispersion.

The advantage of the NMR technique to monitor pH changes is that the method can be used for whole milk and skim milk [37], and for various experimental conditions such as high-pressure treatment of the milk [16] and allows study of effects of the pH kinetics on micellar destabilization [37]. The study of milk was also extended to concentrated casein samples. However, when the casein concentration increased, the variation in relaxation time to changes in pH decreased [4].

The use of water NMR relaxation time to quantify changes in casein micelle structure is not limited to processes involving changes in pH. For example, measurement of relaxation time has been used to study the effects of added salt on the hydration behavior of casein micelle powder [19]. Another study involved the effects of protein—fat interactions on the protein structure in emulsion. It was established that the extent of the structural

Graham A. Webb (ed.), Modern Magnetic Resonance, 1697–1701.
© 2008 *Springer.*

changes induced by adsorption at the interface varies according to the native structure of the protein. For example, variation in water relaxation time induced by formation of an emulsion was greater for β lactoglobulin than sodium caseinate [4].

Because of the sensitivity of water relaxation to protein structure changes, NMR relaxation studies of complex dairy products such as cheese, dairy mix, and ice cream have been reported. The major difficulty with such products from an NMR point of view is that the relaxation cannot be described by a single component and multi-exponential fitting has to be used. For example, a multi-exponential model with four relaxation components was used to fit the spin–spin relaxation decay curve with soft cheeses [38]. At 6 °C the two components with $T_2 < 100\,\mu$ were attributed to crystallized and amorphous fat protons and the two components with T_2 around 12 and 30 ms were attributed to liquid fat protons and water protons, respectively. Since the water relaxation can be distinguished from the liquid fat protons, the water relaxation time can be used to monitor casein structure changes. This has been well illustrated in experiments involving the ripening of soft cheeses [39], to predict the water content of cheese [40] and to provide information about viscoelastic properties [41]. Protein hydration changes during cheese aging were recently reported for the field cycling NMR technique [42].

Another example of multi-exponential behavior of relaxation has been reported with ice cream [43]. At –14 °C, the spin–spin relaxation consists of a Gaussian and two decreasing exponentials. The first component with T_2 close to 20 μs includes the relaxation of both the protons of the crystallized fat and of the ice. The second component with T_2 around 1 ms describes relaxation of the protons of the liquid fat and the non-exchangeable protons of the sugars, and the component with $T_2 > 5$ ms can primarily be attributed to the relaxation of the water protons. Variations in the water relaxation time observed for different ice creams of various chemical compositions has been directly related to the protein type (casein vs. whey protein) added to the mixture [44]. Moreover, changes in water relaxation during ice cream storage show that the aqueous phase, although in small proportion in ice cream, nevertheless appears to evolve during storage [44]. Although the ice proton relaxation cannot be distinguished from crystallized fat protons by T_2 measurements, this can be achieved using measurement of T_1 relaxation time [43]. Indeed, for ice cream the spin–spin lattice relaxation of the solid phase has been described by a bi-exponential model. The two relaxation components were attributed to fat and water in the crystallized state, respectively. In addition to this result, it has also been reported for the first time that the spin–lattice relaxation time of the crystallized water in the ice cream varies between 2000 and 4000 ms, depending on the formulation of the ice cream [44]. This significant effect was mainly explained by the protein type and concentration in the ice cream. The ice relaxation was higher when skim milk powder was used in place of whey protein powder. A change in the ice crystal structure was assumed to explain this wide variation.

Nevertheless, interpretation of NMR relaxation of complex products such as cheese requires careful quantitative analysis of the NMR signal in order to avoid confusion between water and liquid fat relaxation, for example. Indeed, in many cases water and fat relaxation cannot be separated and interpretation of T_2 or T_1 in terms of water mobility becomes questionable [45–48]. Depending on the water relaxation time value of the product under study, the temperature of measurement should be fixed in order to provide a way to separate the water relaxation from the fat relaxation. Another solution is to perform two-dimensional spin-relaxation and diffusion experiments. Fat and water relaxation can be distinguished [49] from T_2 vs. T_1, and changes during maturation have been observed from the D vs. T_2 and T_2 vs. T_1 maps [50,51].

Water Retention

The mono-exponential behavior for water relaxation is only observed when the water molecules in different microscopic compartments are averaged by diffusive exchange [52]. If the diffusion coefficient is slow compared to the relaxation rate or if the distance between two water compartments is large, the averaging is no longer effective and bi-exponential water relaxation behavior is observed. The change from mono to bi-exponential relaxation is a powerful way to quantify curd syneresis. Gels formed from milk by renneting may subsequently show syneresis, i.e expel liquid, because the gel contracts. During syneresis, water relaxation is described by a bi-modal distribution of the transverse relaxation time [53,54]. The two water peaks are related to the location of water in the sample. The long T_2-relaxation time reflects the water expelled from the curd and its value is constant over the period of syneresis. The short-relaxation time is attributed to the water protons and macromolecule exchangeable protons entrapped in the gel. Three kinds of information are provided by the NMR method: curd volume-decreased kinetics, curd moisture-decreased kinetics and the curd relaxation rate [37,55]. The NMR method can also be used to monitor the kinetic effect of lactic fermentation on the water retention properties of yogurts [56] and cheese [57]. A water-holding capacity NMR method based on washing out of water by heavy water was recently proposed [48]. The T_2-experiments were performed before and after washing with D_20. The reduction in the NMR signal is therefore proportional to the amount of water replaced and related to the water-holding capacity of the sample, assuming that the NMR signal for liquid fat protons is negligible.

The rehydration capacity of dairy powders is a crucial quality criterion for dairy companies. Nevertheless, the standard methods are crude and dedicated to milk powder and not suitable for other dairy powders. Davenel *et al.* (1997) have proposed an NMR method for rehydration monitoring [58]. The advantage of the NMR method is that measurement is performed under stirring at a controlled temperature. Consequently, the NMR method provide complete kinetics of the rehydration process and can be used whatever the composition of the powder [59].

Water Diffusion

An alternative way to study water states in macromolecular solutions and gels is self-diffusion measurement of water mobility. This can be achieved by means of the Pulsed Gradient NMR technique (PFG NMR). In comparison with the NMR relaxation technique the interpretation of PFG findings is more straightforward. Moreover, the technique can be applied to most samples and provides structural information about the system being investigated [60–63]. The technique has been used to study water mobility in casein solutions and gels [64], and in cheese [65], and the effect of casein and fat content in model cheese on water diffusion [66]. When water diffusion is restricted within droplets, the droplet size distribution can be determined [67]. This method has been applied to butter [68].

Fat Relaxation

The most widespread NMR application for dairy products is the SFC method [1,67]. Since this method became an international standard [69], certain improvements have been made. Some have involved measurement of the solid-fat ratio in aqueous products such as emulsions [70] and others have focused on the development of more sophisticated curve-fitting methods for the relaxation curve [71]. Compared to calorimetric methods, NMR allows the determination of the SFC both in isothermal conditions and as a function of temperature. Many studies have therefore been published on the crystallization behavior of milk fat. For example, the effects of fractionation [72], high pressure [73], and cooling rate have been studied, and chemical effects such as blending [74–76] and interesterification [77] on crystallization have also been investigated.

The general determination of the SFC is based on the sampling of two points from the NMR signal, one after the dead time of the probe (11 μs) and the next at 70 μs. This method supposes that the relaxation time of the solid part is temperature independent and also independent of fat composition when using an external reference. These assumptions are not always verified. For example, precise analysis of the free induction signal of milk fat at 5 °C, showed that an intermediate phase characterized by relaxation T_2^* (varying from 50 to 250 μs) range could be detected [78,79]. This intermediate phase represents about 4% of the whole fat and thus should be considered when absolute SFC is required. One solution to overcome the choice of sampling time is to fit the complete NMR signal. This solution provides a precise determination of the relaxation time of the solid phase and moreover signal intensity is deduced without the need of correction factor because of the dead time. This method has been successfully applied to fat blends [71], model food emulsion [80] and ice cream mix [81]. The only limitation of this method in cases of emulsion is that the amount of fat should be known or the relaxation time of water and liquid fat should be sufficiently different to allow quantification of the signal intensity of liquid fat and water separately.

The relaxation time of fat has also been studied. When the fat is liquid the relaxation time T_2 is related to the carbon chain length and to the degree of unsaturation [82]. Since much fat in foods is a complex mixture of triglycerides, the NMR signal time is described as a broad distribution of relaxation times [38] and interpretation of such behavior in food becomes difficult. On the other hand, wide changes in the longitudinal relaxation time of solid fat according to polymorphic state have been observed with triglycerides [83]. The longitudinal relaxation time is 12 s at 25 °C for the polymorph β form and decreases to 0.6 when a polymorphic α is obtained. Measurement of T_1 therefore provides a method of following the time course of polymorphic transformation when aging for example. Such variations have also been observed between fat in bulk and in emulsion for model food emulsions [4] or for real food products such as ice cream mix [81]. However, because of the complexity of fat composition the interpretation in terms of changes in polymorphism has not been possible.

Finally, as previously mentioned for w/o emulsion, the droplet size of fat can be determined in o/w emulsion from pulsed field gradient NMR measurements. However, the method has mainly been applied to non-dairy fat-containing products, because of the effect of the crystalline fat. High amounts of solid fat may affect the apparent droplet size because the fat crystal network may introduce a second mechanism to hinder diffusion within the droplet [84]. For dairy products, it was assumed that droplet size measurement with PFG NMR can only be performed at temperatures above 15 °C, in view of the SFC for butterfat according to temperature [84]. For example, the droplet size of fat in cheese has been determined at 37 °C [65].

Conclusion

Despite the complexity of the interpretation of NMR relaxation time parameters, this technique can provide much information that is useful for quality control and for the development of new products based on improved knowledge of molecular and microscopic structure. A new, dedicated, low field spectrometer has recently been proposed (Mouse NMR [85,86]). We are sure that these technical improvements will contribute significantly to the development of NMR relaxation in dairy science and dairy companies.

Introduction

Characterization of molecular mobility in complex systems can provide much useful information that helps scientists understand various biological, chemical, and physical phenomena of a complex system. In this chapter, we will explore the applications of nuclear magnetic resonance (NMR) to determine molecular mobility of primarily cereal systems using multinuclei (proton, deuteron, and oxygen-17), carbon-13 solid-state NMR, proton cross relaxation (CR), and some application use in relation to microbial activity.

Nuclear magnetic resonance spectroscopy has been used to non-invasively measure the mobility of water in complex and heterogeneous systems. Water molecular mobility can be analyzed by NMR spectroscopy [1,2] using proton (^{1}H), deuterium (^{2}H), and oxygen-17 (^{17}O) nuclei much of which have been covered in various books and review articles [3–8].

Water Molecular Mobility by NMR

NMR spectroscopy application in food is primarily based on the ability of NMR to detect water. NMR spectroscopic technique for water is based on a measure of resonant radio frequency adsorption by nuclear spins in presence of applied magnetic field. Depending on the spin quantum number, several energy levels of the resonance is collected which reflects the nature in which the nuclei interact with the applied magnetic field.

The proton (^{1}H) nucleus is the most abundant NMR detectable species and with the spin quantum number (I) of 1, its signal acquisition is relatively easy. However, interpretation of proton relaxation data is complicated by chemical exchange and CR phenomena. Protons associated with different molecules can exchange their position and are subject to CR phenomena between neighboring locations [8–12]. These phenomena can significantly influence the relaxation process [13–15].

Deuterium (^{2}H) is less abundant than proton and its relaxation signal is strongly affected by quadrupolar interactions (because of its quadrupolar moment with spin quantum number (I) of 1). ^{2}H NMR, however, does not escape the contribution from the chemical exchange with other exchangeable deuterons or protons on the solids [8,16].

Oxygen-17 (^{17}O) NMR data are free from the effect of CR and ^{17}O does not likely exhibit a significant oxygen exchange [8,17–20]. Therefore, ^{17}O NMR data are more easily interpreted, but the low ^{17}O abundance (0.037%), accompanied with a strong quadrupolar moment ($I = 5/2$), makes ^{17}O signal acquisition quite difficult. The application of ^{17}O NMR to the study of water mobility is mainly limited to a high moisture environment where bulk water is present. In solid and semisolid systems, water mobility information can be more easily acquired (but more complex to interpret) using ^{1}H and ^{2}H NMR. Enrichment with $H_2^{17}O$ and/or $^{2}H_2O$ can further improve signal acquisition.

Water mobility is characterized by the resonance frequency, spin–lattice and spin–spin relaxation times (T_1 and T_2, respectively). Because possible rapid exchange within the NMR time frame, signals observed are time averaged. Unfortunately, some water molecules may be trapped or associated (chemically or physically) with other molecules. If the water molecule is a distance away in another domain, it may be less efficient in exchanging with other distant water molecules and hence exhibits as a separate population.

On a local level, the physical nature of the tested material plays an important role. In a non-viscous liquid, $T_1 \sim T_2$ and its correlation time (tc is short (Figure 1). As a material becomes more solid at $\tau_c < 10^{-6}$ s, $T_2 \ll T_1$.

At a given physical condition and state, a water molecule exhibits a dynamic processes which may include reorientation (τ_r), translation or diffusion (τ_D), proton or deuteron exchange with neighboring protons or deuterons (τ_e), and (if associated with a macromolecule) tumbling, anisotropic motion [20–22].

NMR to Determine Various Populations of Water

The heterogeneous chemical nature of food components is a known fact but yet least investigated. Molecular diversity of compounds can be characterized according to polarity, ionic property, surface activity, molecular weight, isoelectric point, and so on. Within a molecule (such as protein), heterogeneity in side groups can greatly influence the conformation as well as how the molecular domains interact with the surrounding solvent. For this very reason, it is important to regard water as being different among these different regions. In common terms, water resides around various solid surfaces at residence times short or long depending on the chemical forces between them. The rotational motion (normally described as rotational correlation time τ_r) is one of the properties experimentally described by methods such as NMR using, for instance, typical spin echo experiment.

On a macroscopic and a microscopic scale, food and food ingredients are highly heterogeneous in a variety of length scales. NMR experiments can be performed to detect heterogeneous domains [23]. Relaxometry, by which a time average frequency is measured, determines chemical heterogeneity based on the variation in signal intensity at different frequencies such as amino acid composition of a protein. A time dependence frequency type of experiment is related to time dependence fluctuations of local frequencies, which can be used to determine spatial heterogeneity such as spatial distribution of water or other solvent molecules [23].

In a heterogeneous system, spins exist in a wide variety of environments resulting in a spectrum of relaxation times. Spins are also influenced by chemical and diffusive exchange. Therefore, the measured relaxation decay is a sum of the contributions from all spins, which may have sampled many different environments or exchanged with other spins at different rates within NMR timescale [24].

Spatial distribution of molecules in heterogeneous domains can greatly influence the NMR relaxation signals. Diffusive exchange occurring within the NMR relaxation time has been demonstrated to have a considerable impact on the interpretation of NMR data for biological heterogeneous systems [25]. Diffusive exchange of molecules from spatially separated regions involves random jumps between many different volume elements along the spatial dimensions, whereas chemical exchange between two different chemical species only involves jumping between two types of magnetization density vectors [26]. When the exchange process is fast compared to relaxation rates, only a single average process is observed. On the other hand, if the exchange is relatively slow, two or more processes may be observed depending on the exchange mechanism. In such situation, proton NMR relaxation data can be used to describe some degree of spatial heterogeneity of the system, such as freeze-thawed agarose gel [27] and Sephadex beads [28].

Polymer network depending on cross-linking density may swell in the presence of water trapping the water molecules. The molecules of water, are free to diffuse between the inside and outside of a domain. Spatial dimension can be related to the particle size, and also to the internal cross-linking density of the structural components. These factors affect diffusion distance between water in different internal compartments as well as inside versus outside the particle. This time-dependent diffusive exchange affects the proton relaxation decay observed dependently on CPMG pulse spacing. Hence, pronounced multiple-exponential decay can effectively arise from diffusive exchange.

If inter-pulse spacing (τ) is very short compared to the proton exchange rate (chemical exchange slow), there is less dephasing effect by continually refocusing the transverse magnetization (becoming single exponential). This results in a decrease in the transverse relaxation rate (longer observed T_2). On the other hand, when the pulse spacing is very long compared to the proton exchange rate produces an increased dephasing between refocusing pulses and gives an increased relaxation rate (decreased T_2). As the pulse spacing increases another dispersion becomes noticeable, this arises from water outside diffusing into the particle and then exchanging with other protons. As a result, experiments performed with multiple τ can lead to different number of exponential components some of which are not linked to existence of different sites but rather a reflection of the s spatial morphology of manifestation of the material.

Since the discrete model can be limited to a condition that favors a fast exchange within the NMR time frame, a continuous model has been developed and applied to study heterogeneity of food systems. In the continuous distribution relaxation time model, the discrete character of the basic least squares solution is altered to generate continuous distributions [29].

This model was used to construct a non-negative least squares (NNLS) discrete and continuous spectra for a western red cedar sapwood sample using the data collected with the CPMG experiment [30]. The discrete model shows four to five isolate T_2 values, while the continuous model results in three peaks. The presence of peaks in the continuous spectrum suggests that there were three dominant environments within the wood. The integral area under each peak represents the amount of the fraction of water molecules that have the T_2 values covered by the peak. It is found that the continuous model is the preferred one because it fits the nature of wood in that the lumen water in wood produces a continuous distribution of T_2 values corresponding to the continuous distribution of lumen diameters.

A Fortran computer program called "CONTIN" based on the NNLS approach was developed [31,32]; CONTIN uses a general purpose constrained regularization method and finds the simplest solution that is consistent with prior knowledge and experimental data. More recently, the software program such as RI WinDXP program (Oxford Instruments, Ltd., Abingdon, UK), has been developed to perform the continuous distribution analysis based on the non-negative constraints and optimal smoothing. A continuous distribution of exponentials for FID and CPMG experiments may be defined by the following equation:

$$g_i = \sum_{j=1}^{m} f_j \mathrm{e}^{-t_i/T_j},$$

where g_i is the unknown amplitude of the spectral component at time t_i, f_j the pre-exponential multipliers of the distribution, and T_j the exponential time constants (the T_2 values).

T_2 Distribution of Water in Starch

Multiexponential models are commonly used to analyze NMR relaxation data of food systems. As mentioned earlier, spins exist in a wide variety spectrum of relaxation times, which are influenced by chemical and diffusive exchange within the heterogeneous system [25,33,34]. It is, thus, reasonable to assume that a continuum of relaxation times would arise from a continuum of different environments in which spins exist with different exchange rates. Lillford *et al*. [34] reported that the continuous distribution of relaxation times resulted in an improved representation of what?. Some other researchers have used continuum models to follow the relaxation behavior in various systems [24,30,35–38].

T_2 spectra can be regarded as a probability distribution of spins at various relaxation times. There are often several peaks on a T_2 spectrum. Larger number of peaks (or broader ones) would be expected for heterogeneous samples, whereas fewer but stronger peaks would be expected of more homogeneous samples. The number and degree of variation of the peaks, therefore, can be used to indicate the degree of heterogeneity of the sample being analyzed.

To take this one step further, the relationship between water distribution and starch granule heterogeneity was studied using proton and deuterium NMR techniques [39]. In this work, water proton transverse relaxation times for a packed bed of raw potato starch granules were identified with three distinct water populations. The effect of acid hydrolysis (lintnerization) and the thermal gelatinization of the dynamic state of starch and the microscopic distribution of water within native potato starch granules were also studied [40].

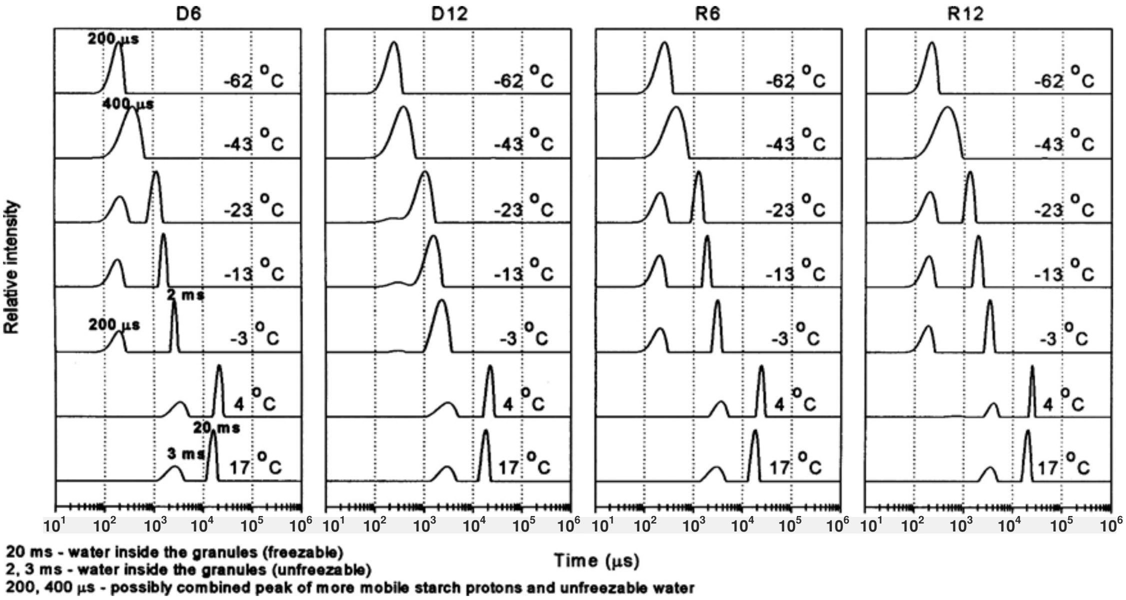
Relative proton CPMG T_2 distribution of cassava starch undergoing stepwise heating exhibited T_2 peaks at 200 and 400 μs (at −62 and −43 °C), respectively (Figure 2). As the temperature was raised, the peak splitted into two peaks (200 μs and 2 ms) before the ice melting temperature above which an appearance of more mobile protons (20 ms) was observed [41]. A significant change in proton CPMG T_2 distribution was also observed upon gelatinization. At the onset of the gelatinization, merging of the two peaks into a broader peak was observed.

In order to assess starch chain mobility, H_2O could be replaced with D_2O (so that only the starch protons would be observed). For cassava starch, a 10-μs T_2 peak component represents the rigid amylopectin and a 800-μs T_2 peak represents the less rigid components (Figure 3). Gelatinization led to a decrease in the rigid chain population and an increase in the mobile chain population [41].

Solid-State Nuclear Magnetic Resonance

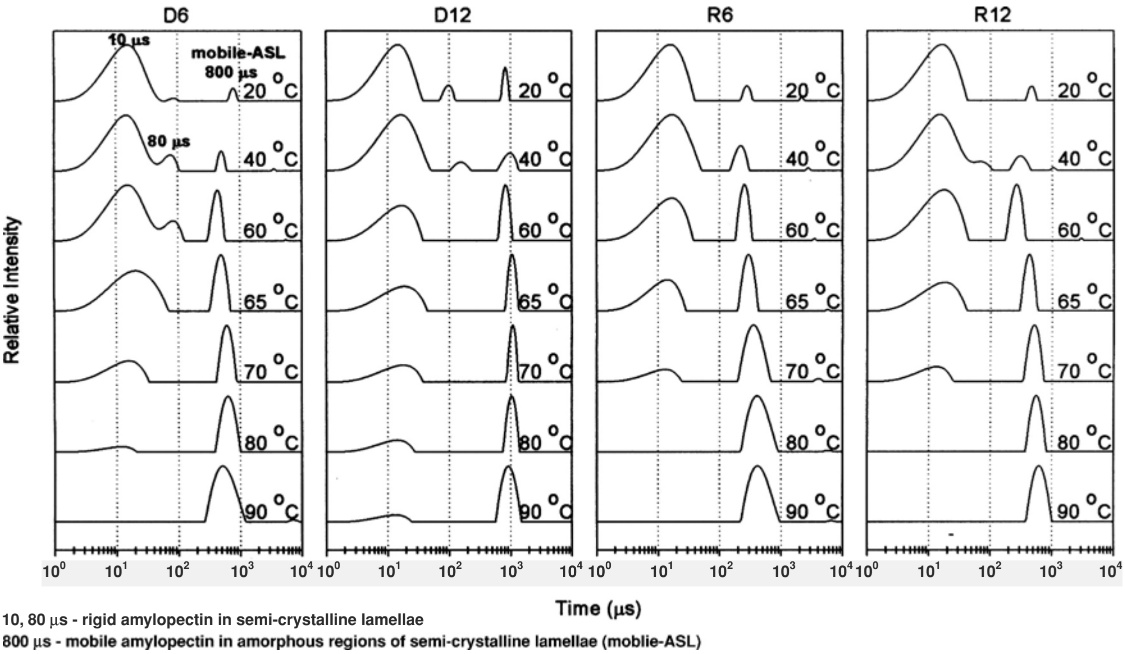
^{13}C Cross Polarization and Magic Angle Spinning

Solid-state NMR is a useful tool to probe the molecular structure in the crystalline solids and glassy states. This powerful technique has been used to probe the structure dynamics and mobility of biopolymers [42–45]. Prior to the implementation of this technique, NMR was limited



20 ms - water inside the granules (freezable)
2, 3 ms - water inside the granules (unfreezable)
200, 400 μs - possibly combined peak of more mobile starch protons and unfreezable water

Fig. 2. Transverse relaxation time (T_2) distribution of protons for cassava starches (planted in drought season, "D" and rainy season, "R" and harvested at 6 and 12 months) saturated in water as measured from the CPMG sequence [41].



10, 80 μs - rigid amylopectin in semi-crystalline lamellae
800 μs - mobile amylopectin in amorphous regions of semi-crystalline lamellae (moblie-ASL)

Fig. 3. Transverse relaxation time (T_2) distribution of protons for cassava starches (planted in drought season "D" and rainy season, "R" and harvested at 6 and 12 months) saturated in water D_2O as measured from the FID.

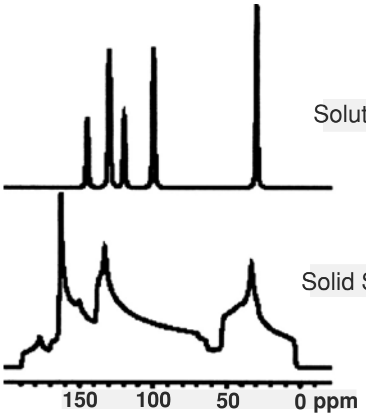


Fig. 4. Comparison of solution and solid-state ^{13}C spectra showing the broadening due to anisotropic chemical shift and dipolar broadening.

to the study of solutions, since solid spectra is generally broad and contains very little specific information (Figure 4) due to anisotropic or orientation-dependent chemical shift and dipolar broadening. The magnetic field experienced by the nucleus varies as a function of the orientation of the molecule in the magnetic field and in a non-viscous liquid, the fields at the various orientations average out due to the tumbling of the molecule. Dipolar interactions averaged to zero in solutions due to rapid rotational and translational motion [46].

Two techniques, namely magic angle spinning (MAS) and cross polarization (CP), are commonly used in conjunction to overcome the anisotropy and dipolar broadening. If a sample is spun rapidly at an angle of 54.74° to the applied magnetic field, the dipolar interactions are reduced. At this magic angle, the chemical shift tensor (s) is equal to the isotropic chemical shift (s_i), which is the one found in solutions when dipolar interactions are not seen. MAS, therefore, reduces the broad chemical shift powder pattern to the isotropic sharp pattern found in liquids [48]. In solid-state NMR, samples are placed in a special sample tube and the tube is placed inside a rotor. The rotor, and hence the sample, are oriented at the magic angle and the sample is then spun at a rate of thousands of revolutions per second. The spinning rate must be comparable to the solid-state line width. CP involves the transfer of polarization from abundant spins to dilute spins in order to enhance signal to noise and reduce waiting time between successive experiments.

For nuclei with low natural abundance (such as ^{13}C), the average of many signals (scans) need to be accumulated to obtain a spectrum when using Fourier Transform, pulsed techniques. The repetition rate is dictated by T_1 (spin–lattice relaxation time) and for ^{13}C, the T_1 values are very long in solids and, therefore, the accumulation of the data required would take a prohibitively long time. Consequently, CP is used in which the polarization of the abundant ^{1}H nuclear spin with short T_1 is transferred to that of the ^{13}C nuclei. After CP, the repetition rate is determined by the short ^{1}H T_1s [46,48]. Therefore, by utilizing CP–MAS NMR, both the resolution and experimental time frames have been improved.

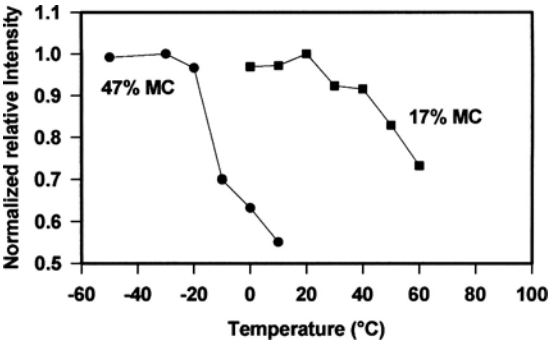

Fig. 5. The change in intensity of carbon 1 of 17 and 47% moisture wheat starch gels at decreasing temperature obtained from ^{13}C CP–MAS measurements [47].

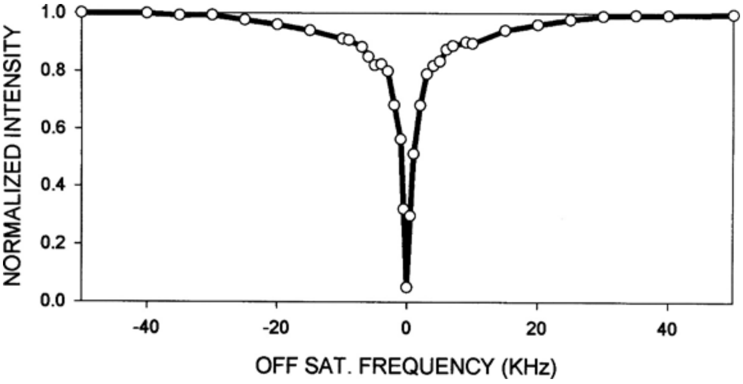
^{13}C CP–MAS NMR can be used to monitor the development of rigid components in starch [49]. This method was applied to the study of different crystalline (A and B pattern [50]) and amorphous [51] structures of starch as well as the effect of hydration [52]. For example, Figure 5 shows the differences in the changes in carbon 1 of a 17 and 47% moisture starch gels upon heating [47]. Carbon 1 has been used to describe the molecular motions of amorphous starch [53]. The increase in mobility (decrease in intensity) at temperatures above 20 °C for 17% vs. above −20 °C for 47% gels was attributed to the glass-rubber transition [47].

Relaxation Time in the Rotating Frame ($T_{1\rho}$)

The relaxation times (which in reality describe the decay of energy) may be used to ascertain the mobility of the probed nuclei in the solid state (the correlation time of motion). The time frame for each of the relaxation times in the solid state range from seconds for T_1 to ms for $T_{1\rho}$ (rotating-frame relaxation time). $T_{1\rho}$ can be used to measure molecular motions in glassy, rubbery, and crystalline solids, since it is sensitive to motions associated with frequencies in the 10–100 kHz range [54]. $T_{1\rho}$ (^{1}H) is performed by monitoring the intensity of ^{13}C NMR signals as a function of the duration of a ^{1}H spin-lock field. The $T_{1\rho}$ (^{1}H) values are obtained by spin locking the proton

Fig. 6. Typical ^{1}H cross-relaxation NMR Z-spectra curves constructed from water resonance saturation as a function of offset frequency [59].



spins in the rotating frame for a variable delay (spin-lock time) prior to CP. The plot of different relaxation times vs. the correlation time at a fixed frequency would theoretically yield U-shaped curves. The minimum observed occurs when the frequency of the molecular motion is comparable to the measured frequency of the spectrometer [55]. Temperature is used to measure correlation time since the two parameters are related with the following equation $\tau = \tau_0 e^{\Delta E/kT}$, where τ is the correlation time, k Boltzman's constant, E the activation energy, and T the temperature.

$T_{1\rho}$ (^{1}H) has been found to decrease in heated starch compared with native starch [44] most likely due to the presence of amorphous domains. Li and co-workers [44] found the $T_{1\rho}$ (^{1}H) minimum (mobility) for wheat gluten depended on moisture content with 2% showing a minimum at -13 °C and at 20% moisture the minimum was shifted to below -30 °C. However, the observed ^{1}H $T_{1\rho}$ is influenced by a number of factors including the molecular motions of each domain, domain size, spin diffusion, cross relaxation, and dipole–dipole interactions between water and starch [44]. $T_{1\rho}$ (^{13}C), on the other hand, provides information of the carbon mobility more directly and therefore changes in the polymer molecular dynamics can be monitored and related to phase transitions [54].

Solid Mobility by Cross Relaxation

Cross relaxation NMR spectroscopy is a high-resolution proton (^{1}H) method for determining the information on the relaxation of the solid component via the observable liquid spin system [56]. The ^{1}H CR NMR method has been shown to be a beneficial tool for probing solid components in gels using a simple and economical NMR spectrometer, without the need for a solid-state instrument [57]. A sample is irradiated with a radio frequency pulse that is off-resonance from the liquid signal. Due to the dipolar coupling between the liquid and solid protons, the amplitude of the liquid spectrum will change with the offset frequency, and a Z-spectrum is obtained [56–58].

Figure 6 shows a typical Z-spectrum generated using the amplitude of the liquid spectrum (water resonance saturation) as a function of offset frequency. At sufficiently large offset frequencies, solid protons are not saturated and no CR occurs between the solid and liquid protons after a 90° pulse. As the frequency offset difference decreased (small offset frequencies, Figure 6), the excited solid protons transfer magnetization to liquid protons. This results in a decrease of NMR liquid signal due to the CR between the spins of restricted mobility and those of the mobile bulk-water pool [59]. The Z-spectrum thus contains information of the internal mobility of the solid components in the sample [58]. An inverted plot of the same data (the y-axis being $1 - M^{z}/M^{z0}$) would closely resemble a typical solids ^{1}H spectrum.

CR NMR has been used to study a variety of physicochemical phenomenon in carbohydrate systems, such as molecular mobility around glass transition region in 50% starch gels [57]. In this starch study, an increase in the relative quantity of rigid protons was observed between 0 and -10 °C that was attributed to the glass transition and/or to ice formation. Inulin and maltodextrin gel aging exhibited immobile fraction due to the re-crystallization as detected by CR NMR [60]. Wu and Eads [61] also found an increase in the area and width of the Z-spectral line shape for waxy starch gels during aging. The complex Z-spectra have been decomposed into a Lorentzian (more mobile, solid protons) and a Gaussian (more rigid, solid protons) component. Assignment of the latter was supported by DSC data [61].

In bread, Vodovotz and co-workers [62] reported no change observed in the Z-spectrum of a bread sample (Figure 7), whereas those for gelatinized waxy starch (GX), gelatinized wheat starch (GW), and heated gluten (HG) increased in the width at half height of the

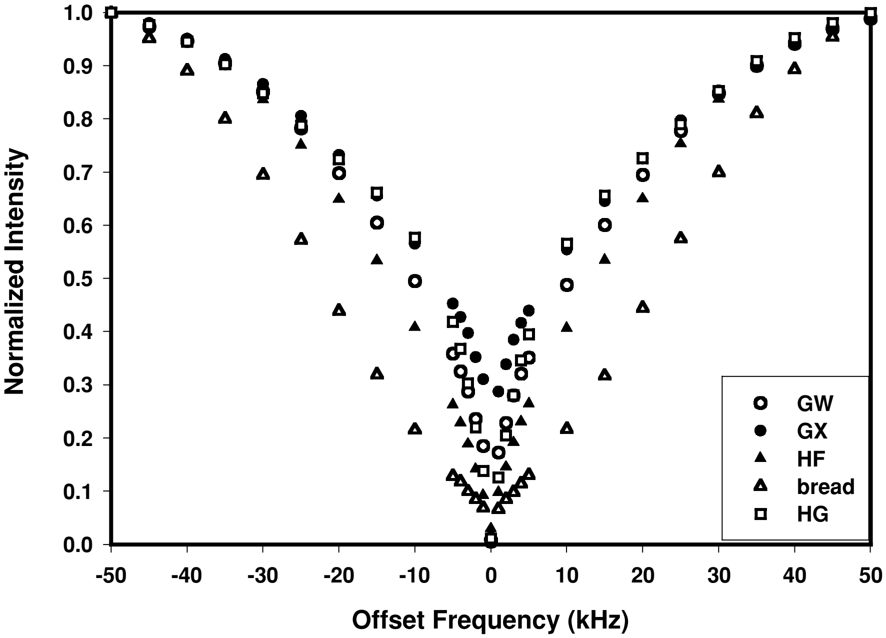


Fig. 7. Results of cross-relaxation ^{1}H NMR experiments for bread and its components at day 0 storage. Abbreviations are for wheat starch (GW), gelatinized waxy starch (GX), heated gluten (HG), and heated flour (HF) [62].

decomposed broad component (presumably an increased rigidity). Since this was not related to amylopectin retrogradation (DSC result), the difference in molecular mobility was attributed to the role of gluten and/or redistribution of water in the amorphous regions of the samples.

NMR Mobility and Microbial Activity

NMR relaxometry can be useful for investigation of water mobility and how it may influence microbial growth and survival. Investigative studies have been focused both on mold germination and growth in semi-solid and solid media and on survival and growth of *Staphylococcus aureus* in liquid media [63–70]. In addition, some reports include the impact of microstructure and water distribution [71,72].

A first investigation about water mobility and microbial response was reported by Chinachoti [73] where an addition of sucrose to a hydrated starch system induced both a reduction in a_{w} and promoted mold germination was proposed to be related to the presence of mobile water as depicted from some ^{17}O NMR results. Evidently because of the redistribution of water from trapped in the hydrated starch granules to extragranular water dissolving sucrose, the water became more rapidly exchanging in bulk solution outside of the granules. Although the short-range rotational mobility was high in both the cases, the extragranular water was able to rapidly exchange and free to diffuse, hence promoting mold spore germination. The presence of this freely exchanging water was earlier assigned to "solute" water and was reported to promote mold germination [63,74].

Because it could be argued that sucrose also served as a carbon nutrient, there was a need to repeat experiments with a more carefully designed system where nutritive contents were the same in all treatments. A media containing only non-nutritive, non-toxic carbohydrates (L-sorbose and cellulose) was used to grow a mutant strain of *Aspergillus nidulans* spores ruling out any possible influence of sucrose acting as nutrient to the cells [66,67]. The composition of the media was designed to alter not only its physical state but also its water molecular dynamics by changing the L-sorbose:cellulose ratio. A substantial increase in water mobility as measured by ^{2}H and ^{17}O NMR T_2 relaxation time was measured when sorbose solubilized. Mold spore germination time and growth rate were both highly dependent on both ^{2}H and ^{17}O NMR T_2 relaxation times irrespectively of system solid composition (sorbose:cellulose ratio) as shown in Figure 8. Mold spore germination time, therefore, correlated closely to the mobile water associated with dissolved sorbose. This experimental evidence indicates that in these solid-semisolid

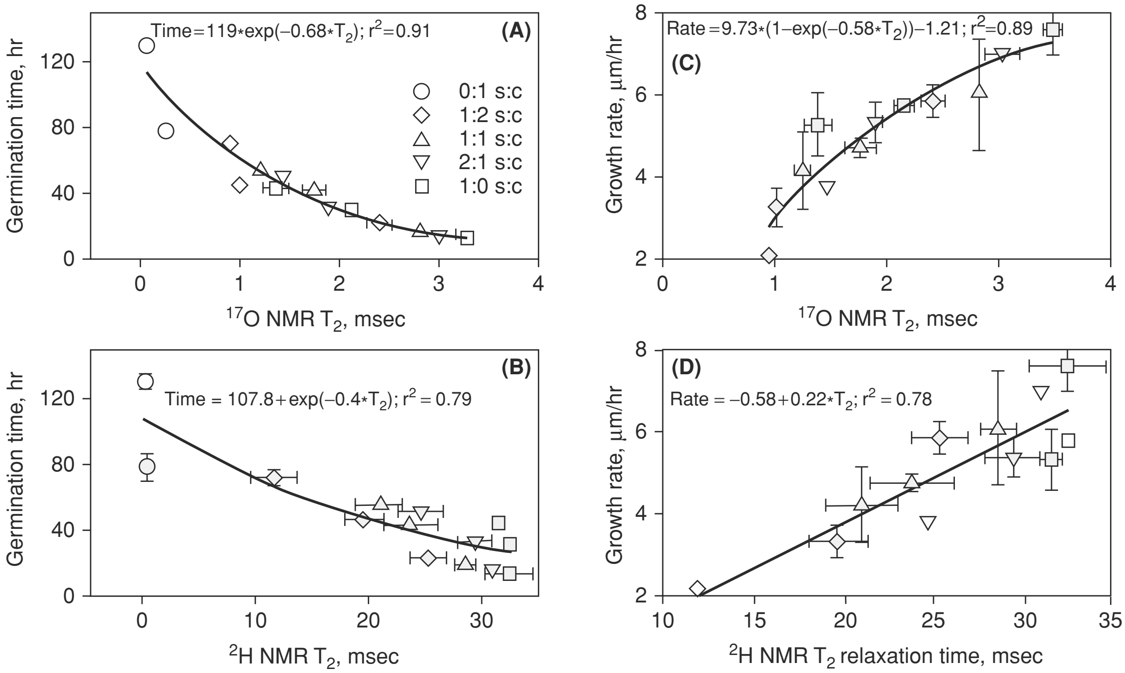

Fig. 8. Aspergillus nidulans (biA-1 sorA-2) germination time and hyphae growth rate as a function of ^{2}H NMR and ^{17}O NMR T_2 relaxation times of cellulose (c), sorbose (s), and orange serum broth solids with different s:c ratios at 25 °C [67].

systems water NMR mobility as described by T_2 relaxation time is key indicator to describe mold spore germination (both lag time and hyphae growth rate). More data and discussion can be found elsewhere [75].

In a liquid media system, growth of *S. aureus* was studied in brain heart infusion media. ^{17}O and ^{2}H NMR were applied to describe a model media with a presence of humectants such as NaCl, raffinose, and glycerol [64,65]. In relatively diluted, liquid media (over 0.90–0.99 a_w range with T_2 in ms range), the most "bound" water exhibited correlation time in ∼10 ps range (highly mobile and free), hence the bacterial growth was found to be far less dependent on the water mobility but rather on the quantity of bound water (10–30% of the water was considered perturbed or bound) [70]. Using a model assuming two-state, fast exchange with anisotropic, two correlation time for bound water [76–79]. In this case, a_w has been consistently shown to be a describing parameter governing the bacterial activity not because of the presence of bound water but rather an osmotic effect. More on this topic has been described [75].

This model assumes the existence of different water populations (anisotropically and isotropically reorienting) and calculates more specific dynamic molecular mobility parameters such as correlation time (^{17}O τ^{s}_{bw}) of the different water populations and the amount of bound water (^{17}O P_w). These physicochemical properties of the media can be used to describe the microbial media activity [70,75].

A few promising studies address microbial response in relation to translational water mobility parameters [80–82]. Moreover, ^{1}H solid-state NMR has been applied to microbial survival study in solid (glassy) systems [64,69]. This is described in more details elsewhere [75].

In summary, it has been suggested that microbial response depends highly on the dynamic properties of the water present in the environment. The study on the molecular dynamic properties of water in culture media for microorganisms could provide additional descriptor of water availability that may potentially become a tool to understand, predict, and modulate the microbial response. This may lead to an innovative means to better control microbial food safety and microbial food biotechnological developments.

Concluding Remarks

Advanced knowledge in Food Science in the future can be accomplished from fundamental understanding of food components and their interactions. The challenge of understanding molecular origins of complex systems, such as food, requires more sophisticated approaches. Applications of advanced methods such as NMR to study and solve Food Science problems can lead to better understanding at a molecular level in areas, such as encapsulation, mechanical strength, phase transition, diffusion, and non-invasive imaging. With new development in NMR together with many other rapidly emerging analytical advances, future discovery in food science can be indeed quite exciting.

Diffusion and Relaxation in Gels

Joachim Götz and Ruth Hinrichs

Lehrstuhl für Lebensmittelverpackungstechnik, Technische Universität München, Weihenstephaner Steig 22, 85350 Freising, Germany

Introduction

Foods are often heterogeneous mixtures of materials with complicated material behavior and structure properties. Redistribution of constituents (water, fat, solvents) and structural changes including phase transitions are induced by many processing operations including storage. Water, especially, acts as a transportation medium, reacting agent, intermolecular link and textural medium. In food process technology, both the integral and local moisture contents, the type of water binding, and the mobility of water molecules (free, retained, adsorbed) are relevant with regard to the yield, sensory evaluation, stability (physical and microbiological), the texture, and flow behavior (diffusive/convective) in many technical applications (e.g. thermal treating, solid–fluid separation, ad-/desorption, de-/mixing, de-/agglomeration). It is, therefore, desirable to obtain deeper insight into the microstructure of food systems in order to forgo time-intensive trial-and-error in food structuring or production like the common practice to apply simple empirical tests. The overall objective of this review is to elucidate the possibilities to characterize the structure of gels with respect to (a) the pore system (generally: solid matrix) probed by the diffusion behavior of the corresponding solvents and (b) the water-binding or, macroscopically, the water-holding capacity (WHC).

Diffusion

Diffusive flow processes in solid systems are mainly influenced by the pore system architecture, chemical composition of the solid surface and resulting solid–fluid interactions. The molecular diffusion of constituents in gels allows one to analyze the transport phenomena of confined fluids [1] [de-/hydration, fat bloom (chocolate), syneresis (dairy products, mustard), and controlled drug –release] and fluid–solid interactions.

Molecular Diffusion in Disperse Systems

NMR PFG techniques allow the determination of self-diffusion coefficients D_S as a function of the effective diffusion time Δ and to calculate the mean distance traveled by the diffusing molecules (pure liquids or fluids confined in gels) during the diffusion time [2–4]. In dilute solutions and gels with low material-specific solid concentration the self-diffusion coefficient D_S is independent of the diffusion time [5,6]. D_S is reduced compared to pure water due to obstruction and hydration of the dissolved molecules (hydrocolloids, proteins) or simply solutes (salts, sugars). This is in agreement with Stokes–Einstein for the Fickian diffusion coefficient D_F

$$D_F = \frac{kT}{6\pi a}\frac{1}{\eta}, \qquad (1)$$

where a is the radius of a spherical particle and η the dynamic viscosity of the solvent. According to the proportionality between D_F and D_S (Equation 1) an increased viscosity of the serum causes a reduction of D_F and D_S (reviews [7,8] of NMR and other methods for self/inter-diffusion). A dependence of $D_S(t)$ on t in diffusion experiments indicates that the diffusion is restricted due to physical barriers, e.g. network systems in gels (collagen [9], gellan gum [10], and starch [11]). NMR PFG allows the observation of diffusion in anisotropic structures or anisotropic diffusion.

Characterization of Pore Systems

In disperse systems the diffusing particles can be used for probing the microstructure with diffusion [6,12,13]. Characteristic lengths inside the solid matrix of a few micrometers are accessible. These spatial resolutions cannot be realized using MRI methods. NMR diffusion experiments provide information concerning fluid saturation or the existence of fluid layers adsorbed at the solid matrix [14]. It can, furthermore, be differentiated between mass transport in the gas phase, the fluid –phase, or through the solid material. A special version of PGSE experiments (diffusion diffraction, q-space microscopy, or imaging [15–18]) has proven its capability to characterize connected porous systems. Porous systems often have fractal properties [19]. Self-diffusion processes are sensitive to the dimensional character of the path of diffusing particles due to the microstructure. For the free diffusion, the

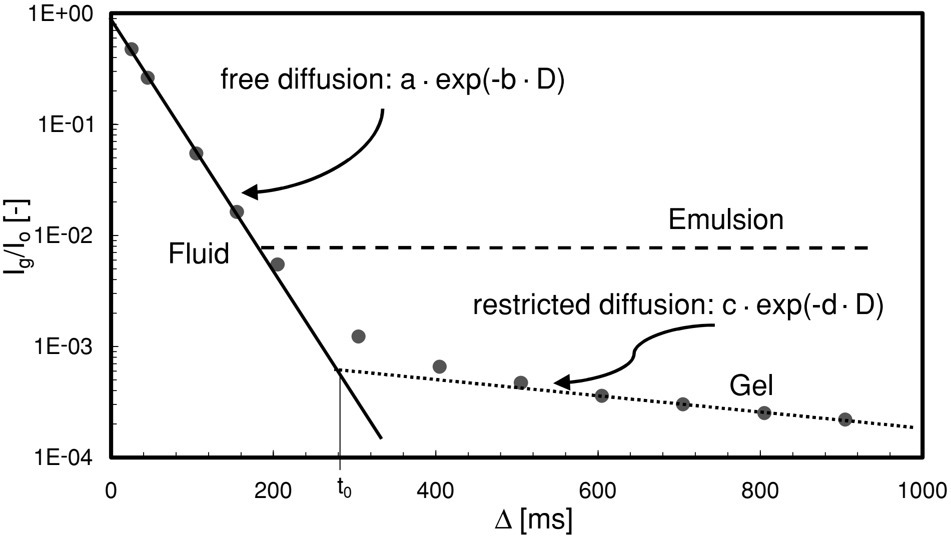

Fig. 1. Schematic presentation of the ratio of the spin-echo amplitudes I_g/I_0 for a fluid with free diffusion, an emulsion with monodisperse drops (matrix signal suppressed) and a network with free ($D_{Sf} \sim b$) diffusion (short Δ) and restricted ($D_{Sr} \sim d$) diffusion (long Δ).

mean square distance from the origin at $t > 0$ is

$$\langle r^2 \rangle \sim D_{Sf} t. \tag{2}$$

For restricted diffusion it holds [20]

$$\langle r^2 \rangle \sim D_{Sf} t^{2/(2+\theta)}. \tag{3}$$

The θ effective dimensionality of the random walk vanishes for Brownian motion [3,14,21]. For sufficiently long times, the mean square distance $\langle r^2 \rangle$ becomes linear as a function of time

$$\langle r^2 \rangle \sim D_{Sr} t. \tag{4}$$

The self-diffusion coefficient D_{Sr} for restricted diffusion is also called effective diffusion coefficient D_{eff} for long times. The time dependence of the self-diffusion coefficient contains information about the structure of porous media [18,21–24]: (a) characteristic dimensions of the gel structure (critical pore radius r_c), (b) free diffusion for short times, dependent on the pore –structure, and the pore fluid, D_{Sf}, and (c), if different from case (b), restricted diffusion behavior for long time D_{Sr}. D_{Sr} is a measure for the macroscopic permeability of the pore structure, D_{Sf} characterizes the viscosity of the serum [8], generally smaller than that of water due to solutes. I_g is the signal (e.g. PGSE or PGTSE), with applied gradient magnetic field $\mathbf{g}$, I_0 is the corresponding signal without gradient. The ratio of the spin-echo amplitude with I_g and without applied gradient field I_0 [2,3] is given by

$$I_g/I_0 = \exp\{-\gamma^2 \delta^2 g^2 [\Delta - (1/3)\delta] D_S\}. \tag{5}$$

Figure 1 shows the ratio of the spin-echo amplitudes with and without gradient, I_g/I_0, (a) for a fluid with free diffusion, (b) an emulsion with monodisperse drops (the signal of the matrix has been suppressed), and (c) a gel-network with free diffusion for short times and restricted diffusion for long times. Figure 1 illustrates the method of how to derive the self-diffusion coefficients at free D_{Sf} (~b: slope for short Δ) and restricted D_{Sr} (~slope d: for long Δ) diffusion and of the critical pore radius r_c of the matrix ($\sim[D_{Sf} t_0]^{0.5}$) with the evolution of I_g/I_0. The intersection point of both straight lines, which are asymptotes for the short- and long-time diffusion behavior, defines the critical time t_0. t_0 depends on the characteristic length scales of the pore system and D_{Sf}. The critical pore radius r_c (spherical cavities) is given by [4,25]

$$r_c = [5 D_{Sf} t_0]^{0.5}. \tag{6}$$

Besides D_{Sf}, D_{Sr}, and r_c, further parameters characterizing the structure the pore system can be derived from D_S as a function of Δ: the tortuosity $T = D_{Sf}/D_{Sr}$ [21] or $[(1-\phi) D_{Sf}/D_{Sr}]^{0.5}$ (ϕ: mean porosity) [26], the surface-to-pore-volume ratio S/V, derived from this, the pore size distribution [23], characteristic lengths r_{ch} [27], and the permeability [28]. Many disperse systems are not only heterogeneous at microscopic, but also at meso-/macroscopic lengths. In some cases, the heterogeneities are caused by phase separation (creaming up) including syneresis (dairy products, mustard), mechanical loading, swelling, the use of fillers/fibers (yoghurts) or process-specific heterogeneities like different morphology of core and shell zones (chocolate, dairy products). Hence, it is desirable to infer structural data (T, S/V), which are spatially resolved by combining MRI and dynamic imaging methods (diffusion/flow, ENMR), especially, if the characteristic lengths are below the spatial resolution of common MRI techniques [29].

PFG NMR allows one to quantify the effect of the composition, the pH value, the concentration of ions and sugars, the denaturation fraction of proteins and the impact of the processing/process conditions on the structure in gels [30,31]. In dairy products, D_{Sf}, D_{Sr}, and r_{c} do not seem to correlate with one another. It is plausible to assume that r_{c}, like the average drop radius of water in w/o emulsions, is relevant for the microbiological stability of the gel. The diffusion coefficient of the serum D_{Sf} and, even to a higher extent, the permeability D_{Sr} presumably correlate with the texture, the sensorial (e.g. sandy), the filtration/washing and syneresis behavior of gels. Furthermore, it is possible to observe structural changes due to sol–gel transitions (hydrocolloids, denaturation), their temporal evolution, dependence on denaturation temperature/duration/fraction or ageing-processes during storage (syneresis) [32]. Combining PFG and T_2 two fractions of water (bound to collagen or retained in channels traversing collagen fibers) were observed in collagen gels [9]. D_{S} of aqueous proteins systems increases with temperature and water content [33]. Analogous experiments have been performed in starch/dextran [32,34,35] or casein systems [36], cheese [37], curdlan [38], and gellan gum [39]. The correlation between D_{Sf}, D_{Sr}, and r_{c} characterizes different sol/gel states. A review of diffusion experiments in disperse media (emulsions, porous foods) is given in Ref. [8].

Relaxation

TD-NMR [40,41] are applied in food technology in order to (a) characterize the food composition, the chemical structure/physical state (solid/liquid, crystalline/amorphous), or molecular dynamics/structural changes caused by processing [42–44] and (b) derive correlations between NMR parameters and macroscopic quality factors applicable as tools for process/quality control (on-line process NMR spectroscopy). Molecular/microscopic (molecular mass [45]) and macroscopic properties (η [45,46], permeability [47]) can be obtained (averaged, partially resolved).

Ad (a): Structural Characterisation

The interpretation of relaxation time data for an unambiguous characterization of different physical states of water or other components present in heterogeneous systems, derived from spectroscopic data [48–50], has not been clarified to its full extent due to chemical [51,52], diffusion [53,54], or spin quantum exchange [55] processes. The relaxation in aqueous systems has been studied by ^{1}H, ^{2}H [56,57], ^{13}C [58], and ^{17}O [59,60] NMR. ^{1}H NMR is applied in the majority of the experiments because of the wide spreading of ^{1}H spectrometers and the possibility to analyze without preparation. ^{2}H and ^{17}O NMR, however, provide many fundamental data on water relaxation mechanisms in heterogeneous media [5,61–63].

T_1 and T_2 allow one to distinguish between free (no interaction with solid particles or dissolved molecules) and immobilized (crystallization, hydration, or other chemically/physically bound) water. Assuming models for exchange processes (chemical, diffusion, spin quantum), the relaxation times and fractions of the corresponding water types can principally be derived. Usually, up to four different groups of spins (two correlated with water, two with the dissolved macromolecules) can be distinguished in protein and polysaccharide solutions [5,64]. Hydroxyl or amino protons can exchange with water protons, other protons are not able to exchange. Combining ^{1}H, ^{23}Na, ^{87}Rb, and ^{133}Cs NMR and adding the corresponding cations three water phases (free bulk, strongly interacting with κ-carrageenan, and weakly bound) were detected in κ-carrageenan gels [65]. For one-phase relaxation the observable T_2 relaxation times $T_{2\mathrm{obs}}$ (analogous T_1) can be used as characteristic T_2. Reviews of empirical or theoretically established models of the correlation between the concentration of dissolved molecules and the observed or the average T_2 of solutions are given by [8,83]. Thus, conclusions concerning the influence of macromolecules and their concentrations on the existence of multiple water phases $T_{2,i}$ and their fractions $d_{2,i}$ can be drawn [5,43,66].

Structural Changes Including Phase Transitions and Denaturation

Many foods and food components are thermally treated (pasteurization, sterilization, rectification, distillation, drying, freezing, freeze drying, and freeze concentrating) [67]. The variation of the temperature generally causes changing NMR parameters (relaxation times, spectra, or D_{S}). For simple fluids like water T_1, T_2 and D_{S} increase with the temperature. High-resolution NMR is an independent method besides X-ray analysis for the characterization of protein structures (denaturation, pH) [68–70]. Investigations concerning the heat treatment of proteins by means of LR-NMR (T_1, T_2, D_{S}) have been performed

[71–76] after and not during the thermal treatment (at temperatures below the denaturation temperature in order to prevent further changes) varying the process temperature, the pH value and the concentrations of protein, ions and sugars. Reversible (increased T_2: higher mobility at higher temperature) and irreversible transformations (decreased T_2: aggregation) can thereby not be differentiated. This procedure provides only reaction kinetic information using a series of tests with different samples. This is a great disadvantage for natural substances due to their compositional variety. In aqueous protein systems generally four phases can be distinguished. There are both proteins whose $T_{2,i}$ of the phases with higher mobility are increased due to the thermal denaturation and proteins with $T_{2,i}$ reduced after the thermal denaturation, whereby only two phases have been detected [72]. The dependence between T_1 or T_2 and the temperature (fixed treatment duration) and the T_2/T_1 ratio indicate structural changes (sol–gel transitions, freezing damage [73]). Online NMR-measurements offer possibility to study denaturation the during the thermal treatment (average time $T_{2\mathrm{m}}$, relaxation times of the single phases $T_{2,i}$, and fractions d_i). The advantage is that several measurements can be performed with the same sample (without interrupting the thermal treatment and/or continuing with another sample), thus achieving higher accuracies of measurements. The reaction orders and rate constant of the participating reactions can be derived. If the relaxation data vary after thermal/pressure treatments, reversible and irreversible structural changes can be distinguished.

WHC Including *Sol–Gel Transitions and Syneresis*

In food technology, the bonding type and mobility of water molecules are relevant with regard to the yield, sensory evaluation, stability, texture, flow behavior, and processing. There are many measuring methods available to characterize the WHC of a mixture [77–80]; many techniques originally developed in practice, provide quick, and easy indications concerning the studied material. Most of the available methods usually provide differing results, which are not absolute values and are, therefore, generally not comparable or transferable to technological processes. These difficulties are due to (i) different measuring principles and experimental conditions and (ii) the frequent destruction/modification of the structure due to the measuring procedure (centrifugation). A precise characterization of the WHC for food constituents like proteins and hydrocolloids is required for a reliable design of products and processes. For different materials, the relationship between the WHC and the other macroscopic (flow/deformation/sensoryl/syneresis behavior) and microscopic properties (fine stranded/particulate network) is not identical, thus complicating a practicable definition of the WHC. Rennet acid gels, for example, have a coarser network with thicker protein strings than pure acid gels [81]. Rennet gels are firmer, with a lower WHC. As mentioned before, the definition of water types depends on the applied measuring technique. The fraction of bound water is defined in rheology as bound physically/chemically at solid surfaces or retained in the interior of solid particles. With regard to NMR water is bound, if it interacts with solid material or if the water molecules are in sufficiently small cavities. For free water it is not of any importance, if fluid molecules are inside or outside of solid particles. Another difficulty is that disperse media usually have different microstructures during rheological (flowing) and NMR experiments (at rest), apart from Rheo-NMR [82] including flow experiments.

In order to differentiate free water, which can be removed through capillaries (non-stirred) or out of the pore system (stirred), from water retained in micelles/agglomerates, the special setup was developed [8,83–85]. The sample is filled into an NMR glass closed at the bottom with a PTFE-thread. T_2 experiments are performed at the original sample and afterward at the sample being washed with D_2O. Between sample and thread is a filter membrane. The mobile free water in the sample is substituted by D_2O non-detectable by ^{1}H NMR. Exchange processes between water and OH/NH/SH groups are neglected. Thus, with the help of the washout test, immobilized, retained free and mobile free water can be distinguished. The fraction of water/serum that contributes to phase-separation phenomena like syneresis possibly correlates with the phase distribution and the amount of the water, which can be washed out. If the water content is known, it is possible to define the WHC (physically/chemically bound plus water retained in pores) with the fraction p_r of washable water

$$\mathrm{WHC}_{\mathrm{NMR}} = \frac{m_{\mathrm{Wnw}}}{m_{\mathrm{S}}} = \frac{m_{\mathrm{Wnw}}}{m_{\mathrm{W}}}\frac{m_{\mathrm{W}}}{m_{\mathrm{S}}} = p_r F, \qquad (7)$$

where m_{Wnw} is the mass of non-washable water, m_{W} the total mass of water, m_{S} the dry mass, p_r the $m_{\mathrm{Wnw}}/m_{\mathrm{W}}$, averaged over all phases, and F the water content of a gel (w/w). It is remarkable that not only water of the phase with the highest mobility, but also of phases with reduced mobility (T_2) is washable. This means that the molecular mobility characterized by T_2 and the washability (Equation 7) are different, but complementary characteristic gel features. The washout test was used to study the influence of the recipe and processing on the evolution of the WHC and p_r of yoghurts (fermented in glasses or cut out) [31].

Hydrocolloids

Hydrocolloids are used (e.g. jellied and dairy products, cocoa, ice-cream, marmalade, sausages, convenience food) as thickeners, gelling agents, or stabilizers. It is to incorporate water into foods (higher yield and lower fat content). Many functional properties of proteins in foods are attributed to interactions with water and other food constituents [79]. Many hydrocolloids exhibit hysteresis of their TD-NMR or rheological parameters for cyclic temperature variations [31,86,87] and a strong pH dependence [88]. Polymer networks are usually thermoreversible due to the H-bridges breaking up at sufficiently high temperatures. The influence of temperature and gelatine concentration on the structure of gelatine solutions was studied with T_1 [89] and T_2 [90]. The water relaxation in biopolymer systems was modeled assuming proton exchange cross-relaxation [91,92]. The mean T_2 relaxation times in gelatine systems increases dramatically at the temperature-induced sol/gel transition. Chemical/diffusive exchange in water/gelatine systems was studied by variation of the CPMG pulse spacing [93]. ^{1}H and ^{23}Na NMR (T_1, T_2) enable one to differentiate up to four water phases in aqueous gelatine gels [94,95]. Properties of starch relevant for food technology are the swelling (temperature, moisture: ^{1}H: T_1, T_2; ^{2}H: T_1, T_2, spectra [96,97]), plastisication/gelatinization (^{1}H T_2, ^{2}H spectra [98]), the degree of polymerization, glass transitions (T_1, T_2, spectra [99]), retrogradation (T_1, T_2 [100]), conformations of dissolved starch molecules like multiple/double-helices or eggbox [86], fraction of crystallinity (CP-MAS [101], ^{13}C [66]), the ratio of amylose/amylopectin [102], water content (T_1, T_2 [89,99,103]), ^{2}H spectra [104], and storage behavior (T_2, MRI [105]). After a heat treatment the carrageenan molecules reveal a disordered coil form. When reducing the temperature, the conformation of κ- and ι-carrageenan changes to ordered helical structure (e.g. double-helices) and aggregates of helices coupled to gelation [87]. Various parameters [concentration, temperature, type (T_1, T_2 [86,89]), molecular mass (^{1}H spectra [105]), composition of carrageenan molecules (κ-, ι-units: ^{1}H, ^{13}C spectra [107]), ionic type/content [87]/composition [108]] have a strong impact on macroscopic (texture, flow/sensorial behavior, sol–gel transition) and microscopic properties (T_1, T_2, spectra). Gelling (hysteresis) and only viscosity-increasing carrageenan types (λ) are differentiable by the temperature dependence of the $T_{2,i}$ and d_i [8,31]. This provides a deeper insight into the microstructure than $T_{2\mathrm{m}}$ alone [86]. $T_{2\mathrm{m}}$ for the solutions correlates with their voluminosity (i.e. immobilized water). The voluminosity in gels is not determinable with rheology yet.

Ad (b): Correlations

The motivation to derive correlations between NMR and material properties is that these correlations are ideal to determine industrially relevant quantities (material process parameters) by partly methodologically/apparatively more comfortable, non-destructive, often less time-consuming and on-line capable NMR methods (no trace analysis). This is a necessary prerequisite for an effective process/quality control [109–112]. Continuous- and stop-flow process NMR spectroscopy are realized [113]. The continuous-flow requires usually premagnetization for a complete polarization of the sample. The sensor is integrated into a pipe, belts, or chutes. Applications are the monitoring of the fermentation (yoghurts) [83], mashing [46], and cooking (rice species, shelling/polishing process: Götz *et al.*, 2004).

Besides D_S determined by PFG NMR, relaxation times are another independent approach to characterize the gel structure and to study the dynamics of de-/hydration of fluids. The relaxation times of fluids in gels (partial/completely saturated) are generally reduced compared to the free and bulk fluid due to interactions between liquid molecules and the liquid–solid interface. In many cases, a simple two-site model is used to interpret the observed enhanced relaxation rates in gels [48,53,114], partly a homogeneous water layer is assumed at the solid surface [24,115]. A practicable approach based on T_1 is the assumption of rapid exchange of liquid molecules between (i) the zone at the solid surface (interactions between the liquid and the solid material), and (ii) the molecules in the bulk. The change of T_1 (porous medium) compared to $T_{1\mathrm{f}}$ in the bulk phase is used to derive the fraction f of the fluid interacting with the solid. In order to characterize the density of reactive surface sites in a fluid-saturated porous system, the influence of ion concentrations from different salts on T_1 was measured [28]. Fluid molecules near solid walls are exposed to relaxation mechanisms different from those in the bulk fluid. Various models have been developed to derive pore size distributions from relaxation measurements. Due to the complex interactions, formalisms generally valid for all porous media have not been developed yet [116]. In spite of these ambiguities, relaxation measurements enable one to characterize individual pore systems. Based on a two-site model, the mean relaxation time T_1 is related to the pore radius $r_\mathrm{p} = 2V/S$. Thus, it is possible to derive the pore size distribution from the T_1 frequency distribution [118–120]. If the gel structures do not significantly alter in the temperature regime above and below the freezing phase transition of the fluid, measurements are performed at temperatures above and below the freezing phase transition. While the bulk fluid is frozen, a non-frozen fluid layer exists at the solid surface due to the different and often incommensurable crystal structures of the fluid adsorbate and the surface structure. The fluid molecules in the adsorbed layer are, even in the frozen state of the bulk fluid, surprisingly mobile (translationally along the surface).

In order to obtain information concerning the size distribution of crystallites in frozen gels the size distribution of pores in freeze-dried starchgels was determined by T_2

relaxometry using acetone (no matrix collapse) instead of water [121,122]. Besides the possibility to calculate the gel permeability (T, S/V) [23,28,123] with empirical models (permeability porosity ϕ) [124], permeabilities by correlating T_1, T_2, $T_{1\rho}$, D_S, and ϕ are derived [125]. Further correlations between macroscopic properties (water activity, microbial stability/shelf-life, solution-rate of spray-dried powders, caking behavior of powders, drug release in proteineous matrices, and sensory texture) or capillary/pressure curves and NMR data are given in Ref. [8].

NMR Relaxation and Diffusion Studies of Horticultural Products

B.P. Hills

Institute of Food Research, Norwich Research Park, Colney, Norwich NR4 7UA,UK

Introduction

The importance of the worldwide production of fruit and vegetables both for human health and as an economic force should not be underestimated. In the United States alone, the fruit and vegetable industry generates over $6 billion in income annually. Much research effort is aimed at maximizing production by optimizing the factors affecting growth in the field such as irrigation, nutrients, and harvesting times as well as finding optimum storage conditions, especially for fruit kept in long-term storage for export and/or off-season marketing. It also involves finding the best ways to sort and grade fruit coming out of storage which means developing non-invasive sensors of fruit and vegetable quality.

Because it is non-invasive, NMR has been widely used to research each of these stages. High-resolution NMR spectroscopy and imaging have been used to study physiological changes during plant growth, development, and storage and these aspects have been reviewed [1]. MRI has also been used to monitor water transport during preservation processes such as drying and freezing and examples of this work can be found in Refs. [2–4]. However, the main focus of this chapter will be the correlation between proton NMR relaxometry and diffusometry and fruit and vegetable quality. As we shall see, these NMR techniques are especially sensitive to the (sub)-cellular compartmentation of water and this is affected by physiological changes during ripening and storage and also holds promise for the development of non-invasive NMR sensors during the sorting and grading stage. We therefore begin by reviewing the relationship between NMR water proton relaxometry and diffusometry and cell tissue structure.

NMR Relaxation and Water Compartmentation

In the absence of paramagnetic ions, there are three main phenomena that affect water proton relaxation in plant tissue, namely,

(a) Fast proton exchange on a (sub-)millisecond timescale between water and exchangeable protons on cell metabolites, especially sugars and biopolymers, including the cell wall biopolymers and starch granules.
(b) Dephasing of transverse magnetization by the diffusion of water molecules through internal field gradients created by magnetic susceptibility discontinuities in the tissue, especially across the interface of inter-cellular air gaps. This effect is especially important at high field strengths when gradients are largest.
(c) Diffusion of water between the various subcellular (vacuolar, cytoplasmic) and extra-cellular water compartments which averages the magnetization to an extent that depends on cell morphology and membrane permeability.

The fact that plant cells are compartmentalized means that, in general, the transverse and longitudinal relaxation are multiple exponential. Moreover, if transverse relaxation occurs by the proton exchange and internal field gradient mechanisms then, in general, the observed CPMG transverse relaxation behavior depends on the field strength and the CPMG pulse spacing. However, relating the NMR data to factors such as organelle size and membrane permeability is far from straightforward though a start has been made by combining the proton exchange model [5] with a simplified spherical cell model of a plant cell [6]. This has proved useful in fitting the changing relaxation data during the drying and freezing of apple [7], carrot [8], and potato [9] parenchyma tissue. In principle, the same theoretical approach could be used to model the changes in relaxation behavior observed as plant tissue ripens, though this has yet to be attempted.

The potential of multi-dimensional relaxation experiments for exploring the relationship between water compartmentation and fruit/vegetable quality has only just begun to be explored. Figure 1 shows the T_1–T_2 cross-correlation spectrum for parenchyma tissue of fresh red delicious apple. The dependence of the peak positions and intensities on physiological conditions such as mealiness are being researched in the authors laboratory and hold considerable promise [10].

Given the likelihood that online NMR sensors will be based on low rather than high field strengths it is

Graham A. Webb (ed.), Modern Magnetic Resonance, 1721–1727.

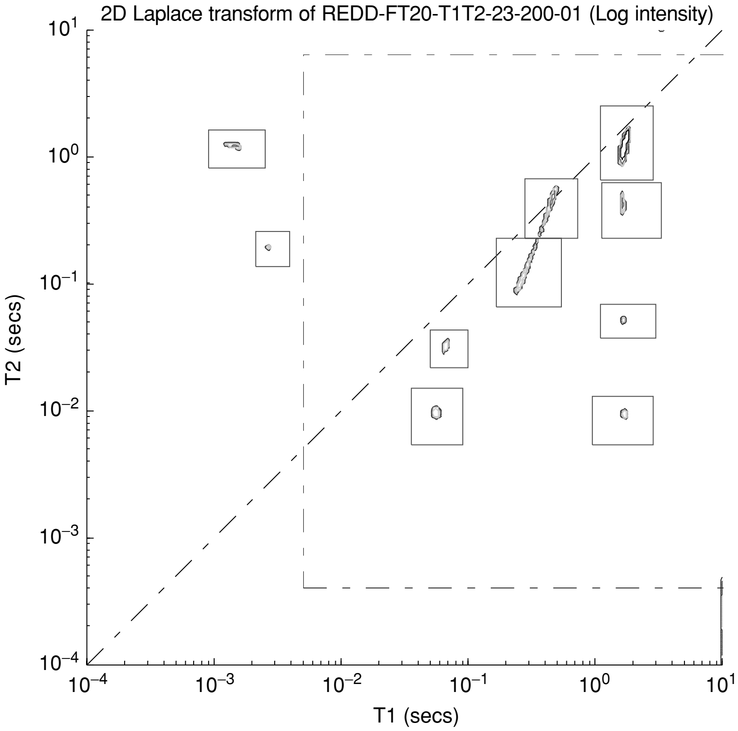
Fig. 1. A typical T_1–T_2 correlation spectrum of parenchyma tissue of red delicious apple acquired at room temperature at 23 MHz with a CPMG pulse spacing of 200 μs. The diagonal line denotes $T_1 = T_2$. The vertical and horizontal dot-dashed lines denote the limits of reliability based on the acquisition parameters.



surprising that so little field cycling relaxometry has been reported for plant tissue. The dependence of the longitudinal relaxation time on field strength gives a direct handle on the spectral densities describing molecular mobility in the tissue, data that could provide a useful test of the numerical cell model. It would be especially useful to see how the spectral densities change during tissue breakdown for conditions such as mealiness and chilling injury.

Although correlations between relaxation and quality naturally focus on simple T_2 and T_1 measurements, it should not be forgotten that these are not the only types of relaxation that can be studied. Relaxation in the rotating frame, characterized by $T_{1\rho}$, is another potentially valuable handle on tissue quality and this, in general, depends on the strength of the spin-locking field and the spin-locking angle. Possible correlations between cross-polarization rates and quality factors are an additional aspect that appears to have been overlooked, yet image contrast based on cross relaxation is an important diagnostic tool in clinical imaging and therefore, potentially, in plant imaging. In this context, cross relaxation refers to the transfer of longitudinal proton magnetization between water and more rigid biopolymers in the plant tissue matrix. These rates can be measured by sequences such as those of Goldman and Shen [11].

NMR Diffusometry and Water Compartmentation

In contrast to water proton relaxation, there have been very few attempts to correlate water diffusivity in cellular tissue as measured with PGSE sequences to plant quality factors. An exception is the early work of Keener *et al.* [12] who found a useful correlation between the apparent water diffusion coefficient and apple maturity as measured by the refractometer Brix value. The paucity of work on water diffusivity is surprising because the restriction of water diffusion by cell membrane and cell wall barriers is a useful and sensitive probe of changes in cell morphology. The potential of PGSE studies of cellular tissue was illustrated by Hills and Snaar in their studies of fresh parenchyma apple tissue [6]. In a PGSE, Stejskal–Tanner experiment the echo amplitude, $S(q, \Delta, \tau)$ is a function of both the echo time, 2τ, the diffusion time, Δ, defined as the time between gradient pulses and the wave vector, q, defined as the area of the gradient pulse, $\gamma G\delta/2\pi$. For

Table 1: Comparison of theoretical and experimental p_i and a_i in Equation (1) for apple parenchyma tissue

i	a_i (experimental)	a_i (theory)	p_i (experimental)	p_i (theory)
1	0.292	0.302	0.78	0.80
2	0.032	0.044	0.13	0.10
3	0.007	0.017	0.09	0.10

variation of Δ at fixed τ we can write

$$S(q, \Delta, \tau) = \Sigma_i\, p_i(q, \tau) \exp(-\Delta/a_i(q, \tau)), \qquad (1)$$

where the $a_i(q, \tau)$ are generalized diffusion times and p_i are the associated fractional populations. Both these coefficients depend on the wave vector, q. In principle, these additional coefficients can be analyzed and related to quality factors in an analogous manner to the relaxation times discussed in the previous section, though no one has yet attempted to do this. Table 1 shows a comparison of the experimental coefficients for fresh apple tissue with those calculated with the numerical cell model. The agreement is quite reasonable and supports the general theoretical framework. It would be interesting to apply this approach to mealy apple and to other types of fruit and vegetable.

Quite clearly there remains a great deal of basic NMR and modeling work to be done before we can claim to understand the relaxation and diffusion behavior of horticultural products. The next section surveys the literature up to 2004 with no claim to completeness.

Fruit and Vegetable Quality

The literature to the end of 1999 relating to internal defects and storage disorders has been summarized by Clark *et al.* [1] and Koizumi *et al.* [13]. The more recent literature to 2003 has been reviewed by Hills and Clark [14]. The types of **product studied and the quality disorders investigated are summarized in Table 2. Space does not permit each product in Table 2 to be discussed in detail, so we illustrate the NMR-quality correlations for the most intensively studied examples, namely apple and potato.

Apple Maturity

Up to three peaks have been reported in the distribution of water proton transverse relaxation times in parenchyma apple tissue measured with the CPMG sequence with a short 90–180° pulse spacing at 2.3 T (100 MHz) [7]. These peaks have been assigned to vacuolar water and water associated with cytoplasm and cell wall. The effect of freezing and drying on this relaxation time spectrum has been modeled with a numerical cell model with moderate success.

Keener *et al.* [12] have investigated the relationship between low-field (0.13 T; 5.4 MHz) apparent water proton diffusion coefficients (D_w), the dominant CPMG T_2 measured with a pulse spacing of 2 ms, and degree of ripeness (soluble solids content) as measured by refractometry. The following trends were reported:

(a) In healthy "Golden Delicious" and "Granny Smith" apples, the T_2 decreased with increasing soluble solid content (Brix) in healthy apples.
(b) The water diffusivity decreased with increasing soluble solid content in all samples, both bruised and healthy. This is no doubt a result of the increasing viscosity of more concentrated sugar solutions.
(c) Internal defects caused by bruising, watercore, and internal browning resulted in a decrease in T_2 in all varieties at this low field strength. It remains to be seen whether T_1 also shows useful correlations with soluble solids and internal defects.

Cho *et al.* [15] reported that the amplitude of the sugar proton peak following water suppression with a T_1 null sequence correlated well with the sugar content in apples (as well as banana and muskmelon). This exploited the observation that the T_1 of exchangeable water protons was at least twice as long as that of the non-exchanging sugar protons, so a simple inversion recovery sequence with a delay time chosen to null the water signal, leaves a substantial positive sugar proton signal.

Apple Bruises

A combination of spin-echo and gradient reversed echo imaging in a high field magnet at 1.4 T, showed that the redistribution of intra- and extra-cellular water arising from cell and membrane damage in the bruised region actually results in a decrease in the mean transverse relaxation rate, T_2, as measured by the CPMG sequence [16]. This established that the enhanced image intensity observed for bruised tissue with high-field MRI could not be a result of intrinsic T_2 changes. Instead, the enhanced brightness results from a reduction in the signal attenuation arising from water diffusing through internal magnetic field

Table 2: Summary of references to NMR studies of quality factors in the major types of fruit and vegetables

				Heat and chill injury

gradients created by the magnetic susceptibility difference between air in extra-cellular spaces and cellular fluid. This is an important observation because the effect of internal gradients on the effective relaxation rate is expected to vary as the square of the applied field as well as on the pulse spacing. Reducing the field strength to say 0.14 T (a proton frequency of ca. 6 MHz) would be expected to reduce the effect of the internal gradients on the relaxation rate by at least two orders of magnitude so that bruises in a low-field imaging system could actually appear with lower rather than higher intensity. This prediction remains to be investigated but highlights the importance of repeating the NMR-internal quality correlations over a range of frequencies, especially the low-field range.

Internal Browning Disorders in Apples

Internal browning disorder manifests itself as light and dark brown patches throughout the cortex and core. The disorder is induced by high CO_2 concentrations, especially during storage in modified atmospheres, but can also appear in unpicked fruit on the tree. As its name implies, the brown patches are not visible from the outside but give contrast in MRI. The light brown regions have a lower signal intensity than normal tissue because of a reduced proton density and a shorter T_2. Dark brown regions have higher intensity than normal tissue because of a longer T_2 [17].

Watercore in Apples

In normal apple tissue, the inter-cellular spaces are ordinarily filled with air. However, in watercore-affected tissue, the air is replaced by a sorbitol solution giving the cut tissue a translucent watery appearance. Watercore is also associated with elevated water content and decreased reducing sugars. The disorder mostly occurs late in the growing season in over-mature unpicked fruit and cannot be visibly detected in the intact fruit. The higher water proton density in the affected tissue gives a higher MRI image intensity, allowing watercore to be readily identified [18].

Mealiness in apples

Mealiness in apples results from a breakdown in adhesion between cells so that chewing the apple tissue results in cell separation rather than cell rupture. Eating a mealy apple is therefore associated with the unpleasant sensory perception of a lack of juiciness, loss of crispness, and hardness. The first significant correlations between NMR measurements and mealiness were reported by Barreiro *et al.* [19,20], who found that the histogram of T_2 values (i.e. the number of pixels having a particular T_2) for mealy apples was skewed to shorter relaxation times with a significant tail located in the maximum T_2 range. In contrast, non-mealy apples had normal, non-skewed T_2 histograms. More recently, increasing mealiness has been shown to cause a systematic reduction in the non-spatially resolved CPMG-T_2 values undertaken at the slightly lower field of 2.32 T [21].

Potato

Most NMR studies of potato have focused on understanding the effects of processes such as boiling, frying, freezing, and drying [9,22,23]. Exceptions are the NMR microimaging of healthy and diseased potato tubers reported by Goodman and co-workers [24–26] and relaxation changes in healthy tubers following induced wounding. Most recently, a number of papers have appeared where NMR relaxometry on raw potato has been used to predict the sensory texture after boiling [27–29]. It is therefore surprising that, despite the importance of potato, there are so few published studies where NMR/MRI has been used to detect internal quality defects in raw tubers. Such internal defects include brown core and hollow heart. Using multi-slice spin-echo imaging, Wang *et al.* [30] have demonstrated that both brown core and hollow heart can be detected by MRI. Brown core, a physiological disorder of potato characterized by medulla tissues in the center of the tuber turning from light- to dark-brown in color, is associated with loss of membrane structures, cytoplasm, and organelles and a thickening of cell walls that results in the affected tissue having a longer T_2 relaxation time. It is therefore recognizable by high signal intensity in scans with long echo times. The "hollow heart" condition results from cells in the pith area of the tuber splitting apart to form star- or lens-shaped air-filled cavities near the center of the tuber. The hollow heart condition is therefore distinguished by the absence of signal in images or one-dimensional profiles.

Another quality defect which is adversely affecting the marketing of potato products has been termed the hardening syndrome. Here, internal lumps form inside the potato during cooking. While a number of biochemical and physiological investigations are underway to try to understand the origins of this syndrome it remains to be seen whether NMR studies on the raw potato can identify regions likely to form internal lumps.

Conclusions

Although Table 2 shows that many diverse quality factors in fruit and vegetables can be detected with NMR it is also clear that a great deal of fundamental NMR remains to be done. Apple is one of the most intensively studied fruit, yet we find no reports on field cycling relaxometry, no attempts to measure cross-relaxation rates or $T_{1\rho}$, and no systematic investigation of water diffusivity in relation to physiological defects such as mealiness. Little work has been done to correlate PGSE measurements of the restriction of water diffusivity to quality factors. The gaps in Table 2 also emphasize the extent of the more applied work that remains to be done before NMR sensors can be applied to all these diverse types of fruit and vegetable.

Very few of the references in Table 2 attempt any quantitative modeling of their NMR data in terms of cell microstructure or composition. Such models would be extremely useful in choosing the optimum acquisition pulse sequences and for rationalizing differences between sample varieties and the effects of harvesting times and storage conditions. The numerical cell model is a first step in this direction but more realistic cell morphologies could be tackled with finite element and Monte Carlo numerical methods.

As mentioned in the introduction, many of the reports cited in this review have been based on measurements made with superconducting magnets at relatively high spectrometer fields. Unless there is a major breakthrough such as high temperature superconductivity, these high field magnets are unlikely to be used in NMR sensors for sorting and grading. There is therefore a need to repeat many of the measurements at much lower fields (<0.5 T) appropriate to permanent and resistive magnet technology.

Proton NMR Relaxometry in Meat Science

Hanne Christine Bertram and Henrik Jørgen Andersen
Department of Food Science, Danish Institute of Agricultural Sciences, P.O. Box 50, DK-8830 Tjele, Denmark

Introduction

The main constituents of muscle and meat are water, protein, and fats, which represent approximately 75%, 18–20%, and 2–5%, respectively. Lean meat content and water-holding capacity (WHC) are of high interest to the meat industry as these are directly reflected in the payment of meat carcasses and the economic value of the meat during storage and further processing. Moreover, WHC and especially the distribution of the water within the meat are known to affect the sensory properties and the shelf life of meat. Consequently, measurement of lean meat content, WHC and water distribution in meat, and an understanding of intrinsic factors (e.g. species, genotype, muscle type), and technological processes (e.g. slaughter procedure, cooling regime, storage, processing) on water characteristics within the meat are of major importance for the meat industry. Especially non-invasive and non-destructive measuring techniques are demanded by the industry to control these important quality parameters.

^{1}H low-field nuclear magnetic resonance (NMR relaxometry) being a non-invasive and non-destructive measuring technique is a potential technique that might be a future quality control tool in the meat industry, as it has been demonstrated a cheap, robust and rapid method to measure fat content, solid/liquid ratios, and water-holding characteristics in many foods.

In common low-field NMR studies, only the contribution from protons of mobile compounds, i.e. water and fat is "visualized." Both longitudinal relaxation (T_1) and transverse relaxation (T_2) have been used to characterize meats, for reviews see [1,2], with T_1 being most successful in fat determination and T_2 being most successful in characterization of water mobility and distribution. Below is given the most successful applications of ^{1}H NMR relaxometry within meat science together with future perspectives of the methodology within the area.

Determination of Fat Content in Meat and Meat Products Using NMR Relaxometry

NMR relaxometry has been applied for determination of fat content in meat and meat products. Using the inversion recovery method, correlations between the amplitude of a T_1 population and fat content in minced meat and meat emulsions determined by chemical analyses have been demonstrated [3]. Fat content in minced meat has also been determined by a low-field ^{1}H NMR application where pulsed field gradients were included to suppress the water proton signal, which resulted in very high correlations to fat determinations by extraction [4].

T_2 Relaxation in Meat

It was early recognized that the T_2 relaxation in muscle and meat is non-mono-exponential [5–11]. Often the non-mono-exponentiality of the T_2 relaxation in muscle and meat has been solved by decomposing the relaxation decay into two exponential components [12–17]. The two relaxation components (water populations) are characterized by a time constant around 35–50 ms representing approximately 80–95% of the relaxation, and a time constant around 100–250 ms, representing approximately 5–15% of the relaxation, respectively. These two relaxation components have been suggested to reflect slow exchange of water between intra- and extra-cellular water pools, respectively, and were initially ascribed to intra- and extra-cellular water [6,8,9,15], as a correlation between the slowest relaxing time constant and the distance between fiber bundles was demonstrated [15]. However, studies attempting to verify or disprove this intra/extracellular model by characterization of relaxometry characteristics after cell membrane disruption in muscle and meats [18,19] or disruption of the overall structures by homogenization [9,19,20] have all failed to show altered relaxation behavior. This implies that intact cell membranes acting as barriers cannot alone explain the non-mono-exponential T_2 relaxation in muscle tissues. Homogenization of muscle tissue has been found to decrease the fraction of the slowest component together with a minor decrease in the relaxation rate of the fastest component [20] or give rise to a clear shift towards more mono-exponential relaxation with a time constant intermediate between the two relaxation components observed in intact tissue [9,19]. Consequently, the degree of disintegration of the overall structural organization is directly reflected in T_2 characteristics of the major relaxation component around 35–50 ms and the slower relaxing component

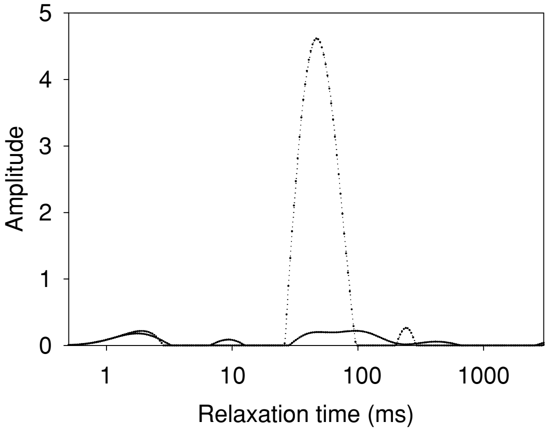

Fig. 1. Distributed T_2 relaxation times measured in a fresh pork sample (dotted line), and upon freeze-drying and rehydration with D_2O (solid line). The T_2 relaxation measurements were performed with a resonance frequency for protons of 23 MHz. The distributed exponential fitting analysis was performed according to the regularization algorithm by Butler *et al.* [45] and carried out in MatLab version 6.5 using in-house scripts.

around 100–250 ms. Thus the major water component, characterized by a time constant of approximately 35–50 ms and accounting for 80–95% of the relaxation, represents water trapped within the protein-dense myofibrillar network, while the slowest water component, characterized by a time constant between 100–250 ms and accounting for 5–15% of the relaxation, represents water located outside the myofibrillar protein network, i.e. extra-myofibrillar water.

Three-exponential decomposition of the T_2 relaxation decay gives rise to an additional fast relaxing component (water population) with a time constant between 0 and 10 ms representing about 5% of the relaxation [6,8]. Introduction of distributed exponential fitting of the T_2 relaxation decay [21] supports the presence of three relaxation components in meats with the fastest component having relaxation times around 2–6 ms [20,22–27]. Figure 1 displays the distributed T_2 relaxation times measured in a pork sample before and after replacement of the myowater with deuterium oxide (D_2O being ^{1}H NMR silent). Noticeably, upon replacement of the myowater with D_2O the major water component and the slower relaxing water component almost disappear while the fast component with relaxation times 2–6 ms is unaffected. This implies that the fast relaxation population represents protons not susceptible to exchange, i.e. hydration water. The existence of the third fast relaxing water component in meat is still a matter of dispute.

Water-Holding Capacity

Traditionally the water characteristics of meat are determined by invasive gravimetric methods [28,29] that not always reflect the water characteristics during storage and processing. Renou *et al.* [12] were the first to report that T_1 and T_2 relaxation characteristics of meat correlated with traditional meat quality traits in pork, and that the proton relaxation contains information about the WHC of meat. Subsequently, several studies have confirmed the findings by Renou *et al.* [12] and revealed that especially T_2 relaxation in meat is highly correlated with WHC measured by traditional gravimetrically methods. Correlation coefficients between WHC determined gravimetrically and T_2 relaxation variables of $r = 0.6$–0.8 have been found [15–17,30]. Considering the relatively poor repeatability of the gravimetric methods, these results must be considered promising in establishing NMR T_2 relaxation as a superior alternative to existing methods for determination of WHC in meat.

The physical rationale for a relationship between the T_2 relaxation in meat and WHC is that water expelled from the meat is directly reflected in a decrease in the amplitude of the slowest relaxing component (extra-myofibrillar water) [22].

Relaxometry Studies During Conversion of Muscle to Meat

Several characteristic physical and biochemical processes are taking place during the conversion of muscles to meat. These processes determine the subsequent meat quality development, and therefore a very great interest attaches to a basic understanding of the underlying mechanisms. The non-destructive nature of NMR relaxometry makes the technique an excellent tool in the investigation of continuous events taking place during conversion of muscle to meat. Thus by combining transverse relaxation, impedance (Py), and muscle contraction measurements during the early post mortem period in porcine *muscle longissimus dorsi* (pork loin) a fundamental understanding of water mobility and distribution, membrane properties, and physical events have been established [27] (Figure 2). The reorganization of water taking place post mortem is closely associated with membrane properties with the changes in the major relaxation component being directly dependent on the structural organization triggered through the *rigor* development, which is in agreement with a relationship between myofilament lattice spacing and transverse relaxation in pork [23]. In summary, a continuous NMR approach has not only been able to establish the reorganization of water in the muscles during conversion to meat, but has also demonstrated how the reorganization of water is related to physical processes taking

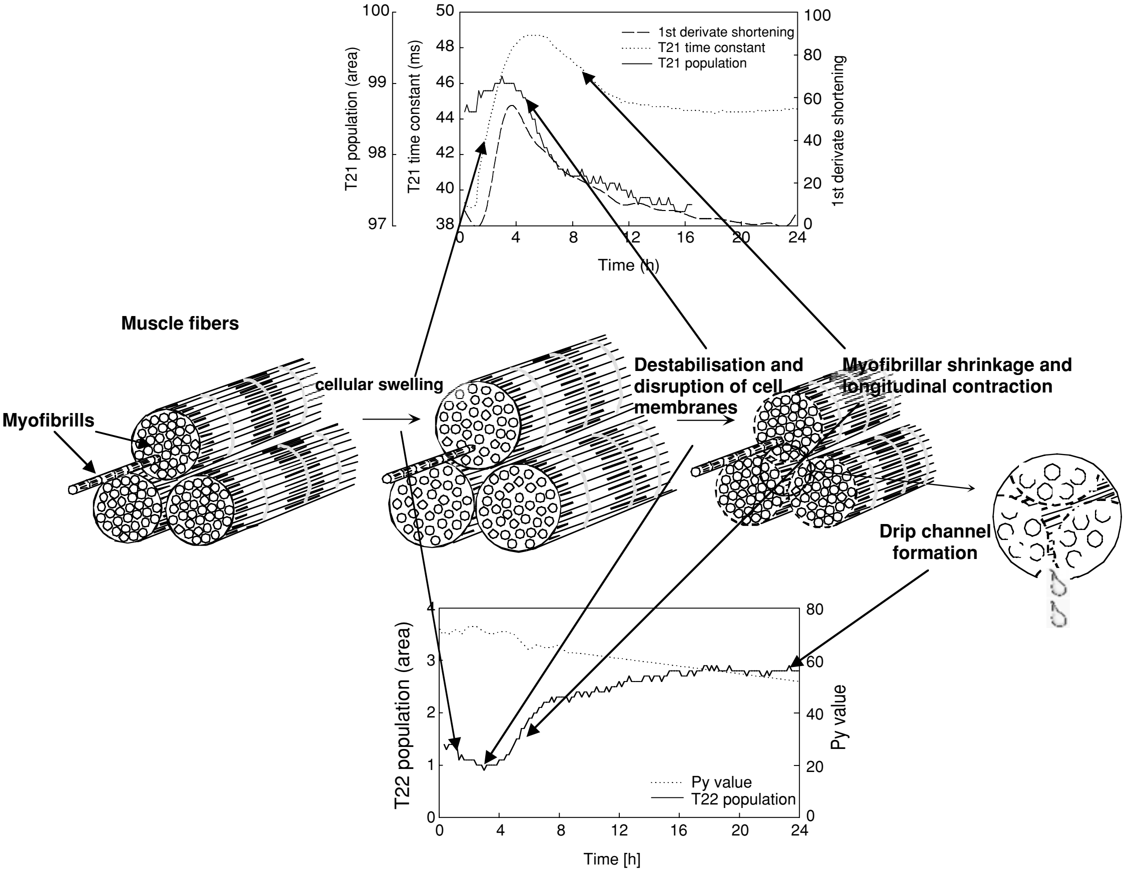

Fig. 2. Illustration of proposed mechanisms in the post mortem reorganization of muscle fluids and its relation to observed changes in the NMR T_{22} population. The initial event is a cellular swelling, caused by the increased intra-cellular osmolarity post mortem. At this stage the membrane structures are rendered almost intact resulting in increased intra-cellular water volume. Subsequent destabilization and disruption of membrane structures is initiated at a stage where the cellular homeostasis begins to debilitate. This initiates the second water redistribution phase where water will be expelled from the myofibrillar matrix by combined longitudinal contraction of the myofilament lattice due to the ongoing rigor process and lateral shrinkage in myofilament spacing due to falling pH, which forces intramyofibrillar water into the extra-cellular space where it becomes potential drip. Reprinted from Meat Science, Vol 66, Bertram, H.C., Schäfer, A., Rosenvold, K. & Andersen, H.J. Physical changes of significance for early post mortem water distribution in porcine M. longissimus, 915–924, 2004, with permission from Elsevier.

place post mortem, i.e. contraction and membrane destabilization, which have brought a novel and more basic understanding of principal mechanisms in the formation of drip from meat.

Transverse relaxation measurements have also made it possible to further elucidate the effects of cooling rates on water characteristics during the conversion of muscle to meat [26] showing that the T_2 populations depend on the structural organization of cellular water post mortem including membrane integrity, which both depend on the cooling rate. Moreover, using T_2 relaxometry on muscle with different energy levels (muscle glycogen and creatine phosphate concentrations) during its conversion to meat has revealed that the progression in the relaxation component reflecting intra-cellular/myofibrillar water is dependent on the pH progress post mortem [31]. Finally, the progress in post mortem pH in meat was by T_2 relaxometry found to influence the extent of the two major relaxation components with a fast pH fall giving rise to broader distributions of relaxation times of the individual water populations. This merges with the more heterogeneous structure found upon protein denaturation and triggered by a rapid pH fall [25].

The Carr-Purcell-Meiboom-Gill pulse sequence [32,33] is most often applied for T_2 relaxation measurements in meats. However, a multi-gradient CPMG pulse sequence where the CPMG sequence is combined with a ramped, external field gradient to include diffusive weighting to each relaxation time component has also been introduced [34,35]. This approach has recently been applied to investigate the significance of diffusive processes on a microscopic scale in muscles during conversion to meat [36]. The obtained data noticeably imply that both diffusion and relaxation contribute to the relaxation of the two water populations in meat. These preliminary data clearly demonstrate that combining NMR relaxometry with NMR diffusion measurements will be of interest to further elucidate the relationship between T_2 relaxation and diffusive motions in meats in the future.

Relaxometry Applied During Meat Processing

NMR relaxation measurements provide the possibility for a continuous study of the influence of cooking temperature on water characteristics within meat [37–40]. Thus applying T_2 measurements continuously over the entire cooking process suggest that the on-set of myosin denaturation taking place at 40–45°C gives rise to either expulsion of water from the myofibrillar lattice or formation of a porous myosin gel [39,40].

The effect of incorporation of additives such as gums or non-meat proteins into processed meats has only been studied by NMR relaxometry to a limited extent [41], and further attention to this area in the future is appreciated as the potential of an improved understanding of optimized water-binding in processed meats and meat batters is of great economic importance for the meat industry. Recently, NMR relaxometry was demonstrated to give information regarding structural changes and reorganization of water during frozen storage [42], which can be used in optimization of storage conditions and cooking procedures of pre-frozen meats.

Finally, NMR relaxometry has also been applied to predict technological parameters such as cooking loss, Napole Yield, and frying loss in meat [12,30,43,44]. Modest correlations have been reported, however, compared with alternative measurements in fresh meat, e.g. pH and WHC, T_2 relaxation has been shown to be superior [44].

Conclusions

Numerous applications of NMR relaxometry have been reported in meat science within recent years. The technique has proven successful in determination of fat content and WHC of meats. Because of the non-destructive character of NMR, the technique has been demonstrated to be an excellent tool for dynamic studies during conversion of muscle and has thereby successfully contributed to improve the basic knowledge about the on-going biochemical and biophysical post mortem processes of significance for subsequent meat quality development. An improved understanding of the origin of the observed relaxation behavior in muscle and meat has further strengthened the potential of NMR relaxometry. In relation to meat processing NMR can be expected to contribute increasingly within this area in future in the elucidation of dynamic changes during processing steps such as cooking, salting, marination, and freezer storage. In conclusion, NMR relaxometry has proven to provide valuable information about substantial meat quality attributes and the expected development within NMR mobile devices upon further development of the hardware will without doubt make on-line NMR relaxometry a reality within the meat industry in the near future.

Introduction

The classic application of time-domain (TD-)NMR in food science and industry are devoted to products containing either a dominating amount of water or fat with the aim to determine the concentration or the amount of a specific component. The analysis result is commonly the fat content, in some examples also the moisture content. This is due to the fact that in TD-NMR almost no spectral resolution is available and that the transverse and longitudinal NMR relaxation properties of fat and water molecules are not substantially different. Moreover, the selectivity in commonly known TD-NMR pulse sequences is too small to guarantee a clear separation of signals. The classical approach was to pre-dry the samples either for example by an oven, chemical reagents like $CuSO_4$ or *via* infrared or microwave drying processes. The disadvantage of the pre-drying is clearly that it is a time-consuming method requiring labor time and rendering the TD-NMR application a two-step approach. Therefore, more elaborate experiments have to be examined in order to address these application questions on food products. Due to the technical development of the TD-NMR spectrometer, especially of the electronic part in recent years, also more sophisticated experiments can be implemented and run for quality control in food science and industry. In this paper the physical background and selected examples of new applications will be shown.

Gradient Experiments

Fat and Water Content Determination

In parallel to the already discussed relaxation parameters, diffusion properties can be exploited by pulsed field gradient (PFG) experiments in order to separate signal contributions of different molecules. As an example, the diffusion coefficients of water and oil differ by about a factor of 100. A variety of PFG sequences is available, allowing dedicated approaches to the individual problem. As an example, the conventional Hahn Echo equipped with pulsed gradients and the PFG stimulated echo sequence are shown in Figure 1.

The key application—as discussed—is the determination of the fat/oil content in fresh food in the presence of a high water content. By adjusting the timing of the sequence properly, the contrast of the components to be differentiated can be optimized. In Figure 2 the echo attenuation of a fresh salmon sample is depicted as a function of the square of the gradient strength. The fast and slowly decaying components are due to water and oil on the time scale of this experiment, respectively. Extrapolation of the slowly decaying phase (solid line) to zero gradient strength provides a measure of the oil content. Calibration of the signal against known standards allows the determination of the relative oil or fat concentration. The calibration can be done very quickly and requires only few well-known reference samples for each type of product.

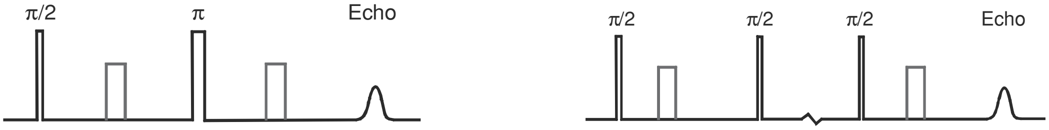

Fig. 1. PFG Hahn-Echo (left) and PFG stimulated echo PFG-STE (right) used in TD-NMR for discriminating components exhibiting different diffusion properties. Whether to use Hahn or stimulated echo depends on the relaxation and diffusion properties of the product to be investigated.

Graham A. Webb (ed.), Modern Magnetic Resonance, 1735–1738.
© 2008 *Springer.*

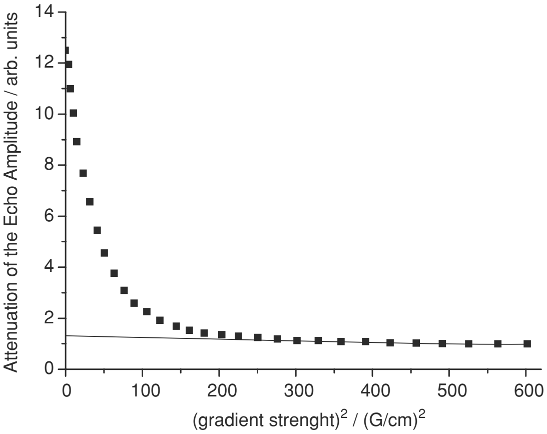

Fig. 2. Echo attenuation as function of the squared gradient strength measured on a fresh salmon sample. The diffusion coefficients of water and oil differ strongly such that at larger gradients only the oil signal is left. By extrapolating the oil signal to zero gradient strength, the oil or fat content can be determined [1].

Clearly, the PFG-NMR approach implies that the sample can be readily investigated without the need of predrying. The method was examined for different products such as sauces, mayonnaises, margarines, and dairy products with fat content in the range of 4–80%.

It should be pointed out that not only the simple Hahn echo pulse sequence with increment of the echo time as in Figure 2 can be applied. More elegant solutions make use of multi-echo sequences such as the CPMG (named after Carr, Purcell, Meiboom, and Gill [2]). In addition, destroying effects of eddy currents at small echo times can be avoided using static gradients.

A disadvantage of the method shown so far is that sample weight is required for determination of fat or oil concentration. This disadvantage can be circumvented by acquiring the FID directly after the dead time of the TD-NMR instrument and back-extrapolating the amplitude to time $t = 0$. This will lead to the total ^{1}H NMR signal that is proportional to weight of the sample. Thus, the overall one-step measurement time can be reduced to several 10 s.

Droplet Size Determination

In emulsions, a very important quantity and QC parameter in food science and industry is the distribution of droplet sizes. The droplet size of the dispersed component determines for example the microbial growth properties, eventually the product's shelf life, and the mouth feeling of the finished product. Examples of common food emulsions are mayonnaise for oil droplets, margarine for water droplets.

The physical background of droplet size distributions measured by PFG-STE NMR can be found in the restricted diffusion phenomenon. It was observed that the δ dependence (duration of the gradient pulses) of the transverse magnetization decay reflects the spatial restriction of the molecules under observation. The decay curves exhibit characteristic curvatures which can be described analytically and analyzed in terms of the geometrical dimensions [3]. Assuming a spherical geometry of the droplets and a log normal distribution of droplet sizes in the samples, an analytical expression can be found. Fitting to the NMR data reveals parameters like mean droplet diameter and width of the droplet size distribution. The analysis can be made volume related or related to the number of droplets.

Of course, either water signal in case of oil droplet or oil signal in case of water droplet has to be suppressed. This can be achieved for example by gradients or by an additional inversion pulse, respectively. In Figure 3, an example of a decay curve measured with a Bruker 20 MHz mq 20 minispec system and the corresponding droplet size distribution are shown.

Combined Relaxation Analysis in Foods with High Water Content

As already indicated, the knowledge of fat or oil and water content of products is of prime importance in food industry. It is well known that the transverse and also the longitudinal relaxation times of water and fat differ. The same is valid for several other ingredients as for example proteins. The relaxation properties of these components are exploited in the application discussed in this section. Clearly, as the differences in relaxation times are relatively small and as magnetization relaxation depends also on other parameters like temperature, salt concentration and the local environment of the molecules, a common measurement of well known relaxation times like T_1 and T_2 is not sufficient for establishing a good correlation to the sample properties. Therefore, a combined relaxation experiment is to be applied, where the magnetization at a given time is determined by both, the longitudinal and the transverse relaxation (Figure 4). There are several approaches to realize this aim. One of them uses a steady state dynamic equilibrium [4], others [5] make use of the longitudinal recovery of magnetization and measure the transverse magnetization at each point of the T_1 curve by CPMG. Using a modified sequence which also acquires the FID in addition to the echoes, "hard" components can also be measured and analyzed. Thus, the relaxation properties $T_1(M(t,T_2), M(t,T_2^*))$, $T_2(M(t,T_1))$, and $T_2^*(M(t,T_1))$ can be measured within one experiment. The information obtained by this experiment is huge and not easily analyzed quantitatively in terms of classic

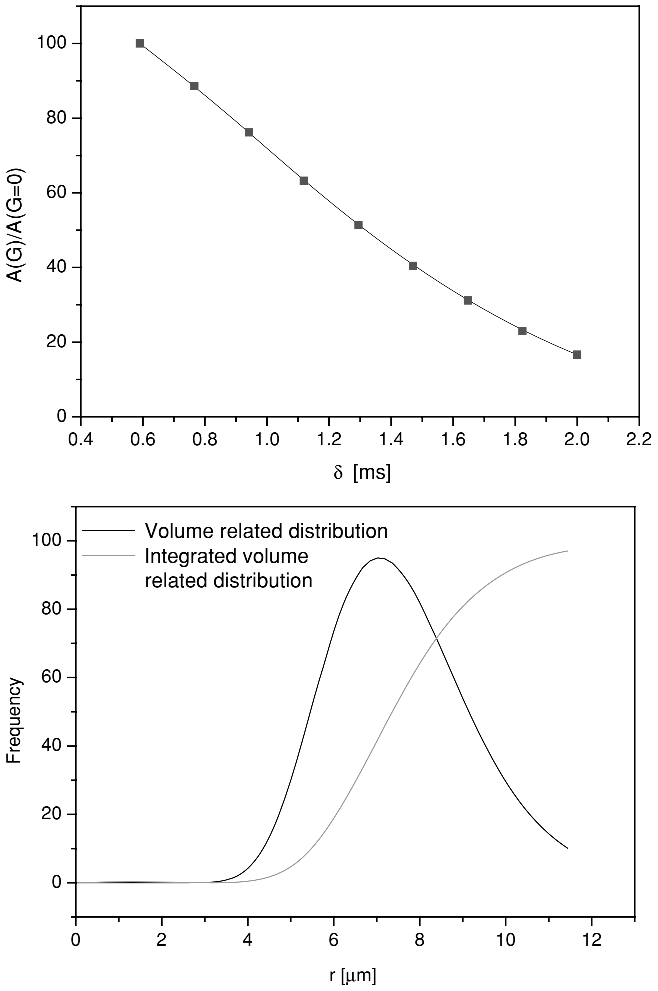

Fig. 3. Decay function A(G)/A(G = 0) and the corresponding droplet size distribution function as measured on an mq 20 minispec and analyzed via the minispec software.

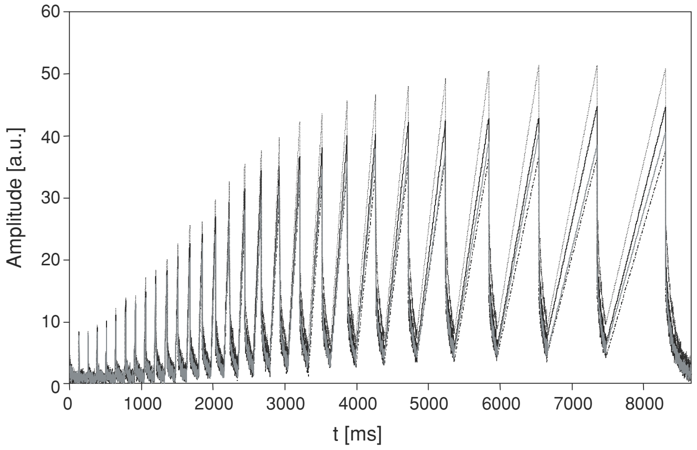

Fig. 4. Time dependence of the NMR signal measured by a combined relaxation time experiment. Four different samples each with a specific composition are shown. The differences in the time dependence due to the specific relaxation times are obvious.

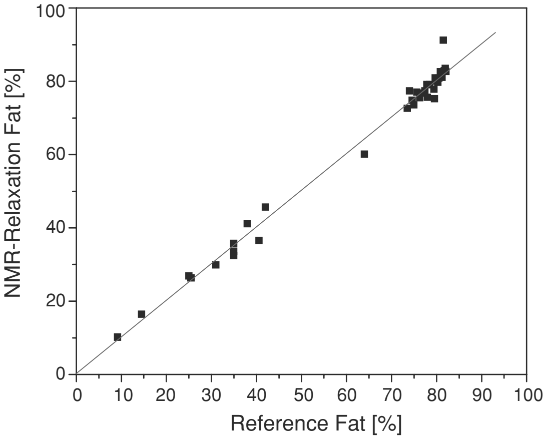

Fig. 5. Fat content as determined by the combined relaxation analysis for margarines, mayonnaises, and sauces. A clear correlation with the reference fat content could be established. The correlation coefficient amounts to 0.994, the statistic F-factor to 2814. The correlation considered 35 different samples with a fat content between 9.2 and 82.1%.

relaxation time analysis. Therefore, another approach was chosen for data processing, using statistical, i.e. chemometric methods [6]. These methods are commonly applied for example in near infrared studies. One of the advantages is, that a correlation with several sample properties can easily be established. As an example in Figure 5 the results of fat analysis on mayonnaises, margarines, and sauces being characterized by wet chemical methods are shown (samples from Unilever Bestfoods, the Netherlands). Please note that the three types of products fall onto the same calibration curve. This implies the possibility to establish a common calibration model which will be valid for several products thus reducing the effort which is usually necessary for chemometric data processing.

Conclusion

Two TD-NMR methods for content determination in wet foods were presented, namely the combined relaxation analysis and the PFG-NMR experiments. The experiments were discussed and typical measurement results were shown. In addition, a typical application of TD-NMR in food industry, the determination of droplet size distribution functions, was outlined. All measurements were performed with Bruker minispec instruments at 20 MHz.

Introduction

Although NMR is ubiquitously applied for chemical analysis and structural research as well as in its clinical adaptation of magnetic resonance imaging (MRI), its use in quality control/quality assurance (QC/QA) is often not very well known. It is this successful application field of NMR, which is dealt with in this contribution.

The field of QC/QA with pulsed NMR has started about 35 years ago in a cooperation of Unilever Research (The Netherlands) and Bruker Physik AG. The idea was raised to build a small table-top time-domain (TD)-NMR analyzer for the solid-to-liquid ratio analysis on fat compositions. The method based on the first TD-NMR analyzers has become an immediate success and was introduced in all major fat facilities world-widely. Nowadays, this method is widely adapted and well known as the so-called Solid Fat Content (SFC) determination [1]. It is recognized as an International Standard Method [2–4].

Presently, the pool of TD-NMR applications in the field of QC/QA summarizes more than 50 different procedures of which more than half are targeted towards food.

In this article, the following application fields will be addressed:

A) Determination of the SFC in fat compositions
B) Simultaneous oil and moisture determination in food (moisture content below approx. 15%)
C) Oil content determination in pre-dried olives

Time-Domain NMR (TD-NMR)

As TD-NMR experiments are either based on relaxometry or diffusiometry, i.e. on differences of the samples in their NMR-related properties, there is no need for highly homogenous magnetic fields or high field strengths as commonly required in FT-NMR. Thus, permanent magnet technology (typically at 10 or 20 MHz proton frequency) is well suited. This significantly reduces overall system costs as well as running costs (no cryogens required as in case of superconducting magnets). Moreover, right from the start, Bruker's TD-NMR instruments have been designed as bench-top systems with small footprint.

Most common TD-NMR applications are based on simple NMR pulse sequences, like the Free Induction Decay (FID) or the Hahn-echo acquisition [5]. TD-NMR systems can, however, also be used to measure relaxation time constants, like T_1, T_2, $T_{1\rho}$, or to perform pulsed field gradient (PFG-)NMR experiments (see also the accompanying article in this book "Time-Domain NMR in Quality Control: More Advanced Methods").

In order to apply the TD-NMR method to QC/QA, the NMR signal of interest (amplitudes or differences in the relaxation time constants) are correlated to the physico-chemical property of interest, i.e. the TD-NMR system is calibrated against reference values. For instance, the liquid and solid fat components differ in their respective relaxation behavior. Therefore, the FID signal of a mixture of both components typically also exhibits two components: a fast (solid fraction) and a slow (liquid fraction) decaying part. Sampling the signal amplitudes directly after pulse excitation and after the decay of the solid fraction provides a measure of the solid (liquid) fat content [6].

A. Determination of the SFC in Fat Compositions

As mentioned in the introduction, the SFC application is widely used. The SFC values of the fat composite are measured as function of temperature of the sample (Figure 1). This way, characteristic melting curves are gathered indicative of the fat composition. These melting curves are critical production parameters for the manufactures of fat compositions.

Different procedures and tempering schemes are described in the International Standard Methods [2–4]. The most important procedures will be introduced in the following.

Direct Method

The direct SFC method relies on a set of three calibration standard samples for instrument calibration. The FID

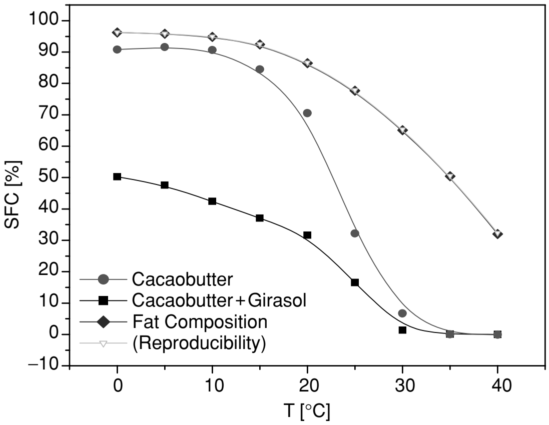

Fig. 1. SFC values determined using the serial method. Different food compositions are shown together with a reproducibility measurement.

pulse sequence is utilized for the acquisition. In order to obtain the SFC value at a particular temperature, correction factors (referred to as F-, K-, and O-factors) need to be applied (cf. Figure 2) which are determined from the calibration standard samples. After the FID acquisition, the amplitudes of two sampling windows are calculated. The so-called F-factor accounts for the instrument dead time (ca. 8 μs), and corrects the amplitude of the solid fraction; the K-factor accounts for the effect of signal decay due to magnet inhomogeneity. Finally, the O-factor accounts for possible signal offsets. In sum, the analysis of unknown samples is carried out by applying one single TD-NMR FID measurement followed by correction using the above described factors.

This method is applied as a QC tool to control the production of the fat compositions according to the desired properties. Regarding the tempering and sample handling procedures, two approaches are adapted (Figure 3), which do not necessarily provide the same SFC values.

Parallel Method

The parallel method uses at least one sample for each temperature. As a matter of fact, it's the fastest method to obtain the SFC values as a function of temperature. All samples are crystallized at once at 0 °C together (typically for 1 h). Subsequently, the tubes are distributed over the different water baths at the different temperatures. The TD-NMR measurement completes this parallel SFC method.

Serial Method

The serial method uses one sample, which encompasses all desired temperatures followed by the TD-NMR measurement. The sample is crystallized again at 0 °C and then inserted into the first water bath. After the tempering time has passed and the first NMR analysis has been

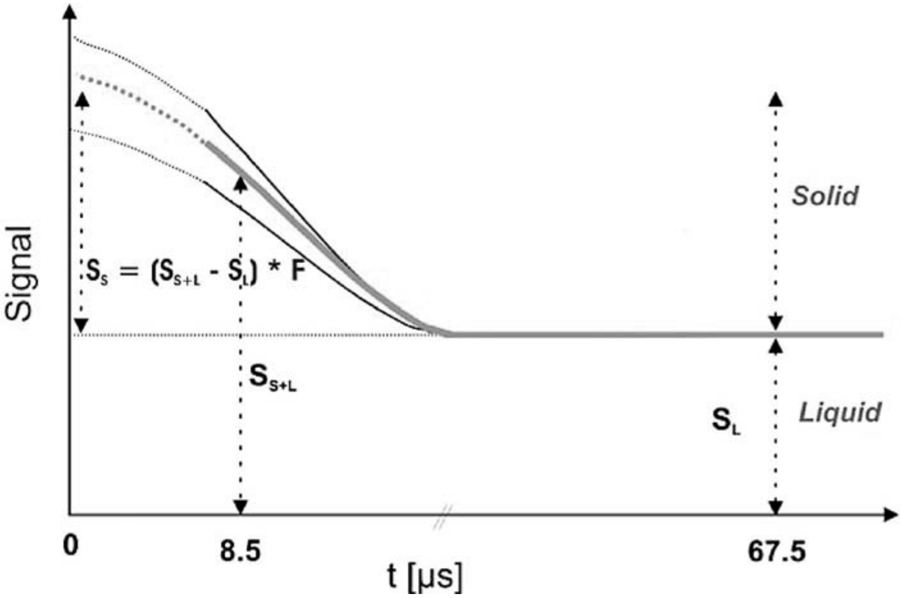

Fig. 2. Time scheme of the FID and its analysis in case of SFC determination.

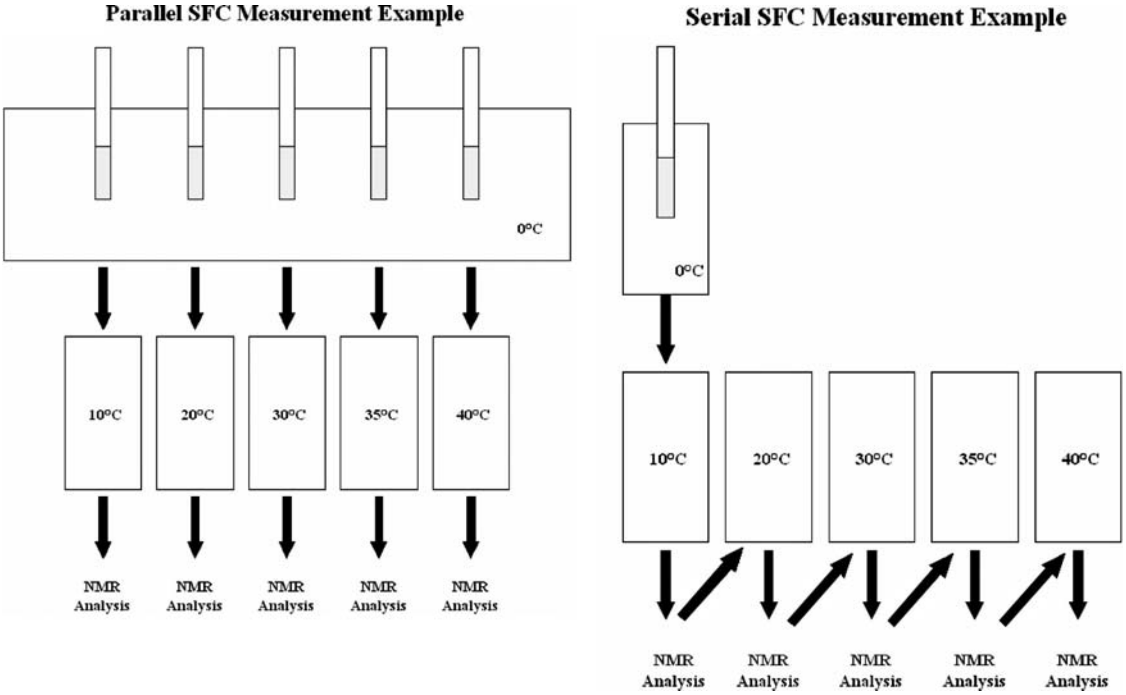

Fig. 3. Sample Handling of parallel (left) and serial SFC method (right).

performed, the same tube is directly inserted into the next bath with next measurement temperature and so on. This method has the advantage that less samples need to be prepared for a complete SFC determination.

Indirect Method

The direct method, which is well suited for QC, assumes that the average F-factor is the same for all samples. This is, strictly speaking, not correct. The so-called indirect SFC method overcomes this limitation, leading to the "correct" SFC values. This is required in research and development (R&D) of new fat compositions. The indirect method is based on a two step TD-NMR measurement: First, at the desired sample temperature, the liquid part of the NMR signal is measured while the sample is placed only within the homogenous region of the RF coil. Secondly, the sample is completely melted (typically at 60 °C) and measured again to obtain the NMR response of the totally melted sample. Both amplitudes are used to calculate the SFC result, taking into account the temperature-dependence of the NMR signal amplitudes. Clearly, no calibration standards are required for this approach.

Solid-Echo Method

Besides the direct and indirect SFC methods, the so-called solid-echo method is used in R&D environment for SFC determination [7]. Due to the nature of the solid-echo pulse sequence, both liquid and solid fractions of the sample contribute to the solid-echo amplitude. However, as in case of the direct method, calibration via calibration standard samples and correction factors is required.

Comparison with Dilatometry/Solid Fat Index

The NMR approach is well-established throughout the world. However, historically dilatometry has been applied, i.e. the change in the sample volume as a function of temperature is measured. The result of which is known as the Solid Fat Index (SFI).

From the TD-NMR SFC perspective, the dilatometry method has considerable drawbacks:

- Sample preparation is more demanding, for instance, the fat (composition) must be de-aerated and an indicator has to added (required for improved visualization).
- Samples containing some ingredients (might) react with indicator—SFI is not applicable for these samples.

- SFI does not work for fats that are higher in solids than about 80%.
- Dilatometry by virtue of the method is a serial method.

Moreover, it has been shown [8] that the TD-NMR/SFC approach is much more accurate. An increased accuracy of a factor of five has been reported. Note, since a chemical indicator is utilized, dilatometry has to be considered as a wet chemical method.

Automation of SFC Analysis

For ultimate accuracy and reproducibility combined with high sample throughout an SFC automation system is required. This is because the time interval for the tempering schemes have to be obeyed. For special fat compositions tempering time errors like few minutes lead to significant changes in the results, as the fat composition might be more or less crystallized. A few robot SFC systems (for instance, at Unilever Research, The Netherlands) with Bruker minispec TD-NMR analyzer are installed in the world.

B. Simultaneous Oil and Moisture Determination in Food (Moisture Content Below Approx. 15%)

Only few years after the introduction of the SFC method with TD-NMR, the application area of TD-NMR has been widened by applying the Hahn-echo NMR pulse sequence (Figure 4) to determined the total oil and moisture content in food samples. Almost all types of food samples could be analyzed providing the water content is minor (typically below 15%) [9], see Table 1. Again, the oil and moisture analyses for seeds and seed residues have become International Standards Methods [10–12]. According to these methods, both the FID signal amplitude, S_1, and the echo amplitude, S_2, are measured (see Figure 4). The amplitudes S_1 (at 50 μs following the 90° pulse) and S_2 (at $\tau = 7$ ms) represent the sum of the oil and moisture signals and the oil content, respectively. Thus, the amplitude difference, $S_1 - S_2$, is due to the moisture content.

The oil and moisture contents can be measured simultaneously with the system after primary calibration. The calibration is performed only once and will be automatically archived.

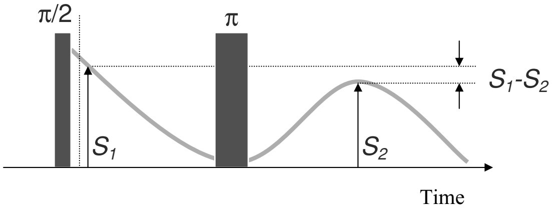

Fig. 4. Hahn-echo sequence and data processing for simultaneous determination of moisture and oil content in seeds.

Table 1: Applications of TD-NMR for determination of moisture and oil.

- Moisture and fat/oil content in (dry) food:
  - Cocoa powder, cocoa beans, and chocolate (mass and liquor)
  - Snacks, cereals, chips, brezel, fischli, bread
  - All types of nuts and almonds, cookies, beans, lentils, linseed
  - Milk Powders, bakery powders, baby food, low moisture cheese, soup powders
  - Flavors, flour, semolina, starch, sugar beet
- Moisture/oil in all types of seeds and residues
- Moisture/fat content in animal feed

Advantages of NMR, compared to other standard methods like chemical oil extraction, are a minimum sample preparation and a quick analysis time which is in the order of seconds. Moreover, chemical solvents are not required lifting the problem of waste disposal. Naturally, the TD-NMR systems are turn-key systems which do not require skilled personnel.

Obviously, different products (e.g. rape seeds/sunflower seeds) require different calibration curves. In Figure 5 a typical calibration curve is depicted. Generally, only a few reference samples typically 3 to 5-are required. The values from reference methods, like Soxhlet extraction and Karl-Fischer Water Determination, are utilized to calibrate the TD-NMR equipment. In seed breeding applications, however, the oil calibration is

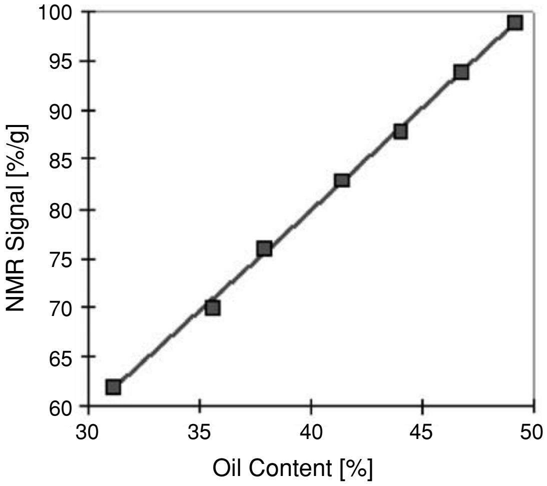

Fig. 5. Calibration Curve for oil determination in seeds. The mass-normalized NMR signal is a function of the oil concentration.

done differently: Pure oil samples are utilized for system calibration. In addition, the oil sample mass is taken into account by weighing. This way, systematic errors and uncertainties from the reference methods are excluded. For inhomogenous samples likes big seeds or nuts, TD-NMR systems with large measurement volumes are available.

Fat Content Determination in Chocolate

Another standard method is the determination of fat content in chocolate, more precisely in chocolate mass and paste as well as in chocolate liquor [13]. As chocolate samples contain a small amount of iron due to the production process, the Hahn-echo pulse sequence is applied with shorter pulse spacing, typically 200 μs only (compared to the 3.5 ms spacing of the seed application). This method also requires that all fat is melted. Whereas pure cocoa butter melts at 38 °C, fat blends containing fats like vegetable oils might required higher pre-tempering temperature, in some cases even up to 50 °C. Calibration of the TD-NMR application can be done conveniently with pure cocoa butter. Alternatively, well-characterized chocolate samples can be used for calibration. Often and unlike the seed application (cf. above) multiple products can be analyzed with one calibration line.

C. Oil Content Determination in Pre-Dried Olives

Oil and moisture determination on food samples containing only bound water can be done easily, though only sample weighing is required. An overview of typical applications is provided in Table 1. However, samples with high amounts of water/free water cannot be handled this way. The NMR signal from water will interfere with that of the oil. This is because the relaxation times of free water and oil are rather similar. Under these circumstances, the samples (like olives, sausages, fish, meet) need to be predried to remove free water from the sample. Following this preparation step, the Hahn-echo sequence is adapted to determine the oil content precisely. This method has found more than a hundred of users only in Spain for the precise oil content determination in olive paste [14]. Experience teaches that the upper limit for moisture and/or water determination without pre-drying is about 15% (see the article in this handbook “Time-Domain NMR in Quality Control: More Advanced Methods” for an alternative approach).

Conclusion

Due to the multiple advantages of the NMR method mentioned above the popularity of TD-NMR in QC/QA is steadily increasing. Especially in food industry more demanding and challenging applications like the analysis of wet food or protein determinations are coming up. Naturally, high-resolution NMR can easily provide the solution to these application. However, like in the early day of TD-NMR (see Introduction) the investment costs for such a system are simply too high. On the other hand, TD-NMR instrumentation seem to be an ideal QC tool to provide answers to these new challenges also because of its relatively low investment costs.

Acknowledgment

As TD-NMR applications in food industry have been often developed in cooperation with Unilever Research / The Netherlands, their input is acknowledged at this occasion.

Introduction

Native starch granules possess some unique microstructures with a distribution of structural domains having different dynamic properties [1–5]. These properties together with the molecular interactions in starch are major factors critically affecting the molecular responses to processing and physical properties of the resultant products. Therefore, in order to understand the starch functionality, such as in adhesives, biodegradable plastics [6] and drug-delivery systems [7], one has to understand the dynamics of the individual components, such as polysaccharides, water, and other additives, and the whole interactive complex. However, the complexity of the starch dynamics are far from fully understood. Few data are available to quantitatively describe the starch dynamics and the effects on starch functionalities. In the literature, starch polysaccharides are still frequently described *only* broadly as “rigid” for the crystalline forms and “mobile” for the amorphous ones.

There are three types of native starch, Type-A, normally found in cereals, Type-B, which are found in tubers, and Type-C, which are from legumes. Two distinct starch polysaccharides are present, namely, amylose that is a polymer of glucose (glucan) with $\alpha(1\rightarrow4)$ linkages and amylopectin, which is an $\alpha(1\rightarrow4)$ glucan with some $\alpha(1\rightarrow6)$ branches. The polysaccharides can either be in the crystalline or amorphous forms. Amongst the crystalline forms, the glucan is present as double helices which are arranged in two distinct fashions [8,9] forming two distinct crystal packings, A-type and B-type.

On the more macroscopic scale, the components of the starch granules, including water, polysaccharides, and some small molecules such as lipids, collectively form the microstructures such as the amorphous growth rings and semicrystalline hard shells. For the hydrated starch, which is arguably one of the simplest starch system, the complexity is expected to include (1) the presence of multiple phases and compartments for the polysaccharides and water, (2) variations in the interactions between the polysaccharides, and (3) the interactions between polysaccharides and other molecules such as water, which often leads to more variations to the polysaccharide properties. When processed, starch structure together with its dynamics and interactions are profoundly altered and the participation of the other molecules such as polyols and proteins, increased the complexity of the starch systems. It is thus not trivial to gain insights into the dynamics of each chemical moiety or the whole systems during the changes. The ideal research methods for these systems ought to (1) be non-invasive and non-destructive to facilitate *in situ* investigations, (2) be able to provide information on molecular structure, dynamics and interactions, (3) be useable for multiphasic and multi-compartmental systems, and (4) to be able to access information at different time and length scales. Undoubtedly, NMR is the method of choice offering a number of nuclei, including C, H, and O, as reporting probes. Water properties have been extensively investigated with NMR in the native starch granules [3,4,10–16] and in the processed starch systems and mixtures [17–20] (e.g. doughs and bread). However, such investigation of molecular dynamics of starch polysaccharides are not comprehensively documented. The proton relaxation times of polysaccharides measured either *via*. ^{13}C signals or directly from ^{1}H under MAS offers an unique opportunity for studies of starch polysaccharides [11,21–23]. Proton relaxation induced spectral-editing techniques provide probability to obtain the structure details for starch polysaccharides in various dynamic states [4,5,21]. ^{13}C NMR properties are also useful for the same purposes. The future of such studies will be increasingly focused on (1) the dynamics of polysaccharides, (2) interactions between the polysaccharides and other molecules, (3) the relationships between the physical properties of starch and the domain distribution and dynamic state of the starch polysaccharides, (4) how these properties are relevant in establishing and determining the response of starch granules to multi-parametric processing treatments, such as acid-hydrolysis and gelatinisation, and ultimately functionality.

This chapter will not attempt to compile the relevant literature exhaustively. Instead, the NMR-relaxation based strategies for studying the molecular dynamics

Graham A. Webb (ed.), Modern Magnetic Resonance, 1745–1754.
© 2008 *Springer.*

of polysaccharides and water in starch systems will be discussed.

General Considerations for NMR of Starch Systems

With modern spectrometers, NMR signals are recorded in the form of free induction decays (FIDs), which are the magnetisation changes as a function of time following a radio-frequency (RF) pulse (Figure 1a) or a pulse sequence (Figure 1). An NMR spectrum is obtained directly from Fourier transformation of such an FID,

$$S(\omega) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} F(t) e^{-i\omega t} \mathrm{d}t \tag{1}$$

In the solid biopolymers such as starch, ^{1}H, and ^{13}C are the most useful nuclei for the purpose of NMR. For ^{1}H in such systems, the scalar couplings are relatively weak (1–200 Hz), the dominant nuclear magnetic interactions include dipole–dipole interactions (up to 100 kHz) and chemical shift anisotropy (CSA) (up to 10 kHz). The typical proton FID of solid starch (Figure 2a) consists of a fast decay part and a slower one [11–14,22–24]. The corresponding ^{1}H NMR spectrum has a broad peak of several tens kHz with a sharp one ($\sim$kHz) superimposed (Figure 2b). The ^{1}H NMR signals of biopolymers can be analysed directly from FID or in the frequency domains, which will be discussed in later sections. Useful information on molecular dynamics can be obtained from the dipole–dipole interactions between protons and that of a pair of protons is given as [25–27]:

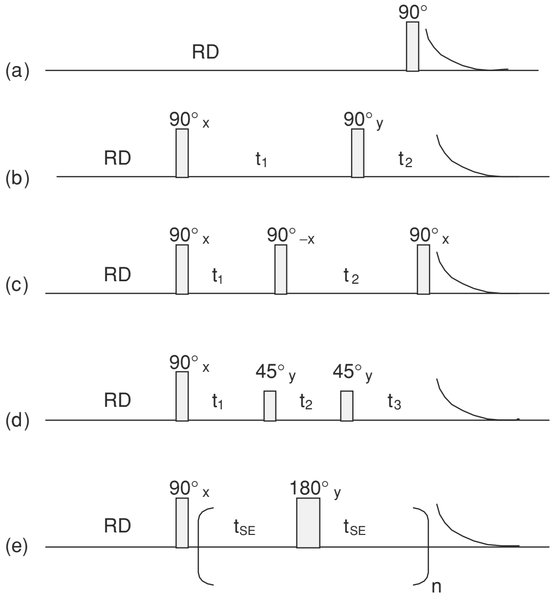

Fig. 1. Some pulse sequences for starch studies. (a) single pulse; (b) solid echo; (c) Goldman-Shen; (d) Jeener-Broaekhart; (e) CPMG sequence.

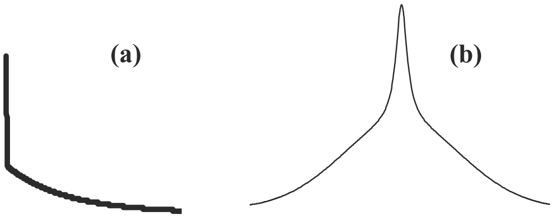

Fig. 2. A typical FID (a) and ^{1}H NMR spectrum (b) for solid biopolymers

$$\langle H_{\mathrm{D}} \rangle = \frac{\gamma^2 \hbar}{r^3} \left(1 - 3\cos^2\theta\right) = \gamma \langle H_{\mathrm{L}} \rangle \tag{2}$$

where γ is the proton magnetogyric ratio, $\hbar$ Planck's constant divided by 2π, $\langle H_{\mathrm{L}} \rangle$ the local dipolar field, r the inter-proton distance and θ the angle between the inter-proton vector and the external magnetic field. It is, thus, apparent that the dipole–dipole interaction is independent on the external magnetic field strength. Chemical shift describes the electronic environment in which spins are situated and is dependent on the dispositions of electronic charge about the nuclear sites. The form of these interactions is generally written as [25–27]

$$H_{\mathrm{CS}} = -\sum_i I_i \sigma_i B_0 \tag{3}$$

where I is the spin quantum number, σ the chemical shielding tensor of nucleus i and B_0 the external magnetic field. In a solution, fast molecular tumbling makes the chemical shift interactions isotropic, resulting in a single value of chemical shift as fingerprints of the spins from different environment. In a solid, however, a single value for chemical shielding is not adequate to describe such interactions since chemical shift varies with the orientation of the magnetic field with respective to the local principal axes.

The CSA has to be used to describe the interactions. This is not necessarily undesirable since CSA bears important structural and dynamic information [28]. Although no results have been reported for starch polysaccharides yet, ^{13}C CSA has already been used to study dynamics of a small sugar [29]. If a sample contains several crystallites with different orientation, the so-called powder spectrum [25–27] will arise (Figure 3), which contains information about the local electronic symmetry of the nuclear site. The CSA of a powdered sample describes the

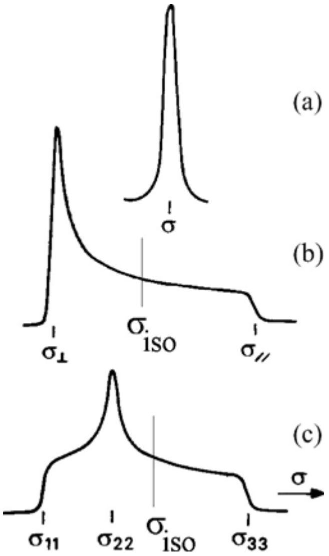

Fig. 3. Powder patterns for (a) spherically symmetric, (b) axially symmetric and (c) asymmetric patterns

three dimensional chemical shielding of the nucleus by the surrounding electrons and is conveniently parameterized with three principal components of the chemical shielding tensor [25–27], σ_{11}, σ_{22}, and σ_{33}, respectively (Figure 3). Three types of powder pattern are normally encountered depending on the principal values. If all three values are the same ($\sigma_{11} = \sigma_{22} = \sigma_{33}$, Figure 3a), it is said the pattern is spherically symmetric [25–27]; if only two of the values are the same ($\sigma_{11} = \sigma_{22}$ or $\sigma_{22} = \sigma_{33}$, Figure 3b), it is said the pattern is axially symmetric [25–27]; if all three values are different from each other ($\sigma_{11} \neq \sigma_{22} \neq \sigma_{33}$, Figure 3c), it is said the pattern is asymmetric [25–27]. The isotropic chemical shift is then given as [25–27]

$$\sigma_{\mathrm{AV}} = \frac{1}{3}(\sigma_{11} + \sigma_{22} + \sigma_{33}) \tag{4}$$

Using the so-called deshielding convention for CSA as shown [25–27] in Equation (5)

$$|\sigma_{33} - \sigma_{\mathrm{AV}}| \geq |\sigma_{11} - \sigma_{\mathrm{AV}}| \geq |\sigma_{22} - \sigma_{\mathrm{AV}}| \tag{5}$$

the shielding anisotropy $\Delta\sigma$ and the asymmetry η are given as

$$\Delta\sigma = \sigma_{33} - \frac{(\sigma_{11} + \sigma_{22})}{2} \tag{6}$$

$$\eta = \frac{|\sigma_{22} - \sigma_{11}|}{\Delta\sigma} \tag{7}$$

Two other functions were suggested to describe the tensor quantities of the chemical shift including the span (Ω), which is the difference between two extreme components, and the skew (κ) [25]:

$$\Omega = |\sigma_{33} - \sigma_{11}| \tag{8}$$

$$\kappa = \frac{3}{\Omega}(\sigma_{22} - \sigma_{\mathrm{AV}}) \tag{9}$$

Care should be taken when analysing the CSA properties since there are several different conventions in use.

In an external magnetic field, spins excited by an RF pulse will eventually relax back to the equilibrium state. Such relaxation processes are informative to molecular dynamics and interactions. Five major relaxation phenomena can be encountered in studying biopolymer systems, spin–lattice relaxation characterized by T_1, $T_{1\rho}$, $T_{1\mathrm{D}}$ and $T_{1\mathrm{Q}}$, and spin–spin relaxation characterized by T_2. These relaxation processes are sensitive to molecular motions with the rotational correction time (τ_{c}) from nanoseconds to milliseconds. Amongst the relaxation processes, the spin–lattice relaxation in the laboratory frame (T_1), is sensitive to the fast motions comparable to the Larmor frequency ($\tau_{\mathrm{c}} \sim 10^{-9}$ s) and the spin–lattice relaxation time in the rotating frame ($T_{1\,\mathrm{\rho}}$) is sensitive to motions comparable to the spin-locking field frequency ($\tau_{\mathrm{c}} \sim 10^{-3}$–$10^{-6}$ s). The spin–lattice relaxation time in the local dipolar field ($T_{1\mathrm{D}}$) is also of great value for studying motions and, in theory, is sensitive to motion frequency comparable to the local dipolar field frequency (10^2–10^5 Hz, $\tau_{\mathrm{c}} \sim 10^{-5}$–$10^{-2}$ s). $T_{1\mathrm{Q}}$ is the spin–lattice relaxation time for the quadrupolar nuclei such as ^{17}O and ^{2}H. When a specific site is labelled with ^{2}H, the line shape analysis for ^{2}H NMR spectra, which is dominated by the quadrupolar interaction, can provide quantitative information about fast dynamic process with a τ_{c} around 10^{-4}–10^{-7} s. Two dimensional ^{2}H exchange NMR experiments [30] allow access of information about slow motions (up to 1 s).

For native and processed starch systems, the nuclei ^{1}H, ^{2}H, ^{13}C, and ^{17}O are suitable for NMR studies to probe the structure and dynamics of the starch systems. Whilst the ^{13}C NMR signals are exclusively from polysaccharides, in the solid starch systems, proton NMR signals consist of those of polysaccharides and of water entangled together. This entangled information is often difficult to interpret unambiguously and the proton signals of the polysaccharides and water are often required to be separated. This can be done conveniently by D_2O exchange. When the polysaccharides are the focus of a study, samples can be suspended repeatedly [3,11,31] in excessive D_2O to remove the water protons in the system although such an exchange process will also remove the exchangeable protons (OHs). Consequently, the ^{1}H NMR signals will be predominantly from ring protons of the polysaccharides [3,11,31]. The natural abundance of ^{2}H and ^{17}O are too low to be sensitive enough for NMR studies of polysaccharides, nevertheless, the ^{2}H and ^{17}O NMR can be extremely useful if water is the focus of studies and the deuterated and ^{17}O labelled water are employed. When ^2H_2O is used, the starch systems will have to be exchanged with sufficient D_2O and the ^{2}H NMR signals will be mostly from water though some will be from exchangeable hydroxyl groups as well [3,4,14,32]. When $H_2{}^{17}O$ is used, on the other hand, the ^{17}O NMR signals will be exclusively from water [20,33–36]. With an appropriate combination of the above, water and polysaccharides signals can be selectively observed. Apart from those two nuclei, other nuclei with natural isotopes can also be employed depending on the purposes of studies. For example, if salts are important, NaCl can be used to provide source of signals for ^{23}Na NMR and NaF can be employed to observe both ^{23}Na [33,37] and ^{19}F NMR signals.

Solid Starch Systems

Starch systems can be either in native granular state, gels, and solubilized forms. For the solublized starch systems, their behavior will be more like polymers in viscous solution, therefore the NMR strategy will be similar to that of the solution state NMR.

All the other forms of starch systems are heterogeneous and contain multiple components in the proton relaxation time measurements [5]. For example, under magic angle spinning (at about 4–5 kHz) at the ambient temperature, wheat starch containing 33% water showed [38] two proton $T_{1\rho}$ components (4 and 7 ms). Another study showed that D_2O exchanged and D_2O saturated starch (Table 1) [5] had single T_1 (2.5–3 s) at 300 MHz and two $T_{1\rho}$ (2–4 ms, ~30 ms) processes. This suggested that the spin-diffusion was efficient on the time scale of a few seconds but not efficient on $T_{1\rho}$ time scale (~30 ms), hence multiple domains are present on the $T_{1\rho}$ time scale. The same system studied with PRISE (Proton relaxation induced spectral-editing) techniques showed [5] that that long $T_{1\rho}$ component (~30 ms) is associated with the polysaccharides in the crystalline lamellae whereas the short $T_{1\rho}$ component (2–4 ms) is associated with amylose in the gaps between amylopectin clusters. T_2 of these wet starch systems is more complex. However, with solid-echo sequence [39,40] (Figure 1B), proton T_2 can be measured for the spins experiencing residual dipolar interactions. Three T_2 components were observed [5] as short (14 μs), intermediate (~300 μs) and long (1–20 ms) components. With PRISE techniques, it has found that the short T_2 component is associated with polysaccharides in the crystalline lamellae whereas the other two components are associated with polysaccharides in the amorphous lamellae and amylose in the gaps between amylopectin clusters [5].

Table 1: Proton relaxation data for D_2O exchanged and saturated starch granules [5]

	T_1/s	T_1/ms	T_2/μs
Corn starch (Type-A) (D_2O ~ 45–55%)	2.64	24.9 (58%) 3.80 (42%)	14 (75%) 354 (12%) 9570 (12%)
Potato starch (Type-B) (D_2O ~ 45–55%)	2.78	29.8(57%) 2.92 (43%)	14 (70%) 296 (20%) 28300 (10%)
Pea starch (Type-C) (D_2O ~ 45–55%)	2.57	28.3(49%) 3.25 (51%)	14 (80%) 372 (10%) 20800 (10%)

Proton Spin–Spin Relaxation and Second Moment of Solid Starch Polysaccharides

For starch polysaccharides, there are two proton T_2 time scales, one that is shorter than 1ms and the other, which lies between millisecond and seconds. In both cases, the observed spin–spin relaxation process can be considered as a sum of the contributions from the dipole–dipole interactions, field inhomogeneity and other mechanisms (Eqution 10). In the dipolar interaction dominated systems, the first term in Equation (10) is so great that the contributions of the other terms are negligible. Therefore, when it is shorter than 1ms, T_2 can be conveniently measured from the time domain NMR signal (FID). However, when T_2 is long (>1m), the contribution of field inhomogeneity and other mechanisms will be significant and measurements from FID are no longer adequate. In such cases, T_2 has to be measured using CPMG method [41], in which the short T_2 component will be "filtered-off" by choosing an appropriate spin-echo delay t_{SE} (Figure 1), leaving only the long T_2 components. Examples of this situation include water in starch systems and amorphous polysaccharides in the water-rich environments, which will be dealt with in later sections. We shall deal with the short T_2 scale first.

$$\left(\frac{1}{T_2}\right)_{obs} = \left(\frac{1}{T_2}\right)_{D} + \left(\frac{1}{T_2}\right)_{IH} + \left(\frac{1}{T_2}\right)_{others} \qquad (10)$$

In solids, the ^{1}H NMR line shape is dominated by the dipole–dipole interactions (H_D) between the neighboring protons. In the absence of molecular motions, the FID of such a system decays rapidly; the corresponding proton NMR spectrum appeared as a broad featureless peak. Whilst many solid polymers featured a Gaussian decay for their proton FIDs, the FID of solid starch as in the cases of most solid sugars can be characterized neither by an exponential function nor by a Gaussian function. Therefore, it is often not practical to analyse the "rigid" starch by the spin–spin relaxation time T_2. Similar to the other carbohydrate systems such as glassy maltose [42], plant cell walls [43–45] and model systems [45–49], however, the proton FIDs can be approximated adequately by a Gaussian decay modified by a sinc function [43–50], from which the second moment of the NMR spectra, M_{2r}, can be evaluated quantitatively.

The rigid lattice second moment of a biopolymer can be calculated with lattice summation described by van der Vleck equation [51] if reasonable structure information is available. Proton positions in X-ray structures are often not accurate and the neutron structures give much more accurate results.

The true second moment, M_2, is independent of molecular motions. However, the measured second moment also known as residual second moment, M_{2r}, can be used to investigate the motions. In general, when the correlation time, τ_c, is greater compared to the inverse of linewidth, i.e. $\tau_c \gg (\gamma\sqrt{M_{2r}})^{-1}$, the hydrogen nuclei (protons) are said to undergo slow motions and give rise to so-called "rigid lattice" NMR spectra. When $\tau_c \approx (\gamma\sqrt{M_{2r}})^{-1}$, the fluctuation of the dipolar interactions becomes fast enough to average H_D to some extent and the M_{2r} is expected to start decreasing. If $\tau_c \ll (\gamma\sqrt{M_{2r}})^{-1}$, the hydrogen nuclei are said to undergo fast motions. The motion modulated reduction of the apparent proton second moment is observed by an amount $\Delta M_2 = M_2 - M_{2r}$.

The FIDs of starch consist of a fast decay and a slow decay parts. After removal of water (and OHs) by exhaustive D_2O exchange, the FID remains as two parts though the slow decay part is often reduced [11] in intensity due to the removal of the contributions of H_2O. The interpretation for such composite line shapes is often simplified as two different structure domains, "rigid" and "mobile" ones. Whilst such interpretation is true in many cases, it can sometimes suffer from oversimplification [52]. In fact, the multiple-decays in T_2 process can also arise in other situations, for example, when there are broad distributions of correlation times [53,54], cross-correlation effects in the anisotropic motion of molecular segments [55], and cross-relaxation between two spin species intermingled at short distances from each other [56]. It is therefore always desirable to ascertain the nature of the multiple-component decays experimentally. This can be achieved by inspecting the shapes of the dipolar echoes and monitoring the behaviour of the magnetisation transfers *via* the Goldman-Shen experiment [56] (Figure 1c).

By using the Jeener-Broekaert sequence [57] (90°_x-t_1-45°_y-t_2-45°_y-t_3-acq, Figure 1d), some Zeeman order can be transferred into the dipolar order, allowing the measurement of spin–lattice relaxation times along local dipolar fields (T_{1D}). For a homogenous solid biopolymer, when $t_1 \approx T_2$, and $t_2 \geq t_3$, a single Jeener echo is expected, whose shape and amplitude depends on the time derivative of the FID [57]. However, if an inhomogeneous distributions of second rank spin interactions are present, three echoes can be observed [58] respectively at $t_3 = t_1$ and $t_3 = t_2 \pm t_1$ and, for long t_1, superposition of echoes are present together with the changes in the shapes of the echoes as a function of t_2 variations [59].

In addition, one can use the Goldman-Shen sequence [56] (90°_x-τ_1-90°_{-x}-τ_2-90°_x-acq, Figure1C) to prepare the spin system in a non-equilibrium state with distinct domains at different spin temperatures. The recovery to a *quasi* equilibrium state can then be monitored as domains achieve a common spin temperature through spin diffusion. When $\tau_1 \geq 5\ T_{2\text{short}}$, where $T_{2\text{short}}$ is the T_2 of the fast decay component, the macroscopic magnetisation of the rigid domain is selectively filtered-off. The residual magnetisation of the slow decay component, characterized by a $T_{2\text{long}}$, is then realigned along the magnetic field and the transfer of the magnetisation between domains (or the changes of spin temperature) *via* spin diffusion can be monitored by varying τ_2. If spin-diffusion or spin translation occurs between some distinct phases of a heterogeneous sample, the return and growth of the fast component of the FID will be observed when $\tau_2 \geq T_{2\text{long}}$. In such cases, the size and dimension of domains can be estimated [60–63] from the diffusion coefficient, D, and relaxation times. This will be described in later sections.

On the other hand, however, in the event of a broad distribution of correlation times or fast spin translation between spins intermingled at short distances or cross-correlation effects of a segment moving anisotropically, only one spin population is expected corresponding to a single homogenous phase. The recovery process of the $T_{2\text{short}}$ component will be rapid ($\tau_2 < T_{2\text{long}}$). In such cases, the domains are absent.

Domains and Spin-Diffusion in the Solid Starch Polysaccharides

Assuming the spin diffusion as a random walk process, the mean diffusion distance $\langle d \rangle$ over the interval T_1 is [60–63]

$$\langle d \rangle = \sqrt{2DT_1} \qquad (11)$$

where D is the diffusion coefficient. For biopolymers in the solid state with a Gaussian line shape, the diffusion coefficient is given [64] approximately by

$$D = \frac{\langle r\rangle^2}{60\pi T_2} \tag{12}$$

where $\langle r\rangle^2$ is the mean-squared inter-nuclear spacing and T_2 is the measured FID decay constant. Since the local dipolar field is given by

$$\langle H_L\rangle = \frac{\Delta H}{\sqrt{12}} \tag{13}$$

where ΔH is the line width (in Gauss) at the half height [65]. By measuring ΔH and working out $\langle H_L\rangle$, an average $\langle r\rangle$ for the proton separation can be obtained from Equation (2). This together with the measured T_1 and T_2 values allows estimation of the domain dimensions according to the Equation (11–12).

However, one has to be aware that in the dipolar coupled systems, spatial inhomogeneity measured by ^{1}H NMR can be achieved *only for a certain range of length scales*. Spatial fluctuations within the correlation length of the local dipolar fields cannot be resolved. This sets a lower bound resolution to a few near neighbour distances, i.e. about 5–10 Å.

Proton Spin–Lattice Relaxation of Solid Starch Polysaccharides in the Laboratory Frame

^{1}H relaxation times are most widely employed for studying the dynamics due to high sensitivity and well-established theories. For biopolymers, the proton T_1 can be conveniently measured using inversion-recovery or saturation-recovery sequences either by directly detecting the ^{1}H NMR signals or indirectly *via* ^{13}C (e.g. CPMAS). In the dipolar interaction dominated system, the proton relaxation time, T_1, obeys the relaxation theory described by Bloembergen, Purcell and Pound [66]. Assuming exponential correlation function and single correlation time, the T_1 can be evaluated quantitatively with the well-known Kubo-Tomita expression (Equation 14) [67–70],

$$R_1 = \frac{1}{T_1} = \sum_{i\geq 1} C_i\left[\frac{\tau_{ci}}{1+\omega_0^2\tau_{ci}^2} + \frac{4\tau_{ci}}{1+4\omega_0^2\tau_{ci}^2}\right] \tag{14}$$

where ω_0 is the proton Larmor frequency and τ_c the rotational correlation time of the motions responsible for the spin–lattice relaxation, which normally follows the Arrhenius activation law

$$\tau_c = \tau_0 \exp\left(\frac{Ea}{RT}\right) \tag{15}$$

where τ_o is the pre-exponential factor corresponding to the rotational correlation time at infinite temperature, E_a the activation energy for the motion and R the gas constant. For a motional process, when $\omega_0\tau_c = 0.6154$, T_1 reaches a minima or R_1 reaches a peak where

$$R_1{}^{\mathrm{Max}} = 1.425C/\omega_0 \tag{16}$$

C in the Equation (14) and (16) is the relaxation constant and is related to the spatial arrangement of protons in the sample, thus, a useful structural parameter. For a powder, C is given by Equation (17)

$$C = \frac{9}{20N}\cdot\gamma^4\hbar^2\left(\sum_j r_{jk}^{-6} + \sum_k\sum_{l\neq j,k} r_{\mathrm{jl}}^{-6}\right), \tag{17}$$

where N is the number of protons to be relaxed and, r_{jk} is the inter-proton distances between a pair of protons j and k, γ is the proton magnetogyric ratio. The first term in parenthesis describes the intra-pair spin properties whereas the second term describes the inter-pair ones. It is thus apparent that, by measuring T_1 as a function of temperature or the Larmor frequency, one can access parameters describing the molecular motions (E_a, τ_o, C) and the geometry of the groups (r) involved in the motions if no phase transition or chemical decompositions were intermingled into the motional processes.

However, even in most of single-phase homopolymer systems, the assumption of a single τ_c is not always valid [71–76]. A distribution of τ_c is more realistic [71–76] although the reasons for such τ_c distribution are not well studied. The distribution of activation energy due to the distribution of molecular conformers is one possibility (P.S. Belton, personal communication). In biopolymer systems such as starch, such distribution is often complex. The dynamics of starch polysaccharides in much slow frequency region (several kHz) is also extremely important especially for the mechanical properties. Such dynamics cannot be easily probed with T_1 but can be investigated by measuring the proton T_2 or M_{2r}, T_{1D} and $T_{1\rho}$ relaxation times.

Proton Spin–Lattice Relaxation of Solid Starch Polysaccharides in the Rotating Frame

To study slow motions in several kHz regions, ^{1}H $T_{1\rho}$ can be conveniently measured by a single pulse followed with a variable spin-lock scheme. $T_{1\rho}$ can also be used to quantitatively analyse the molecular motions by fitting the experimental $R_{1\rho}$ data to an expression similar to that used in R_1 analysis [46,47,49,67–69]:

$$R_{1\rho} = \frac{1}{T_{1\rho}} = \frac{3}{2}\sum_{\mathrm{i}\geq 1} C_i\left[\frac{\tau_{ci}}{1+4\omega_{ei}{}^2\tau_{ci}{}^2} + \frac{5}{3}\times\frac{\tau_{ci}}{1+\omega_o{}^2\tau_{ci}{}^2} + \frac{2}{3}\times\frac{\tau_{ci}}{1+4\omega_o{}^2\tau_{ci}{}^2}\right] \tag{18}$$

where ω_0, τ_c and C have the same meaning as in the case of T_1. ω_e is the effective field for relaxation in frequency units, which is often dependent on both the spin-locking frequency (ω_{SP}) and the local dipolar field (in frequency unit), ω_L.

When $\tau_c < T_2$ and $\omega_{SP} \gg \omega_D$, $T_{1\rho}$ can be interpreted through the theory of Bloembergen, Purcell and Pound [66], therefore, ω_e can be replaced by ω_{SP}. When $\tau_c \gg T_2$, the so-called Slichter-Ailion conditions apply [77]. However, if ω_{SP} and ω_D are in the same order of magnitude and $\tau_c \leq T_2$ stands, the effects of the local dipolar field has to be taken into consideration as follows [78]:

$$\omega_e = \sqrt{\omega_{SP}{}^2 + \omega_L{}^2} \tag{19}$$

In practice, ω_L is temperature dependent and has to be modeled by an empirical relationship, such as the Sigmoid function [43–49,67–69], to give the closest values to that of the experimental ones. For a motional process, when $\omega_e \tau_c = 0.6101$, $T_{1\rho}$ reaches a minimum.

In most of starch systems, multiple components are frequently detected [5,38] for ^{1}H $T_{1\rho}$ of starch systems due to the heterogeneity of such systems. The magnetization transfers between domains *via* spin diffusion over the whole sample can be used to obtain information on the dimension of the domains. In the meantime, the multiple components of relaxation times provide a great opportunity to access information on the structure and interactions of the different domains *via* relaxation-edited spectroscopy. In theory (see Equation 18), $T_{1\rho}$ measurements as a function of temperature or relaxation frequency can also be used to characterize the molecular dynamics quantitatively (E_a, τ_o, C, r) in the similar way to that for T_1. However, in real starch systems, measuring the relaxation time as a function of sample temperature is not always possible without causing samples to undergo physical changes, such as phase transition, and chemical decomposition. The changes often occur "inconveniently" in the temperature range one want to investigate. Nevertheless, such problems can be avoided by measuring T_1 as a function of the frequency [79], ω_o, and analyse the motional processes accordingly. The commercial fast-field cycling spectrometers with field switching speed of 0.1 ms/MHz are now available, covering the frequency range of 10 kHz to 80 MHz. This makes it possible to study molecular motions in the range of several tens of kilohertz to hundred of megahertz at one given temperature [31,79,80].

^{13}C Spin–Lattice Relaxation for Starch Polysaccharides

The T_1 and $T_{1\rho}$ of ^{13}C for starch polysaccharides can be measured directly, providing information on the spectroscopically resolved sites. Using appropriate pulse sequences [81–84], the chemical shift anisotropy (CSA) can also be measured to gain dynamics information. The advantage of using ^{13}C method is that the NMR signals contain only these of polysaccharides and there will be no water signals directly intermingled. So far, there is still a lack of systematic ^{13}C relaxation study of starch though some data have been reported for maltose [85] and starch gels [33,86]. Some early efforts were concentrated on the measurements of ^{13}C T_1 for the prepared crystalline starches [87], which was only possible after the invention of CPMAS experiment. For both A- and B-type dry crystalline amylose [87], ^{13}C T_1 values were about 20 s and 5 s for the C-1 and C-6 respectively. The C-6 has a much shorter ^{13}C T_1 presumably due to the *trans-gauche* conformational motions of CH_2OH group [43–46,88–91]. However, ^{13}C T_1 values are much smaller than these for crystalline cellulose I of cotton [87] (140–210 s), indicating more motional mobility for starch polysaccharides than cellulose.

Full hydration of starch led to only a small decrease [87] of T_1 value for C-1 (13–16 s) and C-6 (3–4 s). Similar observations were made [87] for C-4 (dry$\sim$14, hydrated$\sim$11–13 s). In contrast, glycogen, a similar polysaccharides, showed dramatic decrease of ^{13}C T_1 values upon hydration [92]. It is suggested that the hydration-induced enhancement for molecular dynamics is only limited for the ordered starch polysaccharides. For the V-type amylose as a single helical amylose-lipids complex, T_1 of C-1 showed significant increase upon hydration [87], from 7 s (anhydrous) to 11 s (fully hydrated). Similar observations were made for other pyran ring carbons, indicating that hydration promoted the formation of the ordered structure in this case. The ^{13}C T_1 of amorphous starch are considerably shorter than the crystalline ones. For example, the amorphous wheat starch containing 33% water showed ^{13}C T_1 of 300ms for CH_2OH and 600 ms for the ring carbons [38]. The difference of ^{13}C T_1 has been employed in some spectral editing of ^{13}C NMR spectra, termed as mobility-resolved spectroscopy [93]. It is conceivable that a systematic ^{13}C relaxation studies ought to provide some significant insights into the dynamics of the starch polysaccharides. Nevertheless, for systems as complex as starch polysaccharides, some background knowledge is always helpful on the single-phase starch models such as the crystalline sperulites and short chain amorphous polysaccharides.

Water in Starch Systems

In most starch systems, water is an essential constituent thus plays important roles in starch functionality. NMR techniques have already been employed in studying water molecules in starch systems for decades. The first such

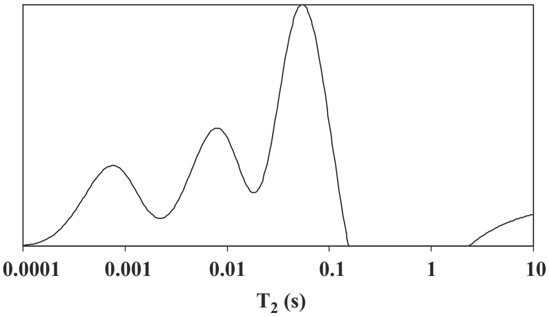

Fig. 4. A TRESY spectrum of water in wet potato starch granules showing four water populations detectable in the system as water in the crystalline region (0.001 s), water in the amorphous region (0.01 s), water trapped between granules (0.1 s) and bulk water (10 s).

study was published in Nature [94] in 1960 on the starch polysaccharide–water interactions, showing the broadening water proton lines in high resolution NMR spectra of starch gels. In 1970s, some low-resolution ^{1}H NMR studies of the "bound water" of corn starch [95] were also published and such studies were continuously reported from 1980s to 2000s [10–15,32,96–98] with the gradual improvement of NMR hardware. Some progress has also been made in understanding of the water dynamics in acid hydrolysis and gelatinisation. This area of research will remain active for sometime.

Since most of water in starch systems is in the long T_2 regime, the CPMG spin echo experiment [41] will be most suitable. The CPMG echo trains are better analysed as a continuous distribution of exponentials, yielding a spectrum [3,4,16,99–103] of T_2 components with distributive T_2 values (Figure 4). This method was called transverse relaxation spectroscopy (TRESY) [3] and has found widespread application especially in the porous systems. The use of TRESY methods has led to new insights into the state of water in starch systems. For example, TRESY methods enabled most populations [3,11,23,104] of water in the native starch granules to be identified in all three types of starch granules; they are bulk water, water trapped between granules, water in the amorphous growth rings, water in the semi-crystalline regions and structural water in the hexagon channels formed by the double helices. Amongst them, the "channel water" in the granules and hydrolysed starch spherulites, which remained unfrozen until temperature reached as low as -50°C [3,4,11], was also observable from the D_2O saturated B-type [3,4,11,14,15] and C-type [3,4,11] starches using ^{2}H NMR as an 1kHz splitting.

^{1}H TRESY methods have also been employed to investigate the effects of acid hydrolysis (Linterization), thermal heating and gelatinisation on the dynamics of starch and microscopic distribution of water within the starch systems [3,11]. By monitoring the changes of proton T_2 spectra of a starch/water system, it has been possible to monitoring the changes of the dynamic behaviour of water such as swelling induced water absorption [4,11]. By replacing H_2O with D_2O, the proton TRESY method were employed to monitor the molecular dynamic changes of starch polysaccharides [3,11], especially near the gelatinisation temperature. Below the gelatinisation temperature, the proton NMR signals are mostly from polysaccharides and ^{1}H NMR signals from FID offers a direct observation of the polysaccharides [3,11]. On the other hand, ^{1}H CPMG signals near and above gelatinisation temperature provide an unambiguous monitoring handle to the mobilized starch [3,11]. To the similar systems, ^{2}H and ^{17}O NMR is useful to monitor the changes of water dynamics in response to the processing such as gelatinisation.

Future Perspective

Although studies of starch using NMR relaxation have extended to various extent to both starch polysaccharides and water, more systematic studies are still in need to understand the systems more comprehensively. Whilst most efforts were devoted to the crystalline starch, limited attentions were paid to the amorphous starches even though most of the processed starch is in the amorphous form and hence is important for the rubbery properties. Furthermore, only few studies have been directed towards the interactions between components in the complex. NMR diffusion is not extensively employed even though it is expected to provide essential information on dynamics and interactions of starch systems. It is thus conceivable that the future studies will be focused more on the dynamics and interactions of polysaccharides. The other important questions, which remain unanswered, include: what are the relationships between the physical properties and the domain distribution and dynamic state of the starch polysaccharides (if any); how are these properties relevant in establishing and determining the response of starch granules to multi-parametric processing and ultimately functionality.

High Resolution Solid State Methods

Magic Angle Spinning NMR of Flours and Doughs

Maria Antonietta Brescia and Antonio Sacco
Dipartimento di Chimica, Università di Bari, via Orabona 4, 70126 Bari, Italy

Introduction

The study of the properties of wheat flours is necessary to understand the mechanical and rheological properties of the resulting dough and therefore of the finished baked products. In the specific case of bread, recent works have concerned low resolution NMR for studying water and lipid mobility [1–3]. The mobility of water in dough is an important parameter being related to the quality of gluten network. To gain more insight in the structural characteristics of dough and of its principal components, gluten and starch, solid-state Magic Angle Spinning (MAS) NMR was applied. The interactions of each dough component with water and effects of heating during bread making were also studied. MAS methods improve resolution by averaging dipolar interactions, along with chemical shift anisotropy and magnetic susceptibility. This permits to detect easily and quantify signals due to various components of dough and flours.

In this chapter applications of ^{13}C and ^{1}H MAS NMR spectroscopy to flours and dough and to their major components, starch and proteins, will be reviewed and the potential of these techniques in exploring the correlation between molecular level information and macroscopic properties of dough and flours will be examined.

^{13}C Cross Polarization MAS NMR of Flours

The first ^{13}C cross polarization (CP-MAS) NMR study of flours was performed by Baianu and Förster [4]. They found that the broad features of spectra of wheat grains were similar to those of the corresponding flours. The subtle differences were supposed to be due to starch damage and mechanical breaking of protein chains. The major signals present in the CP-MAS ^{13}C NMR spectrum of flour are due to sugar carbons in the starch components of the flours, resonating at 96–102 ppm (C_1), 70–73 ppm (C_2, C_3, and C_5), 77–83 ppm (C_4), and 59–62 ppm (C_6). The tail of the 62 ppm starch resonance obscures signals due to Cα's of the proteins, while signals due to protein side-chain aliphatic carbon resonate at 20–35 ppm, and do not overlap with other signals. The relative intensities of the protein and starch resonances allow calculating the protein content of durum and tender wheat flours.

The resolution of the signals permitted the application of relaxation experiments and to determine the average rotating-frame proton relaxation time $T_{1\rho}$(H) of each carbon [5]. From these measurements it emerged that all the starch protons have a similar $T_{1\rho}$(H) while for proteins $T_{1\rho}$(H) is 30% lower indicating that starch and proteins are separated into distinct domains.

^{1}H High Resolution MAS NMR of Flours

Even if ^{13}C CP-MAS NMR has the advantage of avoiding sample manipulation, the information that can be inferred from these spectra is strongly limited by the low resolution due to the presence of very broad signals generated by high molecular weight (HMW) components.

^{1}H High Resolution (HR-MAS) NMR technique permitted to overcome these difficulties combining the typical advantages of solid- and liquid-state NMR techniques. Samples for ^{1}H HR-MAS measurements were prepared in the rotors mixing 33 mg of D_2O with 40 mg of flour to obtain homogeneous samples with similar degrees of swelling. A typical ^{1}H HR-MAS spectrum of durum wheat flour, obtained using a presaturation sequence for water suppression, is reported in Figure 1. More than 80 peaks can be distinguished resulting mainly from lipids and polysaccharides. Lipids assignment was performed [6] on the basis of correlations observed in TOCSY and ^{1}H-^{13}C HMQC spectra (Table 1). A detailed assignment of saccharide moieties was not possible due to overlap among TOCSY correlations. The heights of the resonances showing neither overlapping nor correlation with other signals were evaluated in the ^{1}H HR-MAS spectra of 12 durum wheat flours coming from southern Italy to be used as variables for Principal Component Analysis. The results permitted to detect differences among the samples mainly due to their geographical origin. This procedure demonstrated its reliability also when it was applied on an enlarged data set formed by 26 samples of two cultivars at 13 different locations in Italy [7] and was able to differentiate samples coming from North, Central, and South Italy according to the geographical origin and cultivar.

^{1}H HR-MAS was also employed to study the kinetic release of oligosaccharides due to hydrolases in the amylolytic starch degradation of wheat flours [8]. The increasing intensities of β-glucose and anomeric protons of the

reducing ends of β-maltose were determined as function of time for several durum and soft wheat samples and were fit with a Michaelis Menten kinetic equation to obtain kinetic parameters that are associated to the transformation of starch into maltose and maltose into glucose. A relationship between the kinetic degradation of starch and the botanical origin of the flour was suggested.

^{1}H and ^{13}C MAS NMR of Doughs

The hydration of flour is an important step in the baking process. Differences in the mechanical properties of dough are related to the interactions of water and flour.

Hydrated durum and tender wheat flours were analyzed with CP-MAS and showed a decreased intensity of signals due to protein carbons in comparison with the spectra of the dry flours, being nearly absent in the spectrum of the tender wheat flours [5] (Figure 2). This was explained supposing a reduced effect of water on protein components in durum wheat flours, because proteins are linked to starch–protein particles and remain solid-like. Hydration of the tender flour proteins generates a liquid-like component that can act like a compatibilizer rendering tender flour more processable than durum wheat flour.

Some properties of the flours were investigated, in order to assess its suitability for technological purposes. In particular, the peculiar viscosity and elasticity of hydrated flours are associated to the quantity and quality of gluten. These properties were extensively investigated [9] to understand their origin at a molecular level and the behavior of specific groups or protein moieties on the formation of the hydrated network. These studies were firstly performed on molecules that could be used as simple models [10]. For this reason, the major constituents of gluten, gliadins, and glutenins, were separately analyzed. In particular, it was interesting to gain information about the water-insoluble network obtained by hydration of these proteins to low water content, since this is closer to the protein during dough making.

Table 1: Proton assignment of durum wheat flour lipid moieties (From ref. [6]).

δ (ppm)	Moiety	Assignment
0.83	$\mathbf{CH_3}$–$(CH_2)n$–CH_2–	Lipids
1.22	–$(\mathbf{CH_2})n$–CH_2–	Lipids
1.50	–$(\mathbf{CH_2})$–CH_2–CO–O–	Lipids
1.98	–$\mathbf{CH_2}$–CH=CH–	Lipids
2.18	–CH_2–$\mathbf{CH_2}$–CO—O–	Lipids
2.69	–CH=CH–$\mathbf{CH_2}$–CH=CH–	Lipids
3.26	C2	β-glucose
3.40	C4	β-glucose
3.41	C4	α-glucose
4.64	C1	β-glucose
4.65	C1 reducing end	β-maltose
5.23	C1	α-glucose
5.23	C1 reducing end	α-maltose
5.24	–**CH**=CH–	Lipids
5.41	C1 non reducing end	α-maltose
5.41	C1 non reducing end	β-maltose
5.35–5.50	Non reducing ends	carbohydrates

Gliadins

The first ^{13}C CP-MAS NMR studies on gliadins were performed by Baianu [11]. The wheat proteins ω-gliadins, that are associated with dough viscosity, have a relatively simple structure; therefore they were used as a model to study hydration with ^{13}C CP-MAS NMR [12,13]. The changes in resolution and intensity of the signals present in the spectrum were analyzed at different hydration percentages and were correlated with the protein conformational changes (Figure 3). An improvement of spectral resolution with hydration reflected a change in the protein conformation. Moreover, the loss of the proline Cδ signal was detected, indicating an increased mobility of this group. These observations were enriched with results obtained with the T_2 relaxation time measurements, and were consistent with the formation of mobile protein loops together with residual regions of strong interprotein interactions with hydration. These evidences support the "loop and train" model, common in some polymers, in which "loops" of solvated mobile polymer coexist with "trains" polymer bonded to the surface [9].

The effect of hydration was also studied by ^{1}H HR-MAS NMR on ω-gliadins. Proton T_1 measurements were made under MAS conditions for 19% hydrated samples showing that the most mobile protons were leucine methyl groups [12]. Anyway, great care was required to interpret T_1 relaxation times, since they were found to be dependent on the sample spinning rates [13]. In the spectra of 48% hydrated ω-gliadins, it was possible to observe resonances of backbone NH groups (8.2 ppm), arising from glutamine and phenylalanine residues, as well as side-chains NH groups (6.9 ppm) and aromatic protons (7.3 ppm), indicating that mobility is not restricted to protein side-chains, but includes also protein backbone regions [12].

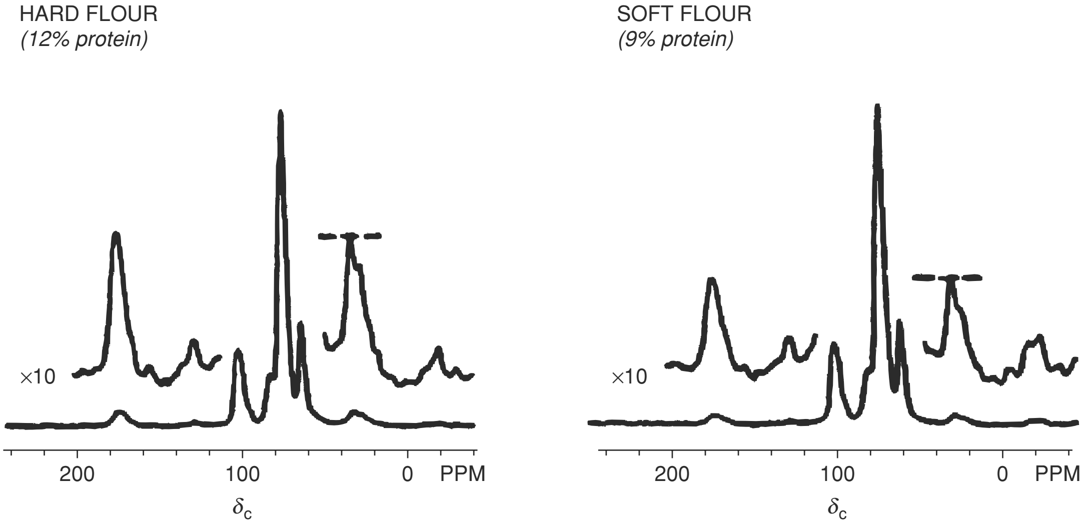

Fig. 2. ^{13}C CP-MAS NMR spectrum of a wheat flours: (left) durum wheat flour, (right) soft wheat flour (From Ref. [5]).

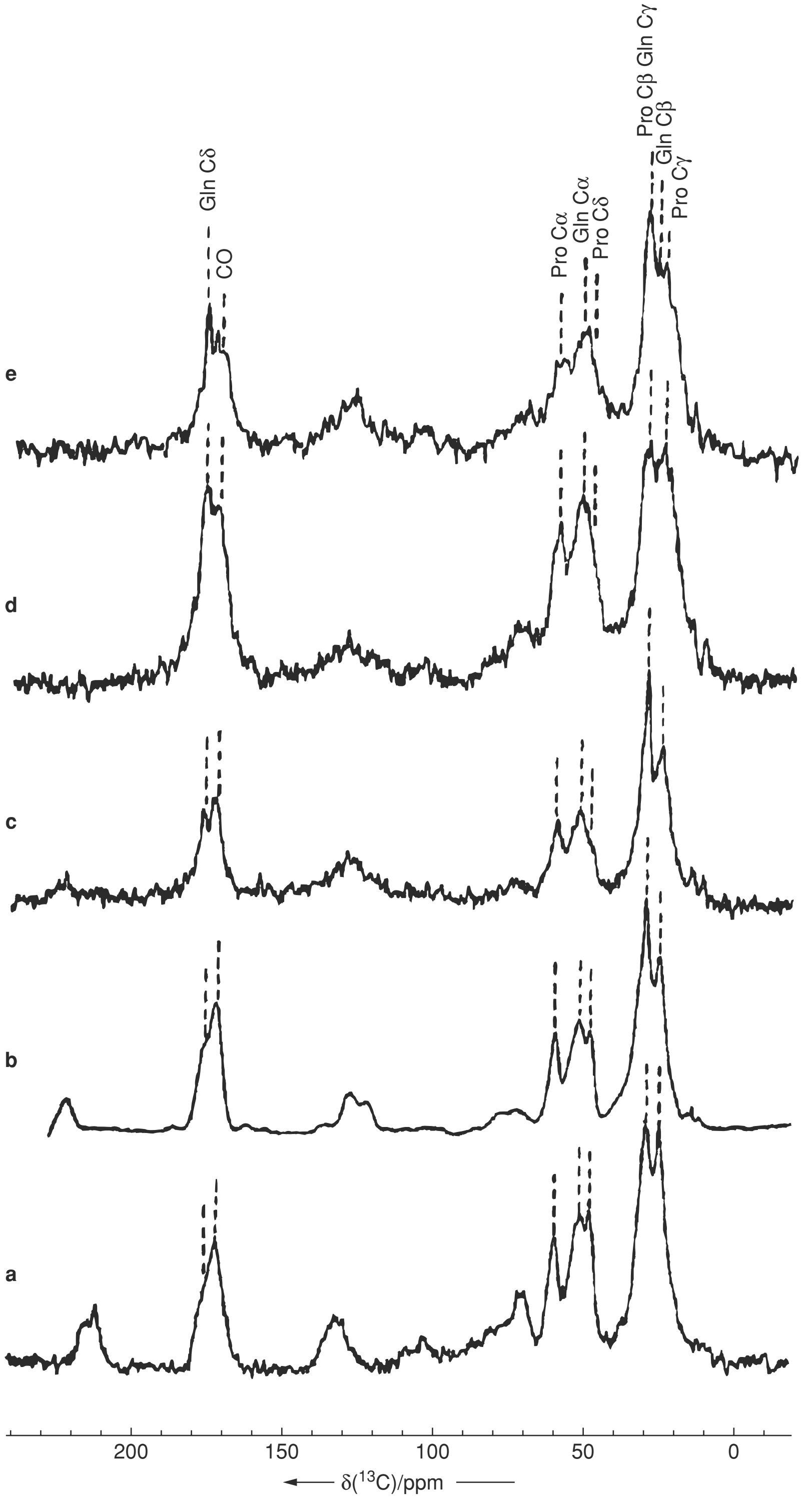

Fig. 3. ^{13}C CP-MAS spectra of ω-gliadins at different hydrations: (a) 0% water, 464 scans; (b) 7% water, 11,720 scans; (c) 19% water, 32,305 scans; (d) 35% water, 5500 scans; (e) 50% water, 17,732 scans (From Ref. [13]).

^{13}C CP-MAS NMR was also employed to the conformational and dynamical study of the hydration of the barley storage protein, C-hordein that is structurally homologous to ω-gliadins [14]. It was found that two types of domains with different mobility were present. It appeared that the relative proportion of rigid and mobile domains was related to the extent of hydration, which was dependent on the proportion of hydrophilic amino acid residues.

High Molecular Weight Fractions

The gluten HMW fraction has been extensively studied due to its high contribution in determining the viscoelastic properties of gluten. HMW subunits are most important in the structure of the wheat proteins glutenins, since they form the backbone of glutenin being linked together by means of disulphide bonds. ^{13}C CP-MAS studies performed on the hydrated proteins helped to individuate some relationships between structural properties and the characteristics of the hydrated network [15]. The decreasing of the signal to noise ratio with hydration, due to higher protein mobility, was analyzed in order to find those structural characteristics that were related to higher or lower mobility. In particular, it was demonstrated that the presence of disulphide bonds was responsible of higher mobility, while the irregular sequences present in chain ends cause hindrance of the network due to the formation of interchain bonds. In absence of irregular chain ends long chain peptides are insoluble in water and form a rather mobile network. The influence of the protein primary structure on the type of network formed was also studied on model systems [16].

^{13}C and ^{1}H MAS studies on HMW subunits helped the elucidation of the structure of the protein segments involved in the loops and trains sections. Trains sections contain glutamine residues close to hydrophobic residues forming hydrogen bonds that hold protein segments together, while loops involve hydrophilic glutamine-rich segments that may also contain glycine. The network formed by the hydrated protein could be further hindered by hydrophobic interactions established by proteins terminal domains [17].

^{1}H MAS spectroscopy was a suitable method to study the effect of hydration on wheat proteins, since the weakened dipolar interactions that characterize these systems enable the acquisition of well-resolved ^{1}H NMR spectra. The resolution of protein spectra was significantly improved using HR-MAS spectroscopy [18] that allowed the application of 2D experiments to obtain the assignment of the protein structures. Considerable shifts were observed for some resonances, relative to the chemical shifts of amino acids in solution, indicating that specific interactions occur in the hydrated protein network. Moreover, evidences were found about the existence of two main environments for glutamine residues: one situated in protein segments adopting the β-sheet conformation, remaining relatively hindered, and the other associated to a more mobile section, possibly adopting a β-turn configuration.

Gluten

Dry and hydrated gluten was directly analyzed by ^{13}C CP-MAS NMR and Single Pulse Excitation (SPE)-MAS experiment [19,20]. While cross polarization detects the solid-like parts of the samples, because the present signals are due to carbon nuclei strongly coupled to protons via dipolar interactions, only mobile nuclei generate signal in SPE experiment (Figure 4). Therefore these two approaches are different and give complementary information about local chemical environments and mobility. It was shown that resonances of residual starch and protein backbone carbons are enhanced in CP spectra of dry gluten, suggesting that they are located in rigid domains. Lipid carbons and glutamine side-chain carbonyl groups are clearly visible only in SPE spectra, indicating that they are present in a more mobile environment. With hydration, starch and proteins gave signals with a lower signal to noise ratio, due to a higher mobility of these fractions, more pronounced for proteins than for starch. The $T_{1\rho}$(H)values of the hydrated gluten were similar for all the carbon resonances. This result is indicative of a mixing among the different domains of the samples (protein backbone, side-chains and starch), induced by hydration.

^{13}C CP-MAS NMR gluten spectra did not differ when various baking quality wheat samples were compared; therefore no correlation was found between protein environment sampled by the technique and the baking quality [19].

^{1}H MAS spectra of hydrated gluten contain well-resolved signals due to lipids, while protein aliphatic chains give broad resonances. As in the spectra of hydrated ω-gliadins, resonances of backbone and side-chain NH groups were observed, supporting the loop and train model.

The variations of gluten due to heating/cooling processes were checked to understand its behavior, at a molecular level, during the baking process. From the study of the relaxation times it was shown that gluten protein aliphatic peaks have an increase of T_2 with heating and a decrease with cooling, which indicates the reversibility of the dynamic changes. The increase of line width at half height of water in gluten samples during heating and cooling was interpreted as reflecting an increasing hindrance of the system.

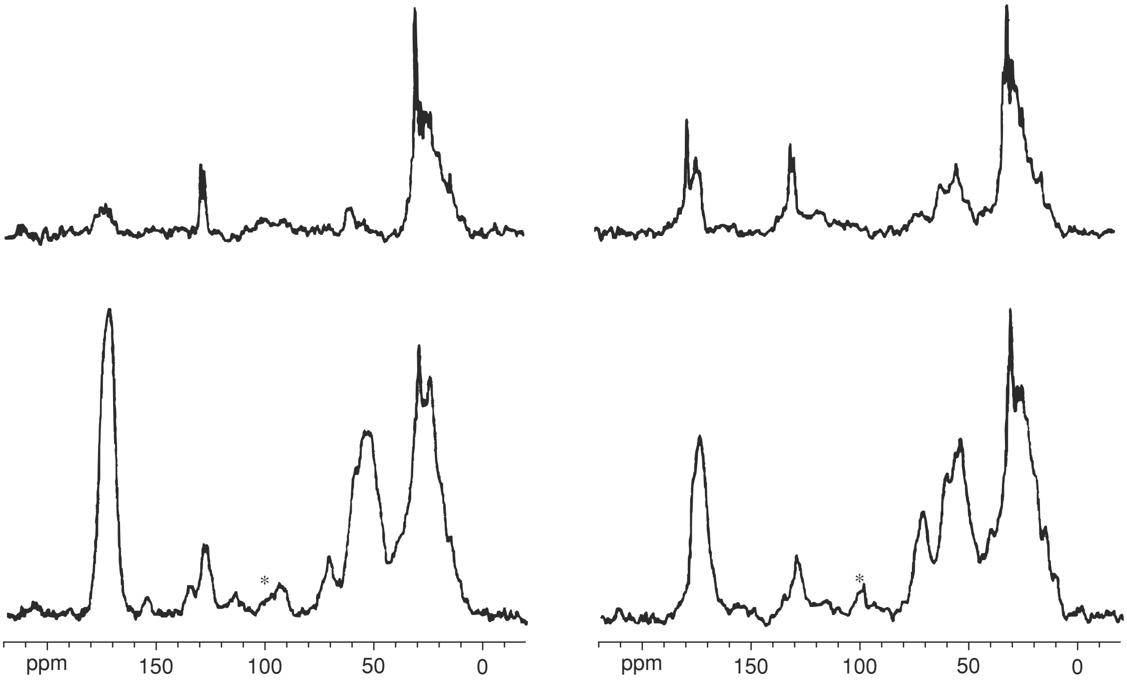

Fig. 4. ^{13}C NMR spectra recorded by means of SPE and CP experiments on dry (sample A, left) and H_2O hydrated (sample B, right) gluten: (top) SPE; (bottom) CP. All experiments were performed under MAS conditions at a spinning rate of 6 kHz; asterisks denote spinning sidebands (Adapted from Ref. [20]).

Starch

The behavior of starch upon heating was investigated in order to understand the processes that occur to this dough component during baking. Starch contains both crystalline and amorphous structures. Its crystalline nature is revealed by the pattern shown by the C_1 glucose peak, resonating at 101 ppm. In particular, in the A-type crystalline form, typical of cereal starches, it appears as a triplet, while in B form, typical of tuber starches, it is a doublet. The existence of a distinct amorphous region was suggested [21] by the presence of peaks resonating at 103.3 and 82.0 ppm having different rotating-frame relaxation rates compared to peaks of others starch protons. These peaks were assigned to random single helices present in the (1→6) linked branching regions.

The major noticeable change in the ^{13}C CP-MAS NMRspectra of heated starch was the loss of signal intensity due to the increased mobility associated to its gelatinization. Anyway, the increase in relative intensity of peaks originated from the amorphous region was also observed. This means that upon gel formation the amorphous form of starch is the dominant component.

The effect of heating and cooling process was studied on starch fractions extracted by wheat flours [22]. From relaxation measurement it emerged that T_2 of water decreases during heating, due to the formation of a starch gel at high temperatures. This parameter decreases during cooling, probably for separation of water from starch, due to starch precipitation. This explanation is consistent with the broadening of starch peak upon cooling and from T_2 values. The addition of the flour oligosaccharides pentosans to the isolated starch resulted in a more mobile network and in a starch higher organization upon cooling.

Bread

Spectra of bread are similar to those obtained for starch gels. During storage of some breads, an increase of C_1 signal intensity revealed a decreased molecular mobility due to starch crystallization or retrogradation. Traces of B-type configuration were revealed in aged breads through the inspection of C_1 resonance patterns. These observations were supported by X-ray diffraction data [23].

Some authors studied the effect of glycerol addition on starch rigidity of bread samples stored with and without crust [23]. The addition of glycerol determined the lowering of signal intensities, revealing a decrease in the rigidity of starch. Breads stored with crust gave higher signal intensities, probably due to higher level of rigid domains.

^{1}H HR-MAS NMR spectroscopy was applied to the analysis of typical bread samples of southern Italy [24]. Apart from the difference in the total lipid content (higher in flours than in bread) substantial differences between the ^{1}H HR-MAS NMR spectra of a bread crumb and of the relative flour were noticed. Two considerably intense signals appear in the crumb spectrum (respectively at 1.91 and at 2.43 ppm). Their assignment was made on the basis of the HSQC ^{1}H-^{13}C spectrum (with ^{13}C signals resonating respectively at 23.12 and 33.09 ppm) and the aid of chemical shifts found in literature [25]. The observed signals were assigned to acetic and succinic acids, formed as a consequence of secondary fermentation processes. These compounds were determined in other analyzed crumb samples and were also detected in the dough before cooking. Nevertheless the amount of these acids was variable in different crumb samples and, in some cases, succinic acid could not be easily detected. The dependence of these differences on the type of yeast, fermentation, and cooking conditions is under investigation. In the sugar region (3–5.5 ppm) of the crumb spectrum it was possible to point out the absence of some peaks present in the flour spectrum. This was due to the scission of some polysaccharides into simple sugars that undergo fermentation. In the crumb TOCSY spectrum a correlation peak was found between resonances at 4.15 and 1.39 ppm, which was absent in the flour spectrum. Neither of these proton resonances could be identified in the monodimensional spectrum due to overlapping with more intense signals. This peak was attributed to lactic acid, formed during fermentation processes, according to the ^{13}C chemical shift values in the heterocorrelated spectrum.

There were no salient differences between the crumb and the crust spectrum of the same bread except for the 3–5.5 ppm range of the latter due to the effects of partial crust carbonization.

High-Resolution Magic Angle Spinning NMR Spectroscopy of Fruits and Vegetables

Ana M. Gil and Iola F. Duarte
Department of Chemistry, CICECO, University of Aveiro, 3810-193 Aveiro, Portugal

Nuclear magnetic resonance (NMR) spectroscopy has long been applied to the detection and quantification of plant and fruit extracts, often after some kind of separation/purification treatment for simplification and concentration of the system. The challenge remaining regards the application of NMR to heterogeneous and intact systems, so that full use of the non-invasiveness of NMR is made. Tackling physically inhomogeneous materials such as intact fruits and vegetables or some of their components (e.g. skin, pulp, pips) must take into account that different physical phases are characterized by distinct magnetic susceptibilities and that anisotropic effects such as chemical shift anisotropy and internuclear dipolar interactions play increasingly important roles in semisolid and solid materials. The NMR lines in the spectrum are broadened to an extent related to the strength of the effect. Magnetic susceptibility effects may lead to hundreds of Hz to kHz line broadening, depending on the nature of the phases, whereas dipolar interactions may broaden NMR signals up to tens or even hundreds of kHz, in the extreme case of rigid solids. In order to recover spectral resolution, magic angle spinning (MAS) is employed. This consists of spinning the rotor containing the sample around an axis making an angle of $54^\circ 44'$ with the direction of the external magnetic field B_0. Detailed descriptions of this procedure and its principles may be found elsewhere [1,2]. A necessary condition for MAS to result in satisfactory line narrowing is, however, that the spinning speed is at least of the same order of magnitude as the line broadening interaction. In the case of intact fruits, resolved spectra of tissues are typically achievable at spinning rates <1–2 kHz, whereas harder parts or components will require faster rates. In some cases, plasticization or swelling of the materials may be required to enable a resolved spectrum to be obtained, using technically achievable spinning rates, without risking mechanical damage of the sample (usually maximum rates used are 4–6 kHz). The designation of high-resolution (HR) MAS has typically been applied to the observation of the ^1H nucleus under specific conditions (described below) that allow resolution improvement relative to the standard MAS method. However, due to the very limited applications of ^1H HR-MAS to fruits and vegetables, the present text will also review the applications of standard ^1H and ^{13}C MAS to those samples.

MAS NMR was for the first time applied to intact fruit tissue for the observation of ^{13}C [3]. ^{13}C MAS spectra of intact grape, peach, persimmon, banana, and apple tissues were obtained. Low spinning speeds (300–1000 Hz) were found sufficient to reduce susceptibility broadening and obtain suitably resolved spectra. Assignment was aided by observing ^1H–^{13}C scalar couplings in spectra recorded with no proton decoupling. Fructose, glucose and sucrose could be quantified by integration of the corresponding signals in the ^{13}C MAS spectra. Measurement of nuclear Overhauser effect and carbon spin–lattice relaxation times (T_1) allowed the dynamic characterization of the sugars, found to undergo isotropic tumbling at rates close to those found in pure sugar solutions. ^1H MAS NMR was, very shortly after, applied to the fruit tissues of grape, banana, and apple [4]. In the absence of MAS, the spectra were line broadened mainly by magnetic susceptibility heterogeneity. The use of standard MAS enabled the detection of components at levels as low as 0.01% of fresh sample weight. Water, glucose, fructose, sucrose, organic acids (malic, citric, and tartaric), and total fatty acyl lipids were quantified by integration. The potential use of the method for non-destructive food analysis is stressed by the authors. Further work clearly showed that MAS NMR only provides information on the less rigid phase(s) of the system. The chosen example was banana tissue [5], for which the solid phase (dominated by starch) was characterized by cross-relaxation NMR and the liquid phase by ^1H MAS NMR. Quantification was achieved in both solid and liquid phases over the duration of ripening and, whereas starch decreased from 20 to 2% of fresh weight, the three main sugars were found to increase, partially due to the conversion of starch.

In recent years, MAS NMR of fruits has been performed making use of the increasing magnetic fields available and the technical development of HR-MAS. HR-MAS involves the use of a high-resolution probe usually optimized for the observation of ^1H in liquids and semisolids, with the possibility of employing MAS for the latter. In addition, the use of MAS rotors with bottom and (optional) top inserts reduces phase separation

and solvent evaporation, as well as reducing magnetic susceptibility effects, thus leading to improved resolution. HR-MAS of mango fruit tissue was carried out as a function of ripening enabling compositional changes to be followed in high molecular weight components, e.g. pectins, lipids and polyphenolics, as well as in small compounds mostly present in the liquid phase [6]. Figure 1a shows the full 400 MHz ^{1}H HR-MAS spectrum of mango pulp and Figure 1b shows the changes taking place in the aromatic region of spectra. *J*-resolved, total correlation spectroscopy (TOCSY; Figure 2) and ^{1}H–^{13}C correlation experiments were performed, thus allowing detailed assignments to be made. A list of compounds found in mango was reported and differences between pulp and juice compositions discussed. More recently, 600 MHz HR-MAS was used to determine the detailed composition of tomato pulp of different cultivars [7]. This work describes the comprehensive use of a combination of high-resolution experiments [*J*-resolved, correlation spectroscopy, TOCSY, diffusion ordered spectroscopy, heteronuclear single-quantum coherence (HSQC), and heteronuclear multiple-bond correlation (HMBC)] to

establish the composition of tomato pulp and differences between two selected cultivars. Figure 3 demonstrates the high quality of the 1D spectra registered under HR-MAS conditions. Differences between pulp and juice compositions were discussed and the potential of the technique, in tandem with statistical analysis, for the rapid characterization of tomatoes is advanced.

Applications of ^{1}H HR-MAS to fruits are still limited, no studies having been reported on intact vegetable samples. However, applications of HR-MAS to selected fruit and vegetable components, rather than to the intact products, are also worth mentioning. The study of plant cutin, one of the main polymeric lipid components found in plant cuticles, has attracted particular attention [8–10]. The knowledge of cutin molecular architecture has been hindered by its insolubility and it was found that ^{1}H MAS and ^{1}H HR-MAS of cutin swelled in DMSO gives valuable information on cutin structure [8–10]. Solvent swelling enhances molecular mobility and this enabled well-resolved 600 MHz ^{1}H HR-MAS spectra to be obtained for lime cutin as well as for potato suberin [8]. Analysis of the corresponding ^{1}H–^{13}C HMBC spectra enabled valuable structural information to be obtained. More recently, a detailed account of HR-MAS of tomato cutin has been reported [10], with information added from solid-state ^{13}C NMR methods. The use of 1D and 2D TOCSY and HSQC (Figure 4) experiments under HR-MAS conditions enabled detailed through-bond connectivities and assignments to be made for tomato cutin. Structural findings indicative of the existence of cutin cross-linking were reported for the first time.

Introduction

Wheat flour is the most important ingredient in baked food products. Rheological properties of dough, which are recognized to be central to the successful manufacturing of cooking products, are governed by the interactions of water, which represents 40–46 wt% of the mixture, with the main components of flour, namely, starch (65–75 wt%) and proteins (8–18 wt%). The water-insoluble fraction of flour, obtained as a rubbery mass with peculiar viscoelastic properties by gently washing a dough in an excess of water or dilute salt solution, is called gluten. Gluten is composed by a heterogeneous mixture of proteins (75–85 wt%), classified into the two main groups of glutenins and gliadins on the basis of solubility, residual carbohydrates (10–15 wt%, mainly starch), and lipids (5–10 wt%). During the kneading process, gluten interacts with water forming a cross-linked network filled with starch granules allowing the formation of viscoelastic doughs, capable of trapping gases produced during fermentation processes in the preparation of baking products. Therefore, the microscopic origin of dough properties, and thus the structural and dynamic changes induced on flour components upon hydration at a molecular level, is of great practical interest.

Among the techniques allowing flour and gluten to be studied in the solid state, either dry or hydrated, solid-state NMR (SS-NMR) spectroscopy has proved to be particularly successful in investigating molecular structure, conformational order and dynamics. In the last three decades, SS-NMR has been increasingly applied to characterize the main components of flour: particular emphasis has been given to the investigation of amorphous and crystalline states of starch, properties of gluten proteins, water organization and mobility, average size of domains with different composition, as well as influence of hydration on the structural and dynamic properties of flour components. To this aim, several high and low-resolution SS-NMR techniques, including the measurement of relaxation times, have been used.

In this section, a survey of high-resolution SS-NMR applications to dough and gluten is presented; the reader can refer to other sections of this handbook for high-resolution SS-NMR applications to starch (high-resolution solid state NMR of starch) and for relaxation studies (relaxation time measurements in water/seed proteins, relaxation time measurements in dough and gluten, relaxation time measurements in water/starch granules and gels). The nuclei investigated in high-resolution SS-NMR studies of flour and gluten are ^{1}H and ^{13}C. Wideline (static) ^{1}H spectra of flour and gluten exhibit no chemical shift resolution, but reveal the presence of components with different mobility which can be quantified by means of suitable free induction decay (FID) analysis techniques. By magic angle spinning (MAS) spectral resolution can be recovered only for the mobile components of the samples, the faster spinning frequencies currently available on most solid-state spectrometers (15–35 kHz) being less than the rigid component line width. The chemical composition of mobile and soluble fractions can be also characterized by high-resolution MAS (HR-MAS) techniques, which allow a liquid-like spectral resolution to be obtained on solvent-added semi-solid samples thanks to a special probe and rotor design [1].

High-resolution ^{13}C spectra can be recorded on solid samples by combining MAS and high power decoupling (HPD) techniques; chemical shifts are determined not only by the chemical structure, as in liquids, but also by molecular conformations and/or crystalline packing. In the case of dough and gluten, this allows different crystalline and amorphous phases to be distinguished directly from chemical shift, but line broadening due to the heterogeneous composition and conformational distribution present in these samples often limits the spectral resolution. Two kinds of ^{13}C MAS NMR experiments, namely single pulse excitation (SPE) [2] and cross-polarization (CP), are usually carried out on flour and gluten samples and their comparison is exploited to highlight differences in carbons chemical environment and mobility. In fact, while the SPE experiment is in principle quantitative, provided a recycle time is used long enough to allow complete relaxation of all ^{13}C nuclei, the CP experiment enhances signals of carbon nuclei strongly coupled to protons via dipolar interactions, i.e. in proton-rich and rigid environments. Signals from carbons in mobile domains can be usually highlighted in SPE spectra with short recycle times (e.g. 2 s) because of their fast spin–lattice relaxation.

© 2008 *Springer.*

Further discriminations among ^{13}C nuclei belonging to domains with different mobility can be performed on the basis of the relaxation behavior of protons which have dipolar couplings to them by using modified-CP pulse sequences. For instance, delayed-CP experiments allow signals arising from rigid phases to be suppressed, due to their short (about 10–20 μs) ^{1}H spin–spin relaxation time (T_2), while ^{13}C spectra of the sole rigid domains can be obtained by short contact time (<100 μs) CP experiments, where only the signals of carbons experiencing strong dipolar C–H couplings appear. Moreover, variable spin-lock time CP experiments may discriminate among carbon nuclei coupled to protons having remarkably different spin–lattice relaxation times in the rotating frame ($T_{1\rho}$) [3].

Gluten

^{13}C MAS

^{13}C CP- and SPE-MAS spectra have been acquired on gluten samples from wheat of different hardness and cultivar, as well as on storage proteins, in either dry or hydrated states; examples of such spectra are shown in Figure 1. In general, the following groups of resonances

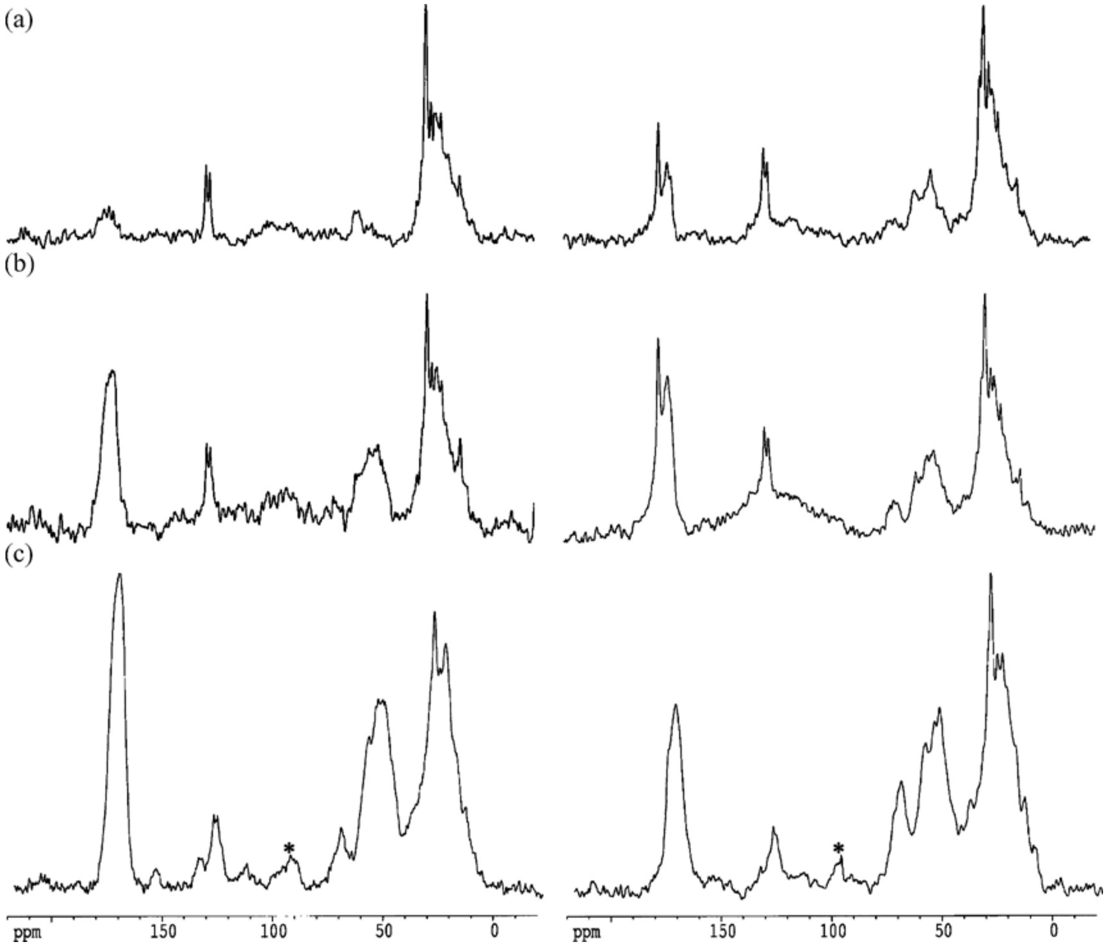

Fig. 1. ^{13}C spectra recorded by means of SPE and CP experiments on dry (left) and hydrated (right) gluten: (a) SPE with a recycle time of 1 s; (b) SPE with a recycle time of 60 s; (c) CP. All experiments were performed under HPD and MAS conditions at a spinning rate of 6 kHz. Asterisks denote spinning sidebands. Reprinted with permission from Ref. [4]. © 2003 Elsevier.

can be distinguished in the spectra and collectively assigned to gluten components: 0–40 ppm (alkyl groups in protein side chains and lipids), 40–65 ppm (alkyl groups in protein main chains), 65–80 ppm (starch), 125–135 ppm (protein aromatic moieties and lipid olefinic carbons), 165–185 ppm (carbonyl groups in proteins and lipids) [4]. Individual contributions of some amino acid residues are recognized within each group of protein resonances. A more detailed interpretation of the spectra in terms of conformations and/or molecular packing can be performed for isolated gluten proteins (for instance ω-gliadins and high molecular weight glutenin subunits), allowing β-sheet, α-helix and β-turns structures to be identified [5,6]. Such detailed attributions are prevented in the case of whole gluten by its heterogeneous character, bringing to a superposition of a considerable number of resonances with slightly different chemical shift values in several regions of the spectrum.

The CP- and SPE-MAS spectra of dry gluten (Figure 1) are somewhat different and their comparison can qualitatively highlight differences in the local structure and dynamics of carbon environments. Signals from starch and protein backbone carbons are enhanced in the CP spectra, indicating that most of these nuclei are located in rigid domains. The mobile fraction of gluten is constituted by lipids (narrow peaks in the 125–135 ppm and, in part, 0–40 ppm spectral regions) and protein side chains (0–40 ppm), as observed from SPE spectra acquired with a short recycle time. Spectra of components with different mobility can be also selectively recorded by resorting to modified-CP techniques, exploiting differences in ^{1}H T_2 and $T_{1\rho}$ relaxation times, as well as on CP times T_{CH}. In particular, it has been observed that protein side chain signals only contribute to a delayed-CP spectrum recorded with a delay of 40 μs and a contact time of 1–2 ms [4], while a CP spectrum recorded with a very long contact time (20 ms) shows signals from lipids only [7]. Upon hydration with a water amount suitable to obtain a cohesive elastic mass (60–100 g of water per 100 g of dry gluten), plasticization of gluten proteins occurs, as clearly indicated by the presence of signals from protein main chain carbons in SPE spectra acquired with short recycle times; however, considerable protein and, especially, starch fractions remain quite rigid as it can be inferred from the comparison between CP spectra of dry and hydrated gluten (Figure 1c). Changes in the dynamics of proline and glutamine residues upon hydration have been highlighted on either whole gluten or its isolated proteins: the side chain carbonyl carbon of glutamine surrounded by water molecules gives rise to a well distinct sharp peak at 177 ppm, strongly enhanced in SPE spectra (Figure 1a and b); proline Cδ (48.6 ppm) and Cγ (25.5 ppm) peaks have been observed to decrease in intensity in CP spectra by increasing the water content because of the speeding up of ring puckering [5,6]. The high-resolution of the ^{13}C spectra also allows the indirect measurement of ^{1}H spin–lattice relaxation times, that, being affected by the spin diffusion process, contain important information on the average dimensions of the different domains present in gluten. For instance, it has been shown [4] that hydration causes an intimate mixing between protein and residual starch domains, otherwise separated on a 200 Å spatial scale in dry gluten. ^{13}C MAS experiments are useful in unraveling dynamic rather than structural differences in gluten; in fact, while ^{13}C CP-MAS spectra of different protein fractions do not show significant differences, mainly because of their similar amino acid compositions, suitable sets of selective experiments allow domains with different dynamic behavior (lipids, storage proteins with different solubility properties, protein backbone, and side chains) to be singled out without requiring sample pre-treatments which could alter the physicochemical properties of the sample. Therefore, any attempt to correlate ^{13}C CP-MAS spectral features of dry gluten or protein fractions with wheat hardness, cultivar, and breadmaking quality has failed so far [7–9]. On the other hand, ^{13}C high-resolution SS-NMR experiments, in combination with ^{1}H high and low-resolution NMR techniques, revealed particularly successful in understanding properties of hydrated gluten, such as average domain size, interactions among components and plasticization effects on different components, thus contributing to the formulation of the “loop and train” model [10,11].

^{1}H MAS

The static ^{1}H spectrum of dry gluten shows at least two unresolved signals with half-height widths of a few and a few tens of kHz, respectively, while a more complex superposition of lines is present in the spectra of the hydrated samples, where the broadest component can still be observed, even though with a lower relative intensity, and a narrower signal with a line width of less than 1 kHz is present. Nevertheless, peaks with line widths of the order of a few Hz are never revealed, thus indicating the absence of liquid-like water domains. A much bigger proportion of rigid domains is present in dry than in hydrated samples, indicating a plasticization of gluten upon hydration. On spinning at the magic angle, some fine structure is observable in the spectra recorded on both dry and hydrated samples even at very low spinning rates, indicating the presence of a fraction of nuclei belonging to very mobile groups. However, the broadest line of the static spectrum remains substantially unchanged under MAS conditions up to a spinning rate of about 6 kHz, while at much higher spinning rates (12–15 kHz) it is split into a central band, with a line width of a few kHz, and a series of sidebands. In the spectra of dry gluten resolved signals are mainly due

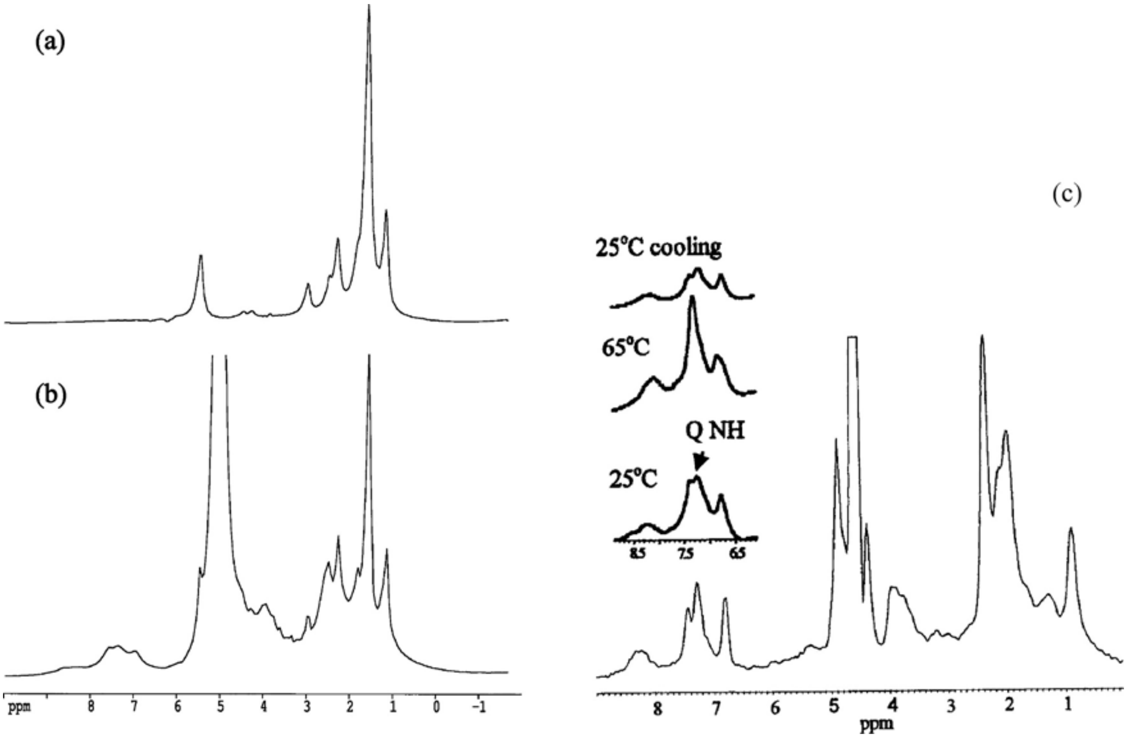

Fig. 2. Expansions of ^{1}H MAS spectra of gluten: (a) dry gluten; (b) D_2O hydrated gluten; (c) D_2O hydrated delipidated gluten. Insets of (c) show NH and aromatic resonances in a sample subjected to heating and successive cooling. Spectra (a) and (b) were recorded with a MAS rate of 12 kHz, while 15 kHz were used in (c). Spectrum (c) was obtained by Gaussian resolution enhancement. (a) and (b) reprinted with permission from Ref. [4]. © 2003 Elsevier. (c) Reprinted from Alberti E. Magnetic resonance studies of cereal proteins and some solid model systems. Ph.D. Thesis. Universitade de Aveiro, Portugal, 2000 and Ref. [12].

to lipid protons (Figure 2a); in those of hydrated gluten several resolved signals ascribable to protons belonging to mobile protein groups are also present (Figure 2b), in agreement with the plasticization effect observed in ^{13}C MAS experiments.

The protein signals have been selectively observed on delipidated gluten samples and a detailed assignment in terms of different amino acid residues has been performed by resorting to resolution enhancement techniques in FID processing (Figure 2c). An assignment of the main resolved peaks present in dry and hydrated gluten spectra is reported in Table 1. The signal due to glutamine side chain NH protons (7.2 ppm) can be exploited to obtain information on the dependence of microscopic phenomena, such as hydrogen bond interactions, on gluten heating and cooling [12].

^{1}H HR-MAS experiments have been performed on ω-gliadins [5] and HMW glutenin subunits [11] (Figure 3a and b). Well resolved spectra have been obtained and 2D techniques typical of solution-state NMR (NOESY, HETCOR, TOCSY) have been employed to perform a detailed assignment of signals.

Flour and Dough

^{13}C MAS

^{13}C CP-MAS spectra of flour [12,13–16](Figure 4c) are dominated by the peaks of starch: resonances from C-1 (96–102 ppm), C-4 (77–83 ppm), and C-6 (59–62 ppm) carbons of α-D-glucose can be easily distinguished, while C-2, C-3, and C-5 carbons all contribute to a signal centered at 70–73 ppm. Line width, multiplicity, and chemical shift of these resonances allow the state of starch to be identified (see “Solid-state high-resolution NMR of starch”); usually broad lines (6–8 ppm line width) are observed, arising from conformational distributions

Table 1: Resonances commonly resolved in proton MAS spectra of gluten, flour, and dough

Chemical shift (ppm)	Assignment
0.9	Lipid CH_3, Leuδ, Valγ
1.2–1.4	Lipid chain CH_2, Thrγ, Alaβ
1.5	Lipid –$\mathbf{CH_2}$–CH_2–COO–
1.7	Leuγ, Argγ
2.0–2.2	Lipid –$\mathbf{CH_2}$–CH=CH–, lipid –CH_2–$\mathbf{CH_2}$–COO–, Proβ, Proγ
2.4	Glnγ, Argβ
2.7	Lipid –CH=CH–$\mathbf{CH_2}$–CH=CH–
3.5–4.0	Starch H2, H6
4.0–4.5	Proδ, protein backbone protons
4.6–4.8	Water
5.2	Starch H1
5.3	Lipid olefinic protons
6.8	Tyrε
7.1	Tyrδ
6.8–7.7	Glnδ
8.0–8.3	Protein backbone–NH

of glucose moieties in amorphous starch. Weak peaks from aliphatic (10–40 ppm) and aromatic (∼130 ppm) side chain carbons and from main chain peptide carbonyl carbons (∼175 ppm) of gluten proteins are also present in the ^{13}C CP-MAS spectrum of flour.

In the ^{13}C SPE-MAS spectrum of flour, recorded with a very short recycle delay (1–2 s) (Figure 4a) [16], the olefin and alkyl carbon signals from lipids, resonating at about 130 ppm and in the range 10–40 ppm, respectively, are clearly observed, because of the mobile nature of lipids in cereal seeds. Signals from starch are also present in SPE-MAS spectra, but the ratio between the intensity of the C-6 peak and that of the other starch peaks is much higher than in the corresponding CP spectra; this feature is ascribable to the shorter ^{13}C T_1 of C-6, due to the interconformational motions of the CH_2OH groups [17].

The ^{13}C CP- and SPE-MAS spectra of dough essentially show the same signals of the corresponding spectra of dry flour (Figure 4) [14,16], but with a different intensity, as a result of the plasticizing effect of water on flour components. For instance, the much lower signal-to-noise ratio for starch resonances in the CP-MAS spectra of dough clearly indicates the presence of less rigid starch domains; however, these domains do not reach a very mobile regime, since they do not give rise to remarkable changes in the SPE spectra recorded with a short recycle delay. On the other hand, SPE spectra of dough clearly show the presence of signals peculiar to hydrated gluten, already pointed out in the Gluten—^{13}C MAS section, thus indicating that gluten, experiencing a dramatic increase of mobility upon hydration, is the component of flour mainly interacting with water. Evidences of different interactions between water and gluten proteins from hard and soft wheat have also been reported [14].

[20]. © 2003 Society of Chemical Industry (permission granted by John Wiley and Sons Ltd.)

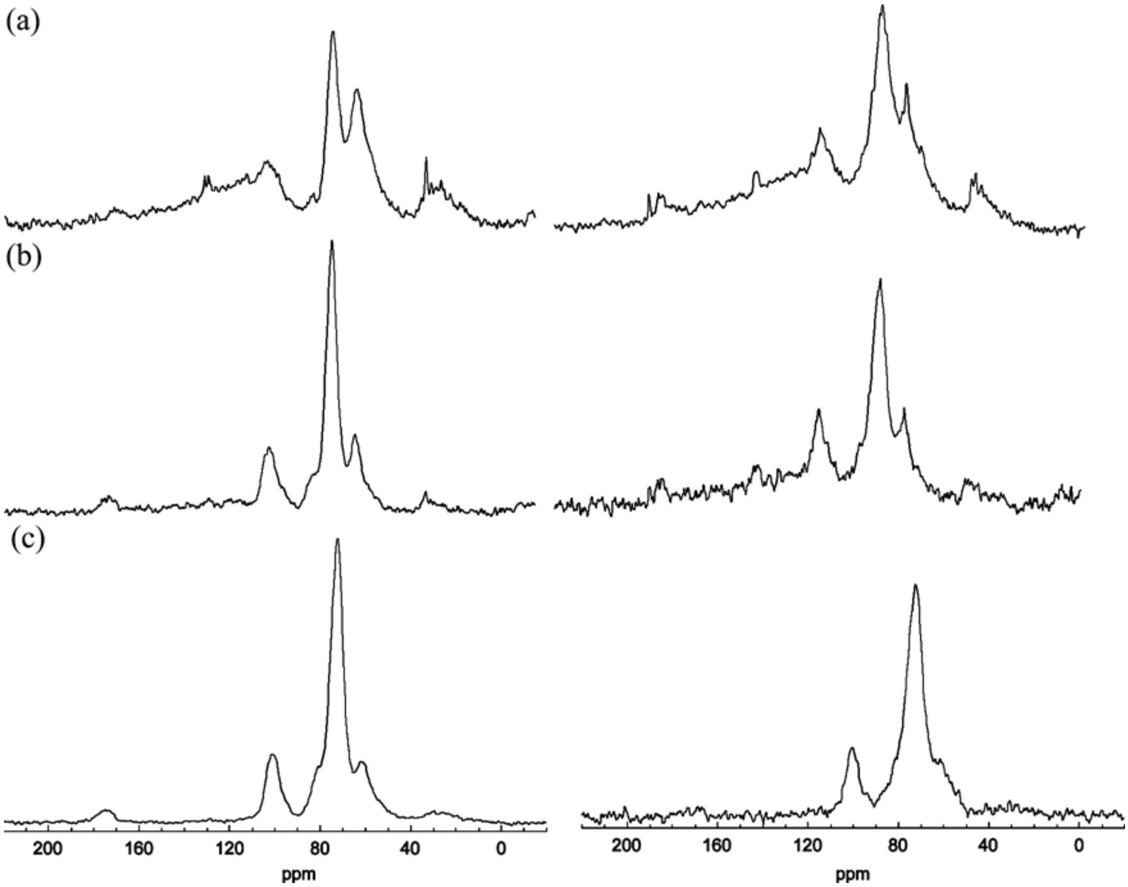

Fig. 4. ^{13}C spectra recorded by means of SPE and CP experiments on flour (left) and dough (right): (a) SPE with a recycle time of 2 s; (b) SPE with a recycle time of 60 s; (c) CP with contact time of 1 ms and recycle time of 5 s. Spectra (a), (b), and (c) were recorded with 10,000, 1000, and 2000 scans, respectively, at a Larmor frequency of 75.47 MHz. All experiments were performed under HPD and MAS conditions at a spinning rate of 7 kHz.

^{1}H MAS

At room temperature, the static ^{1}H spectra of dry flour samples consist of at least two unresolved signals with half-height widths of about 2 and 50 kHz (Figure 5b), corresponding to two main components with high and low mobility, respectively [16]. In the spectra recorded under MAS conditions (Figure 5a and d), some fine structure is observed even at very low spinning rates (500 Hz), arising from the resolution of the narrower line; this resolution improves up to spinning rates of 1.5–2 kHz, but no significant changes are observed increasing the spinning rate further. Resolved signals can be ascribed to lipids, which therefore represent the most mobile fraction of flour, in agreement with what observed in ^{13}C SPE-MAS spectra, and, to a lesser extent, to proteins (Table 1) [4,18]. At high spinning rates (above 6 kHz) a partial splitting of the broader resonance into large spinning sidebands is observed, due to the inhomogeneous component of the homonuclear dipolar interaction, which, however, is not particularly informative.

In the room temperature static spectra of dough, two unresolved signals are present as in those of dry flour, but with approximately halved line widths and a much bigger proportion of the narrower signal (Figure 5c). As in the case of hydrated gluten, no liquid-like water can be detected. In the high-resolution spectra of the mobile fraction of dough, obtained by MAS (Figure 5f), signals due to protons of bound water (about 4.7 ppm), starch (about 3.8 ppm), as well as aromatic (6.8–7.3 ppm) and

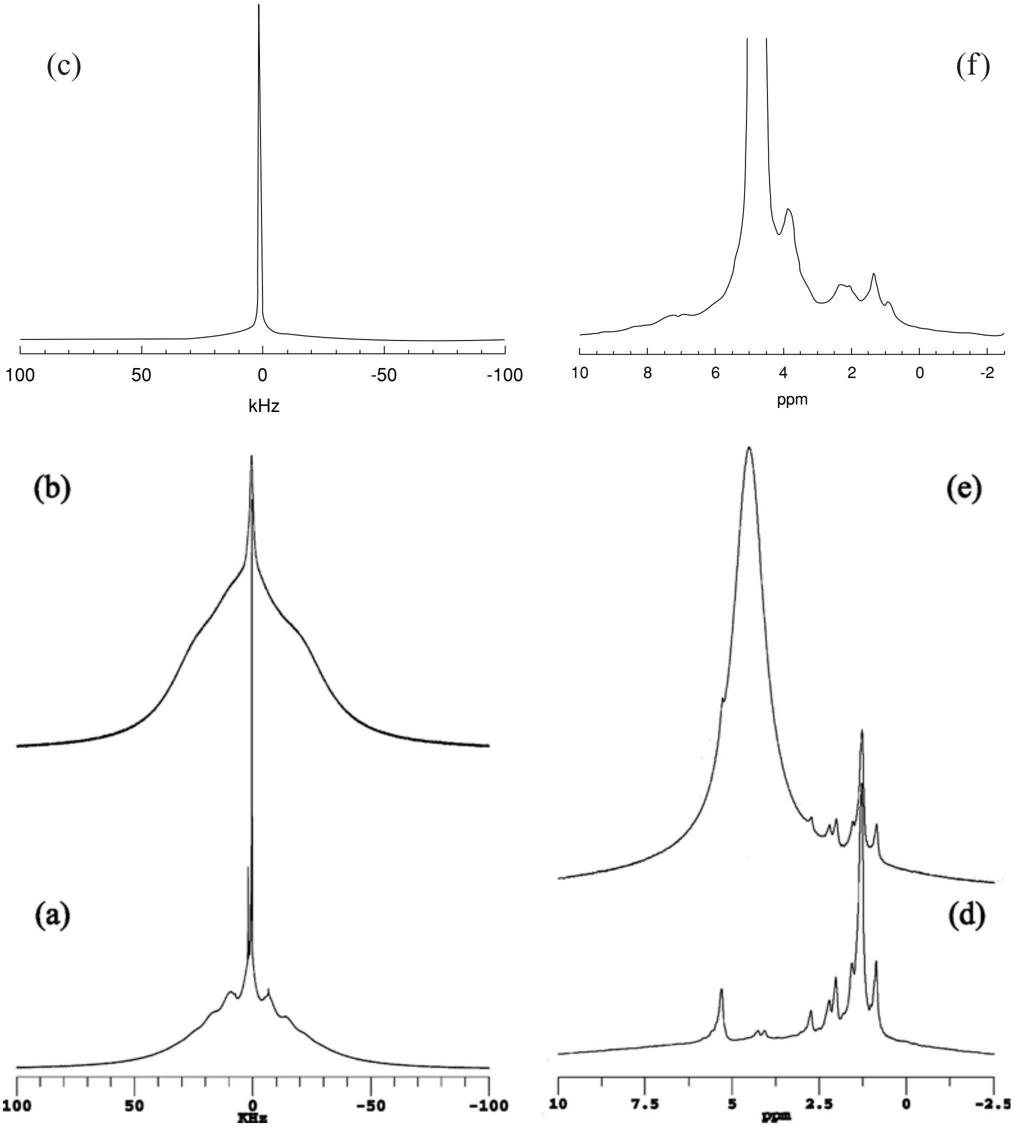

Fig. 5. (a) ^{1}H MAS spectrum of dry flour; (b) ^{1}H static spectrum of dry flour; (c) ^{1}H static spectrum of dough (45 wt% of water); (d) expansion of (a); (e) expansion of the ^{1}H MAS spectrum of naturally hydrated flour (∼14 wt% of water); (f) expansion of the ^{1}H MAS spectrum of dough (45 wt% of water). MAS spectra were recorded with a spinning rate of 7 kHz. (a), (b), (d), and (e) reprinted with permission from Ref. [16]. © 2004 American Chemical Society.

NH (8.0–8.3 ppm) protein groups are present in addition to those observed for dry flour. ^{1}H HR-MAS NMR spectroscopy has been recently applied to hydrated flour samples [18–20]. Spectra with more than 80 signals (Figure 3c and d) are obtained, where sharp resonances are mainly due to simple saccharides, whereas broader signals are ascribed to lipids (signals in the 0.8–2.7 ppm range) and polysaccharides (signals in the central spectral region). A quite accurate peak assignment has been performed [18] taking advantage of the fact that HR-MAS NMR spectroscopy allows the application of high-resolution 1D (CPMG, NOESY) and 2D (TOCSY, HMQC, HSQC) techniques. If combined with a suitable multivariate statistical analysis, ^{1}H HR-MAS can be considered a promising technique for assessing the geographical and varietal origin of wheat flour, avoiding the drawbacks connected with the pre-treatment of the samples and requiring a reasonably short time for the analysis.

High-Resolution Solid-State NMR as an Analytical Tool to Study Plant Seeds

Michel Bardet, Marie Françoise Foray, and Armel Guillermo
Service de Chimie Inorganique et Biologique, Département de Recherche Fondamentale sur la Matière Condensée,
CEA-Grenoble, 38054 Grenoble, Cedex 9, France

Introduction

High-resolution solid-state NMR has found widespread applications in various fields of agricultural and food sciences [1–6]. The technical improvements of high-resolution solid-state NMR have been tremendous for the last 10 years; the sensitivity and the design of probes, the setting and the control of spinning rates at the magic-angle spinning (MAS), the decoupling power strength, the decoupling schemes, and the large number of available pulse sequences are certainly among the most significant technical improvements [7,8].

In that respect seeds are valuable biological materials to be studied with high-resolution solid-state NMR. The initial interest of high-resolution solid-state NMR studies on seeds appeared undoubted in the possibility of a rapid and non-invasive *in situ* characterization of the lipid moiety of seeds with ^{13}C or ^{1}H NMR [9–14]. The large number of studies concerning the oil compositions of seeds gives a clear illustration of this assertion. Lipids can be one of the most abundant constituents of seeds, in oleaginous crops for instance [15–17]. Lipids are very important components not only on a biochemical point of view but also for economical aspects. Indeed, they are a major source of renewable energy and they do not participate to CO_2 enrichment of atmosphere.

An important aspect that has to be taken into account is that the mature seeds are, in most of cases dormant organisms, therefore the gas exchanges are very low [18]. Therefore, seeds can be kept in non-biological environments such as those met inside the rotors, tight cylinder containers, required in CP/MAS probes. Recording NMR spectra of dormant seeds under MAS does not require specific equipments to maintain aerobic conditions such as those required for *in vivo* NMR studies that are performed on cell suspensions or living tissues [19]. Up to now the CP/MAS experiments have not appeared to damage seeds using spinning rates up to 12,000 Hz. This point can be easily demonstrated by performing germination tests on the seeds that were used for NMR experiments. Nevertheless, very high spinning rates, such as 32,000 Hz, have to use with care since roughly a 60 °C temperature increase can be recorded for the samples if no cooling is employed.

Spectral Edition Inside the Seeds

For NMR methodology development, seeds represent an interesting example of a complex biological material. The complexity arises both from their heterogeneous chemical composition and from their specific organization at a cellular scale and at a macroscopic level, that is to say teguments, cotyledons and embryonic axes. The food reserves that are required during the germination are mainly fats (oils), carbohydrates, and proteins. According to the nature and biological origins of seeds, their relative amounts are extremely variable.

Generally, triacyglycerols (TAG) are the form of fat or oil storage and are contained in small subcellular droplets called oil bodies [20]. The natural biological variation found in the types of food reserves is a property that has been fully used by seed producers to select or modify seeds in order to improve the quality or the quantity of these reserves. As a result, from the point of view of NMR spectroscopy, liquid and solid properties of dormant seeds are expected. These behaviors can be defined by NMR through the consequences of the molecular mobility on the more or less complete averaging to zero of the proton–carbon dipolar interactions.

Solid-Like Domains

With the commonly used CP/MAS experiments that combines proton to carbons cross-polarization (CP) transfer and MAS. This sequence is therefore devoted to observe carbons with strong dipolar interactions with the surrounding protons, because of that all the carbons belonging to rigid domains can be observed as shown in Figure 1A.

Liquid-Like Domains

The carbons spectra of mobile compounds can be selectively observed by direct polarization with single-pulse

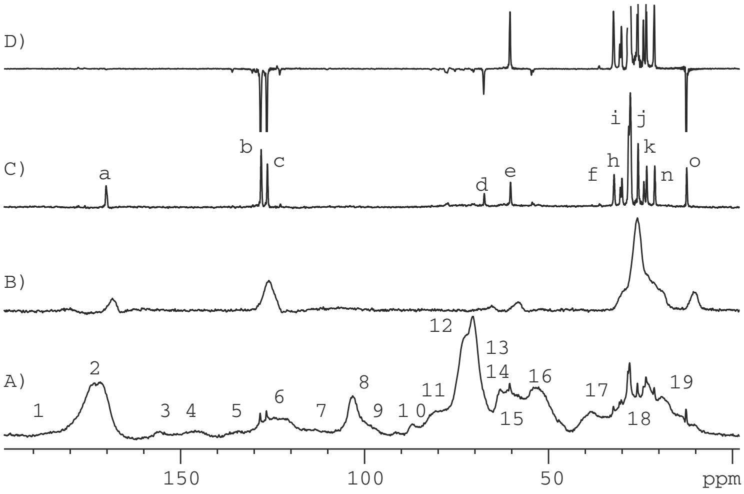

Fig. 1. 100 MHz ^{13}C high-resolution solid-state NMR spectra of *Lactuca sativa* seeds recorded with: CP/MAS experiment (A), SP experiment without sample spinning (B), and SP/MAS experiment (B), SP/MAS experiment (C), and DEPT experiment with a $3\pi/4$ polarization transfer pulse without sample spinning (D).

excitation (SP), proton decoupling being applied during signal acquisition. Nevertheless, this simple sequence has to be combined with rotation (3000 up to 10,000 Hz) of the sample at the magic angle (54.74°) related to the vertical magnetic field) in order to record high-resolution spectra. Otherwise the signals that are recorded in the liquid domains remain broad. The broadening of the signals is easily explained by the magnetic susceptibility anisotropy arising from the strong difference between the susceptibility of seeds and the air filling the space available between seeds. Moreover, the microscopic magnetic susceptibility gradients inherent in seed tissues also contribute to line broadening. These different aspects are exemplified with spectra B and C in Figure 1, that shows typical ^{13}C spectra of liquid-like domains of *Lactuca sativa* seeds recorded with direct polarization of carbons either under static or MAS conditions.

It is worth noting that once the dipolar interactions are averaged by Brownian motions, all the sequences devoted to liquid NMR can be directly applied even on such heterogeneous material.

For instance, the polarization transfer from proton to carbon through their indirect coupling is efficient for the products belonging to liquid domains inside seeds. Thus, the robust DEPT experiment [21] is fully operant, as illustrated in Figure 1D, and allows us to assign the different signals in relation to the number of protons they are bound to, that is to say CH_3, CH_2, CH, and quaternary carbons. Figure 2 gives a 2D example of such sequences with the proton–carbon correlation map recorded with the appropriate 2D heteronuclear experiment. The quality of the correlation map is excellent and illustrates that the use of such sequences appears promising for direct studies of metabolites inside seeds.

Liquid-Like Domains with Residual Dipolar Interactions

Recently we also have shown that it was also possible to detect in the liquid domain [22], the signals of molecules that present residual proton–proton dipolar couplings by using spin echo experiment with proton–proton dipolar decoupling during one of the echo delays. For instance, in the case of *Pisum sativum* seeds broad ^{13}C signals assigned to sugars were shown to present such features.

Assignments of the NMR Signals

Due to the chemical nature of seeds most of the analytical studies carried with solid-state ^{13}C NMR have been performed on lipids and sugar components and a few works have also been reported on proteins of seeds so far [1,23,24]. For the products that present a liquid-like behavior inside the seeds, such as lipids, the amount of available works concerning the assignments of such compounds carried out with liquid-state NMR studies is very important [25–29] and can be used almost directly to identify these compounds and assign their NMR spectra in the whole seeds. In order to help the assignment of spectra recorded on whole seeds, it can be very useful to start analyzes of the different parts of dissected seeds when it is possible, namely teguments, cotyledons, and embryonic axes [2,30]. The assignment of the spectra relies on classical strategies used in NMR, such as analyses of model compounds of the different expected biopolymers combined with analyses of products that can be extracted [31]. Finally, the assignments reported in Tables 1 and 2 give some information on the most common ^{13}C NMR

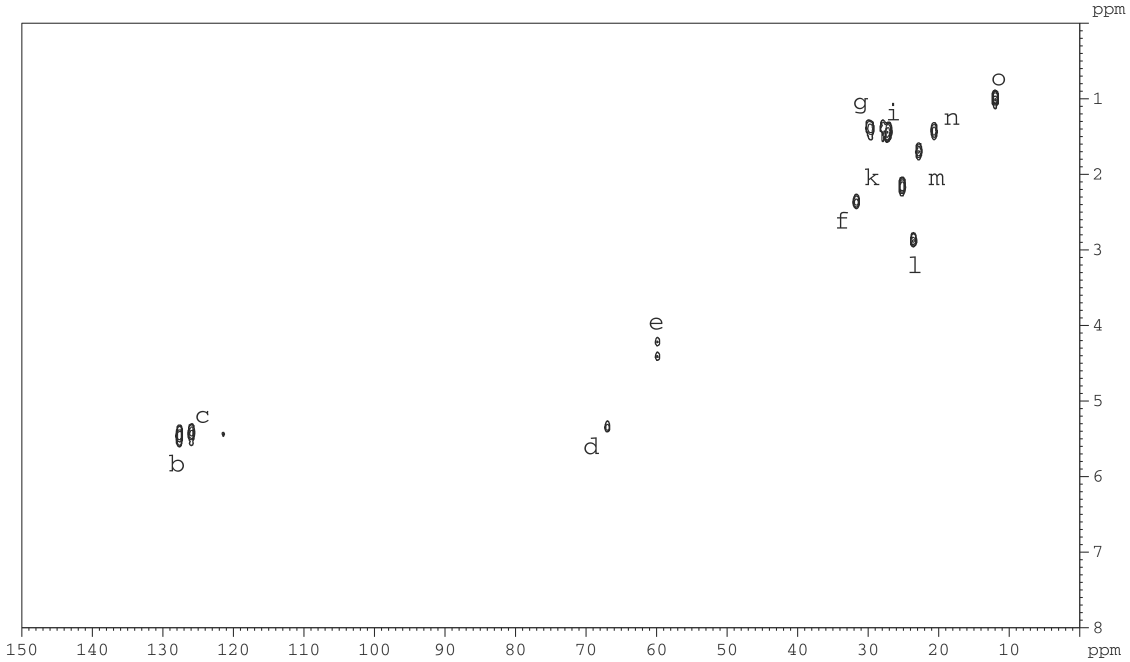

Fig. 2. ^{1}H–^{13}C correlation spectrum of *Lactuca sativa* recorded under MAS.

assignments that can generally proposed for the seeds and can be helpful as a starting point to attribute NMR spectra of seeds. Solid-state NMR has been successfully applied to study physiological processes such as those occurring during the first steps of germination [14]. The assignment of the large number of metabolites that are formed during this process represents certainly the main challenge for this kind of studies. Figure 3 illustrates an example of changes appearing in the spectra of conifer seeds during germination. It can be recalled that provided that some cares are taken, spectra can be recorded under quantitative conditions. Therefore, it is possible to follow kinetic and related experiments.

Solid-State Proton NMR

Proton NMR studies have not been very important so far, several reasons first due to chemical complexity of seeds the proton spectra can appear very broad and featureless as long as the liquid domains of seeds are concerned. If the solid domains are concerned, their proton spectra remain very large even under MAS conditions mainly due to the strong proton–proton dipolar interactions that cannot be averaged to zero. As for classical solid material, CRAMPS multipulse can be used to record high-resolution proton spectra. Generally such studies have concerned relaxation parameter measurements of the seed constituents and of water that are correlated with changes in the biological states of seeds and physiological processes. However, the interpretation of these measurements is not straightforward. The work made by Ridenour *et al.* [32] gives an example of proton NMR of study in the solid state that described the experimental conditions and led to correlate the changes in relaxation parameters with aging of seeds.

Conclusion and Prospects

All these different NMR experiments that have been reported herein can be performed on classical and commercial CP/MAS probes devoted to solid materials. They allow one to edit spectra of solid and liquid domains of seeds. These experiments are easily implemented on modern commercial spectrometers and can be readily carried out either for routine controls of seed sets or for more fundamental researches. The strategy of combining these different experiments is certainly a first step to molecular imaging when working on biological materials. All the modern solid-state NMR experiments that have been appearing for the last 10 years that correlate homo- or heteronuclear chemical shifts should of great interest. They have been already successfully applied to characterize wood or cellulose itself [33,34] but not yet applied, to our

knowledge, to whole seeds. In a near future, the perspective of combining high-resolution solid-state NMR with pulse-field gradient experiments should be a promising development in order to reach localized information about the dynamic of mobile molecules and the size of the subcellular objects on intact biological samples. Other nuclei such as phosphorus or nitrogen should also provide interesting information on these systems.

Introduction

Starch is synthesized from carbon dioxide and water via the plant photosynthesis and is one of the largest storage form of the solar energy. As one of the most abundant biopolymers in nature, starch accounts for up to 90% of cereal seeds based on the dry weight. Apart from being one of important nutrients for mankind and animals, starch has become an important raw material in many applications such as adhesives, biodegradable materials [1], and drug-delivery systems [2]. For the environmental consideration, starch is also important since it is renewable, biocompatible, biodegradable, and synthesized via a pollution-free process. "Complete combustion" of starch returns the same amount of carbon dioxide that plants consumed in synthesizing the polysaccharides, creating no new load to the overall carbon dioxide pool. Therefore, consumption of starch is carbon dioxide balanced for the overall atmosphere.

In industrial applications of starch, it is generally believed that the molecular structure, dynamics, and interactions of the starch polysaccharides are key factors determining starch functionality [3–5]. Elucidation of such properties is, therefore, fundamentally important to understand the mode of actions of starch as the energy storage for plant cells and the starch functionality in applications. For this reason, intensive research has already been carried out on the native starch granules and processed starch using a variety of techniques such as NMR [5–21], X-ray diffraction [20,22–25], microscopy [26,27], and neutron scattering [28,29]. Consequently, substantial progress has been made in understanding the starch structure, which has already been reviewed comprehensively [30–32].

It is now common knowledge that there are two structurally distinct starch polysaccharides [30–32], amylose, and amylopectin. Amylose is a linear $\alpha(1 \rightarrow 4)$-linked glucan (i.e. polymer of glucose) with small amount of $\alpha(1 \rightarrow 6)$ branches having a molecular mass ranging from a few thousand to a few million Daltons. In contrast, amylopectin is the $\alpha(1 \rightarrow 4)$-linked glucan having more $\alpha(1 \rightarrow 6)$ branches with molecular mass ranging from 10^6 to 10^9 Da [30–32]. Both polysaccharides can be in either the amorphous or crystalline forms. In the native starch, these polysaccharides assembled together to form granules with a diameter of 1–100 μm, consisting of layers of the semi-crystalline shells and amorphous growth shells in an alternating fashion [30–32] (Figure 1). The crystallinity of native starch is normally about 15–50% depending on the sources.

The semi-crystalline shells are about 120–400 nm in thickness, almost three times as thick as the amorphous ones, and are formed by so-called "large blocklets" in the "olive shape." The "blocklets," in turn, are formed by some crystalline stacks [30–32]. Within each crystalline stack, there are arrays of amylopectin clusters (Figure 1) arranged in the form of crystalline lamellae (C, Figure 1) or double helices zone (∼5–6 nm) and amorphous lamellae (A, Figure 1) or branching zone (∼4 nm). The gaps between these clusters, as shown in Figure 1, are filled with (∼5 nm) amylose and, in some cases, amylose–lipid complexes [30–32] (V, Figure 1). The X-ray diffraction results showed that there are two types of crystal packings [22–25] for these double helices, types A and B (Figure 1). Type B crystals consist of six double helices arranged in a hexagonal fashion with the middle (channel) filled with some water of crystallization, whereas the type A crystals have another double helix filled the channel of the hexagonal packing [22–25]. Therefore, there are fewer water molecules in type A crystals than type B crystals. Based on the crystal packing, starch granules were classified into three types, A, B, and C, which are found, respectively, in cereal, tuber, and legume.The A- and B-type starches are composed of type A and type B crystal structures, respectively, and C-type starch is a composite of both [21,33–35]. Another type of starch known as V type is the amylose–lipid complex in the form of single helix [17,18,36].

Among many physical techniques, high-resolution solid-state NMR has been employed in studying starch polysaccharides since the first successful combination of

cross-polarization (CP) with magic angle spinning (MAS) [37] in 1976. The detection of starch resonances was initially reported in the ^{13}C CPMAS NMR spectra of flour [38] and seeds [10]. Since then, ^{13}C CPMAS NMR studies of starch have expanded with a breathtaking pace, which is based on a number of important foundation work [13–15,17] in the mid of 1980s. ^{13}C CPMAS NMR results showed unique C-1 resonance patterns for the crystalline polysaccharides in three different types of starch. For crystalline A-type or cereal starch, C-1 showed a distinct three-peak pattern [13–15,17], whereas for the B-type or tuber starch, a two-peak pattern [13–15,17] is observed. C-1 of C-type starch shows a mixed pattern of both A and B types [21]. The V-type amylose [16–19] shows a single resonance for C-1. The C-1 resonances of all these types of starch have been assigned and well-documented in literature [13–19]. So far, however, the resonances of C-2, C-3, C-4, and C-5 for starch have not yet been assigned ambiguously.

Based on the success of CPMAS NMR, the ^{13}C relaxation times were measured to obtain information about the dynamics of starch polysaccharides. The results showed that, generally, the crystalline starch is motionally restricted. For the crystalline starches [17], the values of ^{13}C relaxation time (T_1) are about 14–20 s for C-1 and 4–6 s for C-6. In contrast, T_1 values for the amorphous starch [18] were about 600 ms for the ring carbons and 100 ms for C-6. In both the cases, however, T_1 for C-6 was shorter than the ring carbons probably due to the conformational motions of the CH_2OH group as observed in other carbohydrate systems [39–42]. For both crystalline A- and B-type starches, full hydration leads to only a small decrease of T_1 of C-1. On the contrary, the T_1 value for C-1 in V-type amylose [17] (i.e. amylose–lipid complex) increased from 7 to 11 s upon hydration. This change of dynamics probably results from the hydration induced conformational changes to more ordered structure. Recently, some more ^{13}C CPMAS NMR results have also been reported on the polysaccharides in the amorphous starch [43,44]. Local range heterogeneity has been investigated in terms of both structure and dynamics. In these studies, a resonance at about 94 ppm, which appeared in almost all ^{13}C CPMAS NMR spectra in the literature, was also discussed for the first time [4,44].

Spectral editing techniques have shown great potential in starch research, including the "mobility-resolved" ^{13}C NMR spectroscopy [45] and the proton-relaxation-induced spectral editing (PRISE) [4,5,46] techniques. The former takes advantages of differences in ^{13}C properties to detect starch polysaccharides having different mobility, whereas the latter takes advantages of differences in the proton relaxation times to disentangle the ^{13}C resonances of different fraction of starch polysaccharides. Potentially, both methods can be combined to probe the heterogeneity and dynamics of starch systems. The recently developed 2D high-resolution solid-state NMR spectroscopic techniques are expected to play an important role in studies of starch polysaccharides [47–50].

In this article, we are not attempted to provide an exhaustive review on the high-resolution solid-state NMR techniques available nor on the results for starch in the literature. Instated, it is aimed to highlight the problems related to such systems and to discuss possible strategies for the high-resolution solid-state NMR studies of the starch polysaccharides. Therefore, only a brief theoretic account of relevant NMR is given.

NMR Techniques

Nuclear–Spin Interactions in Starch

Starch consists of three elements, carbon, hydrogen, and oxygen. Among them the NMR active oxygen isotope, ^{17}O, has a spin quantum number I of 5/2 and extremely low natural abundance (0.037%). Consequently, ^{17}O NMR is deemed not so useful for studying starch polysaccharides unless such samples were enriched with ^{17}O. However, the combination of the sensitivity enhancement by CP with the multiple-quantum MAS [51,52] may lead to useful information from the ^{17}O NMR. For hydrogen, on the other hand, ^{1}H has a spin quantum number of 1/2, high natural abundance (99.985%) and is the most NMR-sensitive nucleus in nature. For carbon, the NMR active isotope, ^{13}C, has a spin quantum number of 1/2 with relatively low natural abundance (1.108%), even though it is still much higher than ^{17}O. So far, therefore, ^{1}H and ^{13}C have been the choices of spin probes, in particular, in the high-resolution NMR studies of starches.

For ^{1}H and ^{13}C in solids, the nuclear–spin interactions relevant to NMR include Zeeman interactions, dipole–dipole (DD) interactions, chemical shift (CS) interactions, scalar interactions, and spin—rotation (SR) interactions. The Zeeman interactions are between nuclear spins and applied external magnetic field, providing possibility for spin transitions from different energy levels thus NMR signals. The magnitude of the Zeeman interactions are generally in the order of a few hundreds of megahertz (MHz) and that of the other nuclear–spin interactions is in the order of hundred kilohertz (kHz) at most (see Table 1), producing only a relatively small perturbations to the Zeeman interactions. In the solid state, both scalar and SR interactions are relatively weak compared with DD interactions and CS interactions, thus often neglected. The scalar coupling information, however, can be obtained using the two dimensional high-resolution solid-state NMR techniques [49,50] when necessary. The DD and CS interactions contain some extremely important information in both structure and dynamic aspects, although they are the major line-broadening factors. For high-resolution NMR spectroscopy, the DD interactions and chemical shift anisotropy (CSA) can be eliminated with the combination of high power decoupling and magic angle sample spinning.

Magic Angle Spinning

In as early as 1958, Andrew *et al*. started to use rapid sample rotation to narrow the lines broadened by the dipolar interactions [53]. A year later, Andrew's group [54]

Table 1: Nuclear–spin interactions for ^{1}H and ^{13}C in a 9.4 T magnetic field

	Nuclear–spin interactions			
	Zeeman (MHz)	Dipole–dipole (kHz)	Chemical shift (kHz)	Scalar
^{1}H Magnitude in solution	400.0	~0	Isotropic	<0.2 kHz
Magnitude in solids	400.0	<100	~5(CSA)	<0.2 kHz
^{13}C Magnitude in solution	100.6	~0	Isotropic	<0.2 kHz
Magnitude in solids	100.6	~100(^{1}H–^{13}C)	~20(CSA)	<0.2 kHz

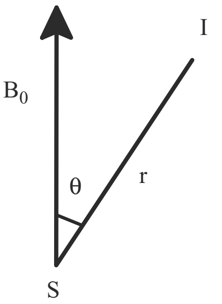

Fig. 2. Co-ordinate system for describing dipolar interactions between two spins, I and S, with a distance of r.

and Lowe [55] independently recognized the magic of the MAS for eliminating the line-broadening effects of the dipolar interactions. Later in 1962, Andrew's group also realized the magic power of spinning sample at the magic angle for removing the line-broadening effects of CSA [56].

In theory, the DD interaction between a pair of nuclei S and I is independent on the strength of external magnetic field. However, it is dependent on the orientation of the inter-nuclear vector relative to the magnetic field and is proportional to the inverse cube of the inter-nuclear distance, $1/r_{\mathrm{IS}}^3$, as given [57–59]:

$$H_D^{\mathrm{IS}} = \frac{\hbar\gamma_{\mathrm{I}}\gamma_{\mathrm{S}}}{r_{\mathrm{IS}}^3}(1 - 3\cos^2\theta)\mathrm{I}_Z\mathrm{S}_Z, \tag{1}$$

where θ is the angle between inter-nuclear vector and the magnetic field B_0 (see Figure 2); γ_{I} and γ_{S} are the magnetogyric ratio for nuclei I and S, $\hbar$ is Planck's constant divided by 2π; I_Z and S_Z are spin operators for nuclei I and S. When $\theta = 54.7^\circ$, the angular dependence term $(1 - 3\cos^2\theta)$ equals zero and the DD interaction vanishes magically! In liquids where molecules tumble rapidly and isotropically, the angular dependence term $(1 - 3\cos^2\theta)$ has to be integrated over a sphere since all angles are sampled. Such integration is zero, thus the DD interactions are said motionally averaged to zero. For a solid containing many spins with restricted motions, the DD interactions can be expressed as a statistical property as the mean squared dipolar field also known as the second moment. In such a case, if a sample is mechanically spun about an axis having the magic angle, 54.7°, relative to the external magnetic field, the dipolar interactions will be eliminated if the sample-spinning rate is fast compared to the magnitude of dipolar interactions.

The CS interaction can be expressed collectively as [57–59]

$$H_{\mathrm{CS}} = \gamma\hbar\sigma_{ZZ}S_Z B_0 \tag{2}$$

and

$$\sigma_{ZZ} = \lambda_{11}^2\sigma_{11} + \lambda_{22}^2\sigma_{22} + \lambda_{33}^2\sigma_{33}, \tag{3}$$

where σ_{11}, σ_{22}, and σ_{33} are the principal values of the chemical shift tensor, which are the values along a set of axes fixed in the molecule; λ_{11}, λ_{22} and λ_{33} are the direction cosines of the molecule's fixed axes with respect to the external field B_0. It is therefore apparent that, for a single crystal, the observed chemical shifts are dependent on the strength of the external magnetic field and the orientation of the principal axis systems with respect to the external magnetic field. If all three values of σ_{11}, σ_{22}, and σ_{33} are not the same, then CS interactions are anisotropic. For a powder sample, the crystals are distributed randomly in every orientation so that a broad spectrum known as "powder pattern" is observed due to the CSA. Mechanical spinning of a sample causes the direction cosines (λ_{11}, λ_{22} and λ_{33}) to become time dependent and such dependence is give as [59]

$$\lambda_Q = \cos\beta\cos\chi_Q + \sin\beta\sin\chi_Q\cos(\omega_r t + \phi_Q), \tag{4}$$

where β is the angle that rotating axis makes with external magnetic field, χ_Q the angle that rotation axis makes with the Qth principal axis of the chemical shift tensor, and ϕ_Q the azimuthal angle of the Qth principal axis at time $t = 0$. If a sample is undergoing so-called the rigid body rotation about an axis making an angle β with the external magnetic field, the CS interaction can be expressed as [59]

$$\sigma_{\mathrm{zz}} = \frac{1}{2}\sin^2\beta(\sigma_{\mathrm{iso}}) + \frac{1}{2}(3\cos^2\beta - 1) \times \sum_Q \sigma_Q\cos^2\chi_Q + f(t) \tag{5}$$

where σ_{iso} is the isotropic chemical shift and $f(t)$ collectively describes the time-dependent terms. When $\beta = 54.7^\circ$ the term, $(3\cos^2\beta - 1)$ is zeroed and the CSA is magically eliminated. Therefore, the axis making an angle of 54.7° with the external magnetic field is called magic angle for the magical effects of eliminating the line-broadening factors such as the dipolar interactions and CSA. With modern spectrometers, the magic angle can be set conveniently with an accuracy of 0.1° by observing ^{79}Br NMR signal (spin-side bands) of a rotating potassium bromide (KBr) sample.

High-Resolution ^{1}H NMR Spectroscopy

For an organic solid such as starch, the ^{1}H homonuclear DD interactions can be as strong as up to several tens of kilohertz (~100 kHz), while its CSA is in the order of

10 ppm or several kilohertz. To obtain the high-resolution ^{1}H NMR spectra of such systems, measures have to be taken to overcome the line-broadening interactions such as DD and CSA. The proton CSA is relatively small and can be averaged by MAS with a rate of several kilohertz, whereas the proton DD interactions cannot be averaged easily with MAS alone.

In reality, starch systems are heterogeneous and contain fractions of polysaccharides with considerable molecular mobility, such as amorphous part, and the motionally restricted fractions such as these in the crystalline phase. For the starch polysaccharides having substantial motions, only weak line-broadening effects are experienced from residual dipolar interactions, CSA and magnetic susceptibility. A good quality high-resolution ^{1}H NMR (HRMAS NMR) spectrum can be obtained with MAS alone at a moderate spin rate (a few kilohertz). On the other hand, for the crystalline polysaccharides, strong dipolar interactions are expected, MAS alone is no longer sufficient to overcome the DD interactions. Therefore, more efficient dipolar decoupling techniques are required to achieve high resolution.

Efficient dipolar decoupling can be achieved by employing multiple-pulse sequences such as WAHUHA-4 [60], MREV-8 [61], BR-24 [62], TREV [63], and BLEW-12 [64]. With modern spectrometers, it is reasonably easy to set up these pulse sequences in conjunction with MAS to obtain high-resolution spectrum for the high natural abundance nuclei, such as ^{19}F and ^{1}H, in the ordered polymer systems. Such combined technique is called combined rotation and multiple-pulse spectroscopy (CRAMPS) [65]. However, these pulse sequences were originally designed for the static samples and therefore are limited to the slow MAS conditions (<3 kHz). Physical rotation of the sample by fast MAS (>15 kHz) impairs the efficiency of the multiple-pulse sequences [48,66]. Over the last decade, nevertheless, a new generation of improved pulse sequences has been reported such as frequency-switched Lee–Goldburg [67–71] (FSLG), phase-modulated Lee–Goldburg [72–74] (PMLG), the MSHOT sequence [75,76]. Most of these sequences work well at moderate to fast MAS conditions (10–15 kHz) with a line narrowing efficiency comparable to the conventional CRAMPS and are robust to experimental imperfections [48,66]. With the constant time CRAMPS experiment [77] ($\omega_r = 12.5$ kHz), the line width of methyl group for solid L-alanine has been narrowed down to 60 Hz (or 0.12 ppm at 500 MHz). More recently, the DUMBO-1 sequence has been developed [78] and vigorously explored [66,78]. Such resolution of ^{1}H dimension also enabled a number of 2D NMR experiments to be performed in similar way to that for solution state NMR such as HMQC [66,79,80], HSQC [80], and INADEQUATE [81]. Undoubtedly, ^{1}H CRAMPS NMR spectroscopy will be improved further and should be extremely useful to provide information for all the starch polysaccharides. The difference between ^{1}H CRAMPS and HRMAS NMR spectroscopy will provide information about the polysaccharides only in the rigid phase. Although ^{1}H has high sensitivity, its small chemical shift dispersion range (<20 ppm) poses a limit to its resolution. ^{13}C has a much greater span of chemical shift range and is expect to provide the higher resolution to obtain information on different structural sites.

High-Resolution ^{13}C NMR Spectroscopy

In solids, the low sensitivity of ^{13}C due to its low natural abundance imposes a huge problem for acquiring ^{13}C spectrum. This problem is further amplified by the lengthy T_1 of ^{13}C due to its low abundance and magnetic moment. For example, ^{13}C T_1 of the crystalline starch can be as long [17] as 20 s, even though it is considerable shorter than that of crystalline cellulose (140–210 s) [17]. Consequently, some prohibitively lengthy repetition time is required for the FT experiments. To solve the problem, the Hartmann–Hahn double resonance experiment [82,83] has been employed as a CP scheme. Under so-called Hartmann–Hahn [82–84] matching condition

$$\gamma_{\mathrm{H}} B_{1\mathrm{H}} = \gamma_{\mathrm{C}} B_{1\mathrm{C}} \tag{6}$$

thermal contact between ^{13}C and ^{1}H spin systems is established. The ^{1}H magnetization is transferred to the ^{13}C to establish a common spin temperature for both spin systems. Since γ_{H} is about four times of γ_C, such magnetization transfer will enable ^{13}C to enhance the sensitivity of by about fourfolds. Furthermore, with such Hartmann–Hahn match, the repetition of the ^{13}C NMR experiments will become dependent on the proton T_1, which is only a few seconds. To eliminate the H–C dipolar interactions, the employment of high-power (~60 kHz) proton decoupling (HPDEC) technique is often necessary. With a combination of CP, MAS, and HPDEC, the high-resolution solid-state ^{13}C CPMAS NMR spectra of starch can be readily obtained to take the advantage of (1) the sensitivity of ^{1}H (fourfold enhancement), (2) shorter ^{1}H T_1 (than the ^{13}C T_1) enabling shorter experimental repetition time, and (3) greater dispersion of ^{13}C chemical shift (than ^{1}H), thus provides excellent opportunities for higher resolution. With efficient proton decoupling schemes, ^{1}H–^{13}C 2D NMR methods in the solid state will undoubtedly offer some powerful tools for studies of the starch polysaccharides in the near future. It is also apparent that the proton relaxation times become potential tools for spectral editing.

Spectral Editing Techniques

Two types of spectral editing methods have been applied in starch studies so far, so-called "mobility-resolved spectroscopy" [45] and PRISE [4,5,46]. These two methods are based on either the differences in the strength of ^{1}H–^{13}C dipolar interactions or the differences in the proton relaxation times (T_1, $T_{1\rho}$, $T_{1\mathrm{D}}$, and T_2) of the starch polysaccharides. The combination of the ^{1}H CRAMPS and ^{1}H HR-NMR spectroscopy can also be regarded as spectral editing tools similar to so-called "mobility-resolved" spectroscopy.

Mobility-Resolved NMR Spectroscopy

The mobility-resolved NMR spectroscopy was used to separate the ^{13}C resonances of polysaccharides having different mobility by exploiting their differences in ability to cross-polarize and their ^{13}C spin–lattice relaxation behavior [45,46,85,86]. A number of situations may arise. In the most mobile extreme, the molecules undergo rapid and isotropic motions, both the ^{1}H–^{1}H and the ^{1}H–^{13}C dipolar interactions are completely averaged; a ^{13}C NMR spectrum can be obtained using the typical solution state NMR techniques. If the residual dipolar interactions of the polysaccharides are not zero but weaker relative to the rate of MAS, then, a high-resolution MAS ^{13}C NMR spectrum is obtainable. Such a MAS spectrum will also contain the resonances of polysaccharides appeared in the above solution state NMR spectrum. Moreover, the rate of MAS and proton decoupling power can be varied in a systematic fashion to differentiate slightly different polysaccharides experiencing various levels of the ^{1}H–^{1}H and ^{1}H–^{13}C dipolar interactions, respectively.

These experiments can be easily performed with a single-pulse excitation (SPE) combined with MAS and proton decoupling [4,5,45,46,85,87] (non-spinning experiments can be considered as a special case of MAS). Such experiments were collectively referred to as ^{13}C SPEMAS NMR. In the SPEMAS experiments, a single-pulse excites all carbons; therefore, in principle, all carbon signals are observable. However, because ^{13}C spin–lattice relaxation times in solids are relatively long (>5 s), the choice of a short repetition time (which ought to be as short as duty cycle allows and is normally shorter than 1s) to selectively observe only the ^{13}C signals with short T_1 and to speed up experiments. The short ^{13}C T_1 component can be simplistically regarded as being diagnostic for the mobile carbon sites in polysaccharides. This simplification, while it is often valid, should be treated with some care when used in different systems [4,5,46,85,87]. This is because that the product of the relevant local dipolar field and the spectra densities at the ^{13}C Larmor frequency, the sum and difference of the ^{13}C Larmor frequency and those of the neighboring dipoles are sufficiently large to cause efficient relaxation. For example, in the case of a methyl group in crystalline samples, its short ^{13}C T_1 does not imply rapid isotropic tumbling but merely that rotations about one axis is rapid. In certain cases, significant levels of paramagnetic species present in dry solid samples also act as a potent source of relaxation, dramatically shortening ^{13}C T_1 even when the spectral densities at the appropriate frequency are quite low.

On the other hand, the observation of a ^{13}C CPMAS signals may be interpreted as the present of carbon sites experiencing a static local dipolar field under MAS conditions. This implies that at least some motions are in the rigid lattice regime, even though as in the case of methyl groups this does not preclude highly anisotropic motions involving some motions in the rigid lattice and motional narrowing regimes. Therefore, care has to be taken to interpret polysaccharide mobility using this "mobility-resolved" spectroscopy simply because there are some overlapping regions of dynamics which SPEMAS and CP-MAS experiments cannot distinguish. A combination of proton relaxation and ^{13}C NMR spectroscopy may offer an alternative strategy to relate polysaccharide structure with dynamics.

Proton Relaxation Induced Spectral Editing Techniques

It is well known that the measurements of proton relaxation times (T_1, $T_{1\rho}$, $T_{1\mathrm{D}}$, and T_2) are extremely useful to probe molecular dynamics of carbohydrates [39–42,88–96]. The spin–lattice relaxation times (T_1, $T_{1\rho}$, and $T_{1\mathrm{D}}$) are sensitive to motions, respectively, in the proton Larmor frequency, effective field frequency for the spin–lattice relaxation in the rotating frame, and the local dipolar field frequency. When heterogeneity is present as in the case of many starch systems, some of these relaxation processes will be observed as multiple components depending on the relativity of the spin diffusion efficiency and length of the relaxation time. If spin diffusion is efficient on a given relaxation time scale, spins in question will have a common spin temperature [97]; relaxation time will be a single process. On the other hand, if the spin diffusion is not efficient enough on a given relaxation time scale, the whole spin pool will show some domains (heterogeneity) and this relaxation will show a multiple-component features [97]. Detection of the multiple components for the proton spin–lattice relaxation times enables one to estimate the dimension of domains [98–100]. The structural features (spectral characteristics) of these domains can also be obtained by PRISE methods, which can be conveniently implemented by preparing the proton magnetization before CP as shown [46] in Figure 3.

In Figure 3A, proton magnetization is prepared with an inversion-recovery "relaxation filter" to separate the

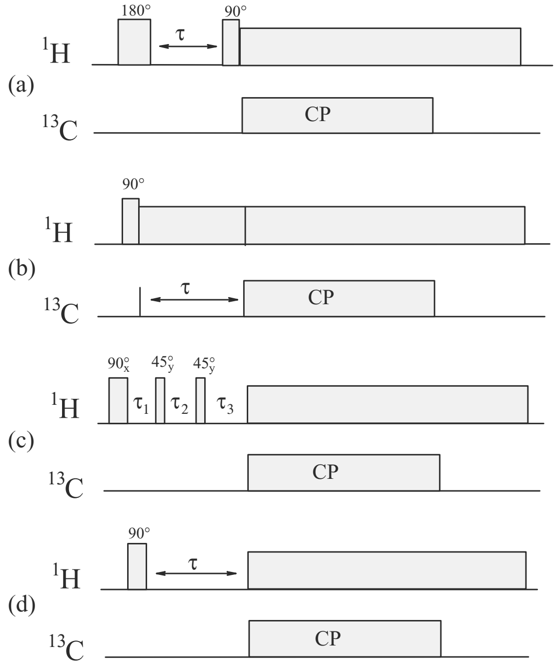

Fig. 3. Pulse sequences for the PRISE experiments with (A) ^{1}HT_1, (B) $T_{1\rho}$, (C) $T_{1\mathrm{D}}$, and (D) T_2 editing.

domains with different proton T_1. In a simple case of two components, the values of relaxation delay τ can be chosen such that the NMR signals in the final spectrum have intensities depending upon the length of τ relative to T_1. For example, one can conveniently choose τ to enable the relevant signals to have a positive peak $(\tau > T_1^* \ln 2)$, negative peak $(\tau < T_1^* \ln 2)$ or no peak at all $(\tau = T_1^* \ln 2)$.

As shown in Figure 3B, the proton magnetization can also be prepared using a spin-locking sequence $(90^\circ_x - \tau_{\mathrm{SPy}})$ such that components with different $T_{1\rho}$ can be separated by choosing an appropriate spin-lock time, τ_{SP}, and spin-lock power. Moreover, The Jeener–Broekaert sequence [101] $(90^\circ{}_{x-}\tau_1 - 45^\circ{}_{y-}\tau_2 - 45^\circ{}_{y-}\tau_3-)$ can be used to transfer some Zeeman order into the dipolar order. For a homogenous solid biopolymer, when $\tau_1 \approx T_2$, and $\tau_2 \geq \tau_3$, a single Jeener echo is expected, whose shape and amplitude are dependent on the time derivative of the FID [101]. The decay of the echo amplitude as a function of τ_2 is characterized by the relaxation time $T_{1\mathrm{D}}$. Therefore, by selecting appropriate τ_2 in the proton preparation part of sequence shown in Figure 3C, the ^{13}C signals of the components with different $T_{1\mathrm{D}}$ can also be selectively observed. In the case of proton T_2 editing, the magnetization can be prepared using a simple pulse-delay preparation as illustrated in Figure 3D. Such an experiment is essentially a slice in so-called 2D WISE experiment [102,103].

The proton relaxation times can be measured either directly by observing protons or indirectly via CPMAS experiments. Direct proton observation offers excellent experimental sensitivity and simplicity. However, it is extremely important to measure the proton relaxation times under identical conditions to that PRISE experiments are performed. This is because (1) sample spinning lead to some degree of sample heating and (2) more seriously, all proton relaxation processes are affected by the sample spinning [46,104–109] at the magic angle.

Under MAS conditions at the room temperature, the fully hydrated granules of all three types starch showed a single proton T_1, two $T_{1\rho}$ components and at least three T_2 components [4]. PRISE experiments have revealed that the long $T_{1\rho}$ component (~30 ms) in the native starch granules is associated with the crystalline polysaccharides, whereas the short $T_{1\rho}$ component (2~4 ms) is associated with amylose in the gaps between amylopectin clusters. For the proton T_2 components, the short one (~14 µs) is associated with polysaccharides in the crystalline lamellae, whereas the long one (10–20 ms), accounting for about 10%, is associated with polysaccharides with molecular mobility so high that CP was not efficient. The intermediate component (T_2 ~ 300–400 µs) is associated with polysaccharides in the amorphous lamellae. Similar multiple (^{1}H) $T_1\rho$ components have also been related to the domain structures for polysaccharides in the moisten starch granules (33% water) [18] and bread [110]. However, little has been reported with $T_{1\mathrm{D}}$ editing though that should be useful.

Future Perspectives

So far, most of the high-resolution solid-state NMR work has been concentrated on the crystalline (or ordered) polysaccharides in starch. Relatively fewer reports focused their attention on the less ordered or amorphous starch polysaccharides, which are more relevant to the functionality in applications. With the catalogue of methods available, it is probably the right time to take the challenge to focus the attention to the structural, dynamics and interactions of amorphous starch. Furthermore, a number of aspects of starch structure remain inadequately understood. For example, the presence of "small blocklets" in "the growth rings" and "large blocklets" in the semi-crystalline shells remains to be fully established, although the concept of "blocklets" emerged [111] as early as in 1858. The relationships between the starch functionality and the domain distribution, dynamic state of the starch polysaccharides in the native and processed starch are not well understood even though these properties are important in establishing and determining the response of starch granules to multi-parametric processing treatments, such as acid-hydrolysis and gelatinization, and ultimately functionality.

From NMR technique point of view, although high-resolution ^{13}C NMR spectroscopy has been extensively exploited in starch studies, few high-resolution ^{1}H NMR results have been reported so far. Furthermore, with some recent developments in the two dimensional NMR in the solid states, heteronuclear correlation spectroscopic techniques such as HETERCOR, HMQC [66,79,80], HSQC [80] and INADEQUATE [81] have already been demonstrated in the solid states. Measurements of H-C scalar coupling have been reported using so-called MAS-J-HMQC [66,79,80] and MAS-J-HSQC [80] methods. Hydrogen bonding interactions in the organic solids have been studied [49,50]. The solid-state INADEQUATE experiment [81] has also been developed to establish the C–C connectivity [81,112]. This together with the 2D NMR exchange experiments has shown particular usefulness in unambiguously assigning the ^{13}C spectrum of cellulose [113]. Although most of these high-resolution 2D NMR methods were developed for studying peptides and proteins, it is conceivable that similar strategies should be extremely valuable for studying the starch polysaccharides.

Introduction

Bread making is a process consisting of four basic steps, mixing, kneading, proofing, and baking. Although each step contributes to the set up of the aerated structure of bread, the baking process of the dough foam is the ultimate and more impressive part of the bread making process. The final open sponge structure with interconnected cells results from more or less simultaneous physical, chemical, and biochemical changes during baking such as volume expansion, evaporation of water, protein denaturation, starch gelatinization, and formation of a open network of pores.

Significant increase in computing power authorized the construction of complex dynamic models for the heat and mass transfer and physical and chemical changes during baking of dough. Due to the lack of precise experimental data, none of the numerous theoretical approaches of the baking process [1] could be fully validated. The assessment of both water transport and local expansion is especially required. This made the control of the baking operation incomplete at the industrial scale. The chilling step is also poorly controlled as it is often neglected relatively to the preceding baking step. Nevertheless, some changes of particular interest at the industrial scale still occur in the cooling product, among them, weight losses and collapses in the porous structure.

Non invasive and dynamic monitoring by using X-ray tomography or MRI may provide insights into how porosity, humidity, gelatinization evolve during these particular steps in the bread making process. A first challenge is to monitoring porosity by the MRI technique (see chapter on NMR imaging of dough) during the slow dough proving process, not significantly affected by moisture, temperature, and macromolecular structure variations, but resulting in a drastic MRI signal loss due to a primary volume expansion. A bigger challenge is to monitoring the fast baking process with a further volume expansion and spatially dependent moisture losses and starch gelatinization resulting from the large temperature increase.

The codification of the MRI images based on the application of magnetic gradients in each space direction only confined the technique to the partial observation of the more mobile protons by scanning spin-echoes. Additionally, MRI parameters of the food matrix, i.e. transverse T_2 and longitudinal T_1 relaxation times and apparent proton densities, drastically evolve during baking. The evolution of the gray levels in MRI images during the baking process cannot be simply fitted by the two monotonous conjugated effects of the increase of the relaxation times related to the increase of the molecular mobility (Arrhenius' law) and of the decrease of the MRI sensitivity with temperature (Curie's law). This evolution is largely affected by the growing interactions between water and starch during gelatinization and the loss of water at the periphery of the food matrix (Figure 1). It must be emphasized that MRI differs from X-ray by its sensitivity to temperature and molecular structure.

This review presents the state of the investigations to characterize the bread crumb and to identify the contributions of the different phenomena, porosity, moisture, and molecular structure, to the MRI signal in the view of quantifying their kinetics in every part of the matrix.

Monitoring the Baking Process

Conception of an MRI Oven

The first challenge in monitoring the baking process is the construction of an oven compatible with the MRI system. At least two devices of this kind have been described in literature [2,3]. Among all the constraints, the first one is the insulation from heat as air temperatures to be reproduced from the industrial scale range from 160 to 250 °C. Good insulation can be performed with traditional insulator, but often requires large thicknesses. This may impair in turn the quality of acquisition, as a receiver antenna with a much larger size than the product and consequently with a lower signal-to-noise performance, must be chosen. Second, the usual and cheapest heating system includes electric resistances and hence must be set outside the Faraday cage. A system dedicated to the air circulation from the heating system to the product is then required. Third, the use of metal in the construction of the oven part surrounding the product is obviously forbidden. A particularity of the metallic walls in conventional ovens is the generation of a heating source by radiation; to our knowledge, such levels of radiation will be hardly obtained with other

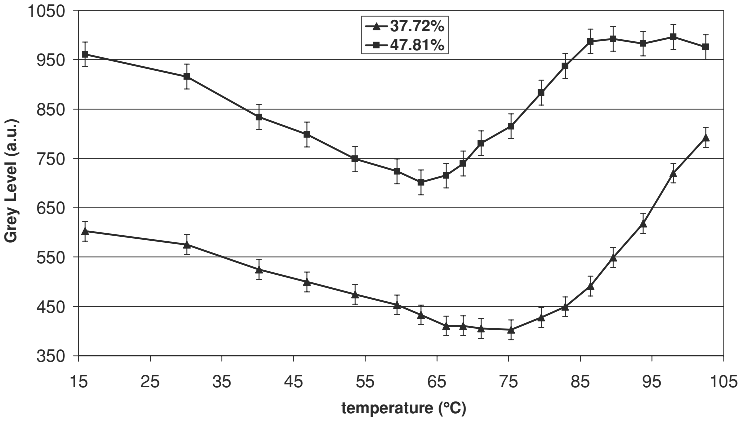
Fig. 1. Evolution with temperature of gray level in dough/crumb at two different levels of water content (Open Siemens 0.2 T, spin-echo sequence, $T_E = 8$ ms, $T_R = 420$ ms, slice thickness = 10 mm, FOV = 64 × 128, matrix = 128 × 128, number of scans = 2) (From Ref. [3]).



material. In fact, very few matter (only Teflon and glass to our knowledge) are compatible with both MRI and high temperatures. At last, the oven surrounding the product should reproduce a thermal environment, if not identical, at least approaching the industrial one. For instance an adequate heating of the base-plate on which the product lies must be ensured. The small volume available around the product is often a severe constraint to complete with this objective.

Factors Influencing the MRI Signal During Baking

The MRI signal is sensitive to several sources of variation during baking: temperature, water content, macromolecular structure, and porosity. Thus MRI could be a tool relevant for characterizing during the process: heat and water transport, protein denaturation and starch gelatinization, and volume expansion. But these modifications are concomitant (Figure 1) and all affect the MRI signal during baking to a certain extent. This will be illustrated in Figure 2 with MRI images acquired during the baking of bread [3].

The volume expansion is exhausted by the superimposition of the outlines of the first image on the image acquired at 5 min. In parallel, the MRI signal progressively reduced from top and bottom surfaces, passing from warm to cold colors. An analysis of sensitivity showed that in areas where temperature did not overpass 38 °C within this period (e.g. at core), more than 80% of the signal decrease could be explained by the increase of porosity. Anywhere else in the bread section, none of the contributions to the signal variations can be negliged and a general method should be developed in order to decouple or isolate the different contributions.

Beyond 7 min i.e. after externally visible expansion was complete, few variations in MRI signal were observed at the exception of the appearance of local brightnesses (warm colors in the last five images from Figure 2). It must be emphasized that these bright areas were observed even after bread temperature had stabilized at 100 °C—with a supposingly stable molecular structure. Hence this increase in the MRI signal could be interpreted by a local increase either in density or in water content. Observations made on the final bread slices (2 mm thick) cut at the same location as the MRI slice, tend to attribute the brightness to zones of higher densities. Indeed it is highly probable that at this stage of baking, the volume expansion of the core was not fully realized and its expansion would have exerted compression forces on the regions surrounding the whole core; if their mechanical properties

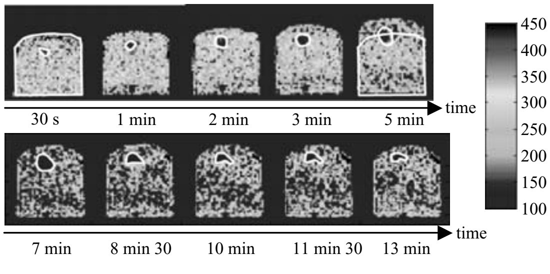


Fig. 2. MRI images of bread baking (air temperature 185°C, air velocity 2 m/s, insulated side walls of the mould). Bread composition: wheat flour: 300 g, water: 225 g, sucrose: 6 g, salt: 6 g, compressed yeast: 9 g, rape oil: 6 g. Same imager and sequence parameters as for Figure 1 except the number of scans (only one) so that images were taken at 30-s intervals (From Ref. [3]). The range of variation is given by the gray level scale located on the right of the figure. (See also Plate 132 on page XXIV in the Color Plate Section.)

were not resistant enough, these regions may in turn have densified.

The preceding analysis emphasizes not only the rich-character of MRI images during baking, but also the difficulties in interpreting the MRI signal variations and the need for developing an MRI method, which would decouple the different sources of variation of the MRI signal during baking. Again it would be dangerous in the view of producing mechanistic interpretations of baking, to directly convert the lowest GL in terms of high porosity, or to relate the variations from the MRI signal of crumb directly with changes in water content, without taking into account the effects of temperature and of structural changes at the molecular scale.

At last it is worth underlying that the development of quantitative methods should be accompanied by an experimental strategy for calibration and validation. In this view, the overall approach proposed by Heil *et al*. merits full consideration [4]—although one may find the experimental procedures not enough detailed. Sagittal 2D T_1-weighted images were acquired and segmented to estimate the variations in porosity during baking. The calculated porosity showed high correlation with displacement although unavoidable loss of moisture was not taken into account. Water–oil ratios were estimated by MRI spectrometry localized by a planar pulse sequence in six experimental volumes (4 mm^3) in the dough during baking. The authors confronted water concentrations deduced from MRI and from gravimetric measurements. The linear correlation was not excellent (large data dispersion with $R^2 = 0.84$). Nevertheless the method can still be improved, for instance by correcting the signal inhomogeneities produced by the non uniform magnetic field [4], or by taking into account the effect of temperature on the proton signal.

Specific Interests of MRI in Better Characterizing the Mechanisms Underlying the Baking Process

Surprisingly, very few MRI results referring to the baking process and its interpretation have been published so far [2–5]. This may be partially due to an unrealistic reproduction of the baking process within the MRI magnet (see the first sub-section) and to the difficulty in interpreting the MRI signal (see the preceding sub-section).

However, already published results are quite promising. They mainly refer to the spatial and temporal changes in moisture content during baking. Heil *et al*. produced kinetics of water concentration at different locations in biscuit; however the baking conditions do not allow full confidence in the set of data (baking was interrupted for the MRI acquisition and then continued on). Increase in water concentration at the center of biscuits was reported but unfortunately no evidence of it was given in the paper [4]. Although geometrical changes (external diameter and height in biscuit [2]) could be monitored in a quantitative way, data of local porosity were rarely found [3,4] and with no real quantitative analysis.

Monitoring the Post-Chilling and Freezing Steps

The variations of the MRI signal during the chilling step will be detailed below in the case of part-baked breads (partially baked before chilling and freezing), but the conclusions to be drawn will be of broader application. An echo-gradient sequence was selected for this purpose as it revealed to be very little sensitive to differences in susceptibility between air and crumb when implemented on a low magnetic field imager (0.2 T), with small echo time values [6].

Variations of the MRI Signal During Chilling and Freezing of Part-Baked Breads

In the crumb at core, the MRI signal remained constant for a while and then decreased steeply to the signal intensity in the image background (Figure 3A). The latter decrease was relevant of the freezing process [7]. Hence no variation was observed during the pre-chilling step. Some voxels in crumb, located in particular just beneath the upper crust of the loaf, may exhibit a specific behavior during the pre-chilling step, with a primary increase in signal—up to 30% (Figure 3A).

During the chilling step, the MRI signal may vary under different mechanisms. Temperature decreases locally. Water concentration in crumb may locally decrease as vapor still escapes from the product surface or locally increase since the vapor filling the bread pores is expected to condensate under cooling. The changing structures of starch or proteins in crumb accompany both the retrogradation and gelling processes. At last, under gas compression and/or active retraction of the network under cooling, collapses of the porous structure are often observed hence producing variations in the local gas fraction. A preliminary study permitted to rank these different sources [7]. Molecular structure and temperature effects could be neglected with respect to the level of noise in the images. And the 30% of increase in the MRI signal could be explained by either a 9% decrease in porosity or a 24–37% increase in water concentration, or a combined effect. Sampling in the thawed loaf for dry matter measurements gave no evidence of a significant water concentration gradient in the crumb under concern. At this stage, the increase in the MRI signal was thus mainly attributed to the collapse of the loaf structure [8].

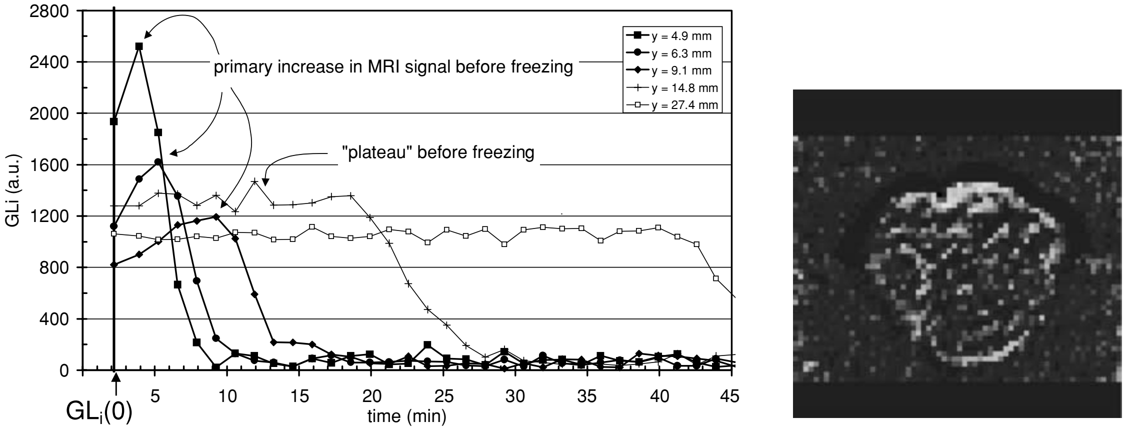

Fig. 3. MRI signal during freezing of part-breads (Open Siemens 0.2 T, gradient echo sequence, $T_E = 4$ms, $T_R = 200$ ms, slice thickness = 12 mm, FOV = 66 × 88, matrix = 48 × 64, number of scans = 2) (From Ref. [8]). Left: y refers to the position along a vertical profile, with $y = 0$ for the upper crust and $y = 27.4$ mm for the approximate geometrical center of the loaf section. Right: differences of gray level between the start of acquisition and the start of freezing (decrease in the signal). Red and dark blue represent respectively the highest and lowest values of increase. (See also Plate 133 on page XXV in the Color Plate Section.)

This conclusion may change with other configurations. No effect of temperature or porous structure was assumed during the chilling of wheat flake biscuits, and the MRI variations were converted into cartographies of water content directly using a calibration curve obtained from final products at different levels of humidity and measured at ambient temperature [5].

MRI for Better Controlling the Final Product Quality: A Theory for Explaining the Occurrence of Crust Flaking

Crust flaking is a well-known default of frozen part-baked breads. It was initially believed that sub-structures of different mechanical properties (e.g. crust/crumb) could be weakened by the bread collapse and that mechanical chocks during transportation or hydro-thermal chocks during final baking could then participate to the splitting up of crust pieces.

Practically, the chilling and freezing processes were monitored by MRI [8] in breads producing either low or high flaking [9]. The bread with low flaking presented the highest increase in the MRI signal and revealed to be able to respond to constraints by a relatively high extent of deformation. At the contrary, the bread with high flaking deformed to a lesser extent. As a consequence, higher tensile forces could have been generated within the loaf structure, especially on its flanks where most flakes are formed [9]. It is noteworthy that collapse was observed by MRI from the early step of pre-chilling and was continued during the freezing step, with a higher intensity and a higher rate [8]. This last point is coherent with the industrials' experience, which considers the freezing step as a necessary step for observing flaking.

Assessing the Bread Crumb Structure

The final bread crumb structure is a criterion, at least easily accessible with the view of all the difficulties in instrumenting the bread in the process of baking. It can serve the evaluation of the effects of the formulation and of the bread making process. The different techniques for examining the bread crumb structure have been recently reviewed with their major limits [10]; among them: the lack of 3-D information (most give 2D images of a 3-D reality), the complicated process of preparation or the limited size of samples. An easy-to-use MRI method for depicturing the 3D architecture of breads or for reducing to the extreme the slice thickness (0.3 mm) has been recently proposed [10,11] (Figure 4).

Though baked breads contain approximately 40% of water, it is difficult to obtain clear images of grain structure with conventional (spin-echo) sequences (see the Introduction section). The originality of the method lies on the pre-soaking of the bread pieces in an organic solvent; the bread structure thus appears as a "shadow" in the solvent image. Among the tested solvents, acetone was selected because of its single peak that prevented chemical

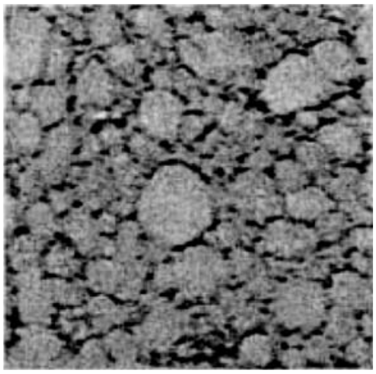

Fig. 4. MRI microscopy of bread (Bruker DRX300 7T, $T_E = 4$ ms, $T_R = 1$ s, matrix = 256 × 256 × 256 with a corresponding 100 μm voxel resolution) (reprinted from Ref. [10] copyright, with permission from Elsevier).

shift effect on images and of the retention of the bread structure. The addition of heavy metals, especially a 8 mM concentration of Fe^{3+}, shortened the overly long relaxation times of acetone to practical lengths for imaging. Two types of NMR imagers and sequences have been tested (refer to the legend of Figure 4).

Under such operating conditions, the histogram of pixel frequency against gray level was bimodal and allowed to handle the MRI images as binary ones. The distribution in the cell sizes could then be estimated after a simple thresholding method has been applied to the images.

NMR Imaging of Dairy Products

F. Mariette
CEMAGREF, Food Engineering research unit, 17 avenue de Cucillé, CS64427, 35044 Rennes Cedex, France

Introduction

Most MRI applications to dairy products are based on the sensitivity of relaxation time to chemical composition and changes in structure. It should therefore be borne in mind that for many dairy products the NMR relaxation signal is multi-exponential. This behavior is mainly explained by the chemical composition, since protons from water, fat, and protein contribute to the signal. Moreover, two phases can be observed according to the measurement temperature, i.e the liquid and solid fat. All these aspects complicate the interpretation of NMR relaxation time parameters and contrast in the MR image. Nevertheless, as the spin–spin relaxation time of protein protons and crystallized fat protons are very short, the image intensity is only dependent on the relaxation of the liquid phase, i.e the liquid fat proton and the water protons. Of course, if MRI acquisitions are performed at low temperatures where most of the fat is crystallized, the gray level intensity will describe only the water protons. This explains why most work has been done on low fat products or at low temperatures, or in high fat products such as cream and cheese, although some methods have been proposed to suppress water and fat signals selectively.

Our intention in this chapter is to present a wide range of MRI applications in dairy science. It will be broken into four parts: determination of water distribution, the macroscopic information that can be obtained from MR images, molecular and micro-structural information and temperature, and flow measurements.

Water and Fat Content and Distribution

Using MRI to obtain water and fat content distribution is one of the applications that is widely represented in the literature about food. Two reasons can be proposed. Firstly the gravimetic technique for water determination and the chemical extraction method for fat determination are known to be time consuming, and this limits their use for the determination of spatial distribution in the food matrix. Secondly, water content is one of the most relevant factors to the quality of food [1] and its distribution is rarely uniform in a product. This therefore explains why considerable efforts have been made to devise effective techniques to quantify the spatial distribution of fat and water non-destructively.

Two NMR parameters are used to determine water content: proton density and spin–spin relaxation time T_2. The spin–lattice relaxation time T_1 can also be used but because its sensitivity to water content is lower than T_2, the latter is preferred. When using proton density image, the water content is given by:

$$W(x) = K\rho(x)(1 - \mathrm{e}^{-T_\mathrm{R}/(T_1(x))})\mathrm{e}^{-T_\mathrm{E}/(T_2(x))} \qquad (1)$$

with K a constant which depends on the scanner and $\rho(x)$ the proton density, T_2, T_1 the spin–spin and spin–lattice relaxation time for each voxel x, respectively and T_R and T_E the repetition time and echo time, respectively. It is important to recognize that the signal strength, constant proportionality, and relaxation time will all vary with position and within the sample. Variations in the relaxation time are induced by changes in the concentration and also by changes in temperature, as generally observed in the case of drying. As a consequence, specific methods for the correction of variations in relaxation time and inhomogeneity of the scanner are required [2]. When the inhomogeneity in the image intensity induced by the scanner is high, the water content can be assessed from a T_2 map. As the gray level inhomogeneity is independent of the relaxation time, the inhomogeneity is the same for the whole image for a multi-echo sequence, whatever the echo time. The computation of T_2 therefore provides a simple way to correct the images. This method has been successfully used for the determination of water distribution during the draining of curd (Figure 1) [3,4]. With this specific application, other information can be extracted from MR images such as the size of the curd, the location of whey, and the amount of whey in the container [5,6], and modeling of the drainage can be performed [7,8]. The same approach has been used to study the effects of freeze-thawing on the macroscopic structure and water distribution in the curd [9].

Equation 1 is only valid when the NMR signal is mono-exponential. When the relaxation is not exponential, multi-exponential fitting has to be performed in order to extract the fraction of each relaxation component. This requires a more sophisticated acquisition sequence and the complexity of the model between the gray level intensity and the water content increases. This situation if

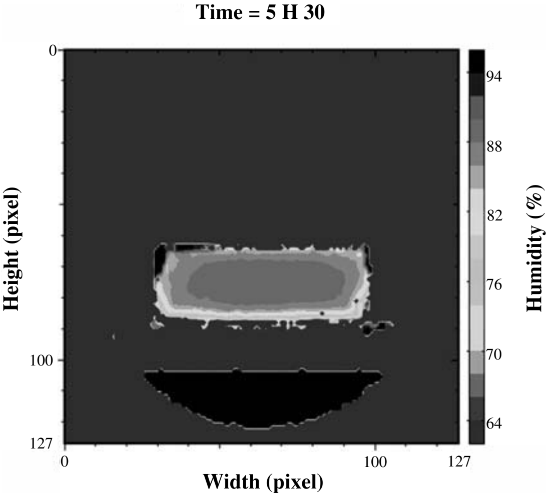

Fig. 1. Water distribution in curd according to draining time (From Mariette *et al*. [4] with permission). (See also Plate 134 on page XXV in the Color Plate Section.)

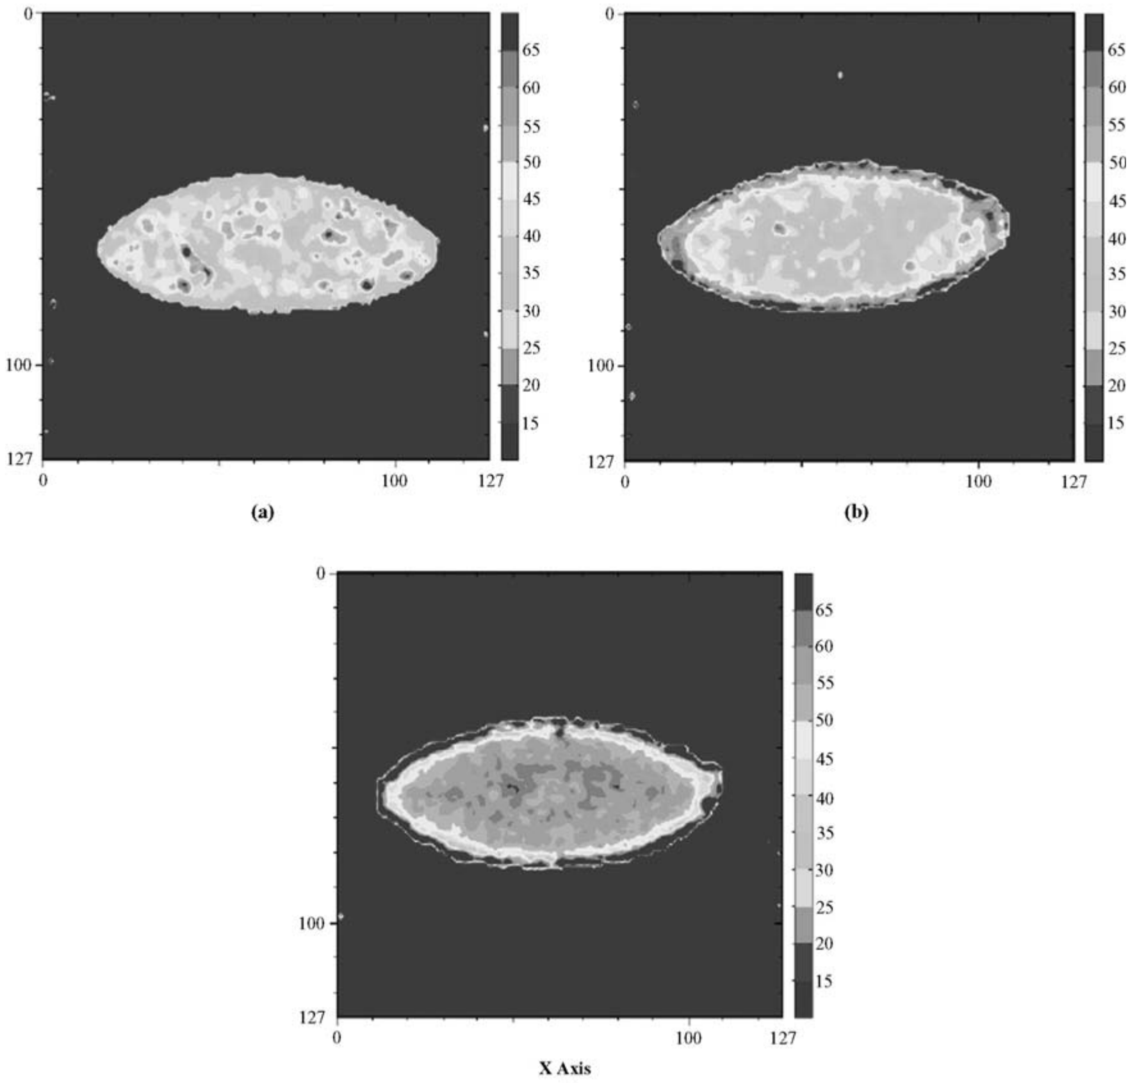
often observed for fatty products and the best solution is to implement a specific MRI sequence to suppress one of the components in order to apply the simple case defined by Equation 1. This approach has been used to quantify separately the water and fat distribution in cheese [10] and in cream [11]. Two approaches have been proposed, the first uses difference in the relaxation time between fat and water protons, and the second uses the difference in resonance frequency. For dairy products, the chemical shift based methods are preferred as the fat relaxation time is widely dispersed and fat suppression is then difficult to achieve. For example, the chemical shift Dixon imaging sequence was used to study the movement of lipids in cream to the top of a vial of milk [11], and the chemical shift selective (CHESS) suppression technique was used to obtain water only and fat only MR images of cheddar cheese [10].

Macrostructure Information

Dairy products, especially cheeses, are inhomogeneous products at a macroscopic length scale. For example, the size, number and shapes of the holes are modified according to the manufacturing process, and contribute to the overall quality of the product. Regular sphere-shaped holes are the result of the production of CO_2 from the biochemical activity of the bacteria, but non-regular shaped holes are explained by mechanical constraints during the manipulation of the curd. Moreover, the thickness of the rind increases and morphological defects can be observed during the ripening of cheese, which have an effect on the overall appearance of the product and on consumer perception. Many attempts have therefore been made to quantify the macroscopic structure or organization of cheese and to relate the feature to quality criteria. This approach was first applied to Swiss cheese for quantification of the morphology of holes [12–14]. A standard spin-echo sequence was used, and the MR images were analyzed. The number of holes was determined, the thinness ratio, cross-sectional area, and hole center locations were calculated. The mean gray level, angular moment, and contrast of gray scale images were calculated to define the internal texture of Swiss cheese. Using these parameters a classification procedure was devised. This approach was also used for the classification of soft cheese according to the processing condition, and also to predict the sensory textural properties of the cheese [15,16]. For this application, several images were acquired for each cheese with different experimental conditions: spin-echo sequences with different T_E, and T_R, for T_2-weighted and T_1-weighted images, respectively, and gradient echo sequence for magnetic susceptibility-weighted images. Textural features were computed using the co-occurrence matrix method on each image. Classification was performed directly according to the textural features, allowing the complete discrimination of the cheese according to the processing conditions. A predictive model of the sensory parameters was also obtained from stepwise linear regression. Although the texture analysis methods to quantify the structure of MR images are very powerful for food applications and for medical applications, attention should paid to the sensitivity of these methods to normalization procedures of the images which can significantly affect the significance of the results [17]. Other examples have dealt with the determination of rind thickness [18] and analysis of the structure of blue-veined cheeses [19].

Micro-Structure and Molecular Structure

The micro- and molecular structures of dairy products can be ideally investigated by T_2 water relaxation time. Numerous NMR studies have demonstrated the sensitivity of water relaxation to the casein micellar structure [6,20–22]. As a consequence, any modification of the structure of the casein gel can potentially be demonstrated by MRI. Moreover, since relaxation time parameters are sensitive to micro-heterogeneity when the diffusive exchange between the water compartments becomes slow, information about the water holding capacity can be obtained. This has been well illustrated in experiments involving the ripening of soft cheeses [23]. After enzymatic coagulation of the milk, the gel is drained and salted and then all the biochemical changes that occur during



(a)

(b)

(c)

Fig. 2. T_2 map of soft cheeses according to ripening time. D + 9 (a), D + 14 (b) and D + 44 (c) (From Chaland [23] with permission). (See also Plate 135 on page XXVI in the Color Plate Section.)

ripening begin. The lactate produced by the lactic bacteria during the acidification period is oxidized during ripening. This metabolism of lactate causes an increase in pH. The combined action of pH and salt precipitation (especially calcium) changes the protein gel structure and softens the cheese. These modifications in turn induce an increase in the water relaxation time. For example, the transverse relaxation time of the water phase is 35 ms for a commercial non-mature soft cheese and reaches 60 ms when the cheese is mature. This variation in relaxation depends on the dry matter in the cheese: the lower the level of dry matter, the greater the variation. However, the sensitivity of the relaxation time to ripening is enough to use the relaxation time as a parameter for application of MRI. Figure 2 represents the T_2 map of soft cheeses according to time of ripening. The T_2 map was calculated from a relaxation decay curve measured with a 2D Fourier transform multi-echo sequence [23]. After 9 days the relaxation time of the cheese was low and little heterogeneity was observed. After 14 days an increase in T_2 was observed on the periphery of the cheese. Moreover, there was a gradient from the center to the cheese surface. The high T_2 value voxel number increased over time, to the detriment of the low T_2 value voxel number. After 44 days, all the voxels reached the same T_2 values and the cheese was totally mature. The variation in T_2 observed during ripening was in close agreement with the expected ripening mechanism. The MRI technique could therefore be applied to different ripening conditions, and the ripening kinetics could be followed.

The effects of freezing on mozzarella according to the T_2 distribution in the T_2 map have been studied [24]. Differences were noted in the T_2 histogram between unfrozen pasta filata and non-pasta filata. Moreover, after a freezing-thawing process the T_2 histogram was modified and this effect was dependent on the initial structure of the cheese and also on the storage time. The differences are explained by the micro-structure of the gel and by the damage to the protein structure induced by the freezing-thawing process.

Relaxation time distribution is highly sensitive to the formation of small water compartments inside the gel and this situation is encountered in young cheeses. The water distribution is non-uniform after draining and salting. Moreover, because of cutting of the curd before draining, small numbers of residual water pockets are entrapped between the curd pieces. These water compartments lead to increased T_2 distribution if studied by NMR but can also be detected by MRI [18,25]. The water pockets characterized by longer T_2 values appears in white in the MRI image presented. The water pocket can be quantified according to ripening time after the threshold of the image (Figure 3).

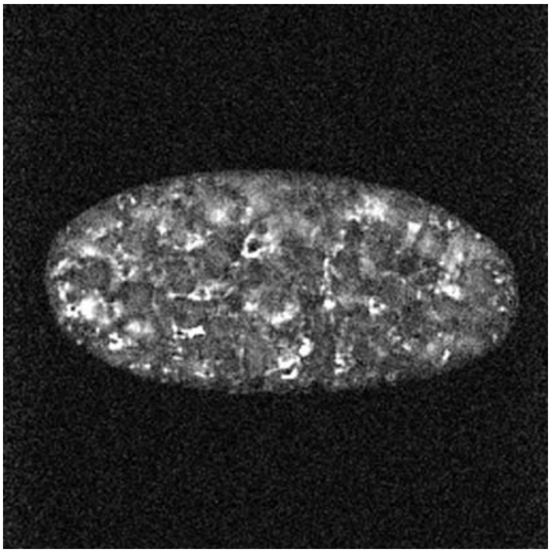


Fig. 3. T_2-weighted MR images of a young soft cheese (From Chaland [23] with permission).

Temperature and Flow

Many NMR parameters are sensitive to temperature and can be used as tracers for the non-invasive measurement of temperature. Among all the NMR parameters sensitive to temperature such as T_1, T_2relaxation times, diffusion coefficient, and chemical shift, the latter has been found to be the most effective as it does not suffer from dependency on any physical structure. Some examples have been reported study heat transfer in cheese [26,27].

Using MRI, flow can be measured with appropriate experimental protocols. These techniques are referred to as NMR velocimetry. The advantage of this technique is that a velocimetry profile or map can be obtained without assumptions concerning the uniformity of the shear rate. For example, the behavior of processed cheese melts during pipe flow [28] and the effects of temperature on the rheology of butter fat and margarine have been studied [29,30]. Measurements were performed with a 7 T NMR spectrometer equipped with a micro-imaging probehead. A pulse field gradient spin-echo sequence was applied. A Couette cell consisting of two concentric glass tubes filled with the sample of interest was inserted into the probehead. Figure 4 shows an example of an MRI image for water in the Couette cell. The right part corresponds to the water in the annulus space and the left part to the water in the central space. Note that the fluid in the inner tube is used as a marker to find the velocity of the outer surface. A velocity profile can be computed (Figure 5) from these images. A power law fluid model was therefore used to fit the velocity profile and to describe the shear thinning and thickening. The velocity profiles

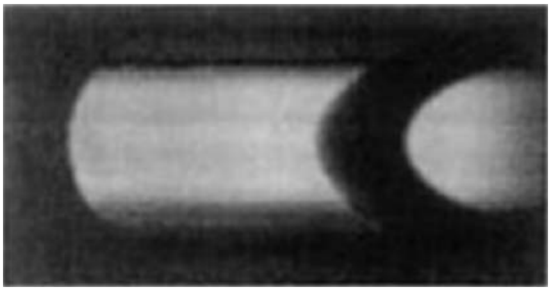

Fig. 4. MR Image of water in the cylindrical Couette cell (From Britton *et al*. [30] with permission).

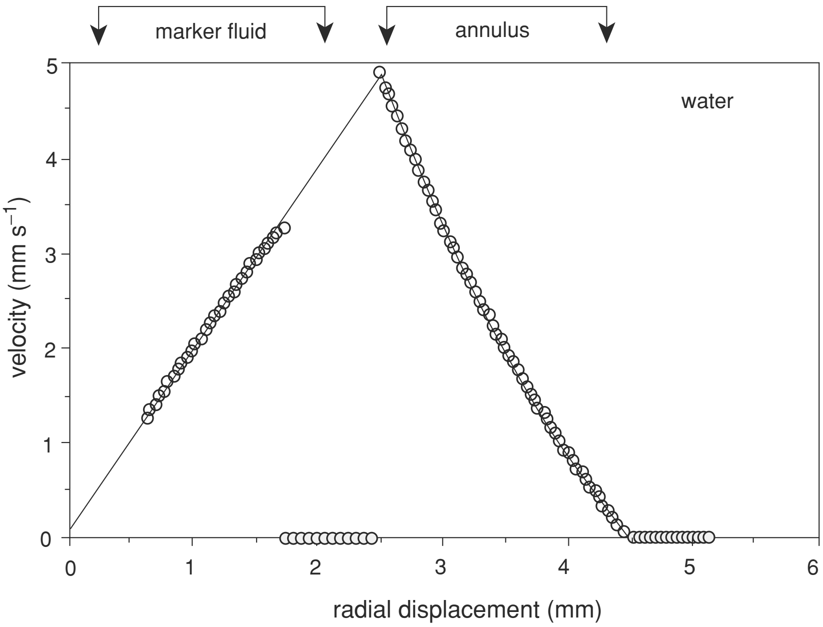

Fig. 5. Radial velocity profile taken across the cylindrical Couette cell in the case of water (From Britton *et al.* [30] with permission).

for butter between 25 and 42°C exhibited a yield stress transition around 35°C. Below this value, the shear rate was heterogeneous. This method appears very promising to investigate the particulate and molecular origins of complex rheological properties of dairy materials.

Conclusion

The MRI applications illustrated in these examples demonstrate the potential for non-invasive characterization of dairy processing and how information about composition and internal structure of the product can assist understanding about dairy engineering. New developments in NMR and MRI methods will enable new applications with improved image quality to be proposed in the future.

NMR Imaging of Dough

Lucas Tiphaine, A. Grenier, G. Collewet, and A. Davenel
Cemagref, Food Process Engineering Research Unit, 17 avenue de Cucillé, 35044 Rennes Cedex, France

Introduction

The flavor and the structure of crumb are the main factors in consumer acceptance of bakery products. The final structure depends to a significant extent on the creation and control of gas bubble structures in the unbaked matrix, and the retention of these gas bubbles in a suitable form until the matrix becomes set or baked. Bread making may be viewed as a series of aeration stages: bubbles are incorporated during mixing, the bubbles are inflated with carbon dioxide during proving, and the aerated structure is modified and set by baking. For greater convenience to craft bakers and greater compliance in logistics management, the immemorial continued process of proving and baking, has been sophisticated by introducing intermediary steps such as retarding techniques by cooling yeasted doughs, deep freezing of unproven fermented doughs, or part-baked bread in centralized production plants (Figure 1). The new steps have contributed to make more complex the physical and chemical changes that occur inside the dough during processing. Bread making quality of frozen green dough is affected by the degradation of both yeast activity and dough rheology. The water crystallization process plays a major role in such degradations. The rate at which ice forms with lowering temperature, the microscopic structure of ice crystals as well as its evolution during cold storage are known as parameters of importance. As invasive measurements may provoke dough collapse, the characterization of the expansion process has been reduced to a number of global volumetric parameters. In the last decades, sophisticated measurements and macroscopic invasive techniques have allowed a better understanding of these changes. If the resolution of confocal microscopy is efficient to yield the number of bubbles and the porosity of dough, only bubbles close to the dough surface can be observed. If the X-ray tomography and the MRI technique both have the potential to investigate the porosity in all parts of the dough, only MRI offers the possibility to measure simultaneously porosity and to localize ice gradients during the thawing–proving process. Actually MRI parameters characteristic of the dough, i.e. transversal T_2 and longitudinal T_1 relaxation times, and apparent proton densities, are sensitive to structural changes such as water crystallization, but also moisture modifications, expansion process, and temperature changes in the matrix. The codification of the MRI images based on the application of magnetic gradients in each space direction before spin or gradient echo scanning, combined to the rapid relaxation of water protons in dough (e.g. T_2 is comprised between 0.5 and 35 ms depending on temperature) confined the technique to the partial observation of the more mobile protons: a more or less important fraction of the protons of liquid water and a fraction of the hydroxyl protons of macromolecules in interaction with water. Large reduction in the MRI signal is associated, on the one hand, to the crystallization from up to 50–60% of the water during freezing of green dough and, on the other hand, to the expansion during proving with the incorporation of up to 60–70% of gas in bubbles. This involves to pay attention to maintain exploitable signal-to-noise ratio all along the processes, by finding the best compromise in the choice of the spatial resolution, the echo time and the number of excitations for signal averaging. After that, the complex relationship between gray levels in the dough images and physical state of the different parts of the dough requires large investigations to quantify the precise contribution of each phenomenon. This review presents the state of art of the performances of the MRI technique to visualize and quantify the phenomena occurring during the making of dough (freezing and proving) and to help their complex modeling.

Assessment of Ice Fraction Cartographies During Freezing, Storage, and Thawing of Raw Dough

Factors Influencing the MRI Signal of Frozen Dough

As only liquid protons give the MRI signal, the increasing ice fraction in the voxel volume results in a decreasing intensity of the MRI signal. The MRI signal in the voxel i is thus proportional to:

$$\mathrm{GL}(i,t) \propto (1-\varepsilon(i))\left(1-\frac{\rho_{\mathrm{dough}}}{\rho_{\mathrm{ice}}}\omega_{\mathrm{ice}}(i,t)\right) \times \mathrm{GL}_{\mathrm{remain\ liq}}(i,t), \qquad (1)$$

where ω_{ice} is the ice fraction (kg of ice per kg of dough), ρ_{ice} and ρ_{dough}, the densities of ice and dough (kg m^{-3}),

ε, the volume fraction occupied by air bubbles—incorporated at the mixing step, $GL_{\text{remain liq}}$, the MRI signal from a voxel that would be full of the remaining liquid phase, and t, the processing time. The porosity of raw dough is often considered constant—no gas compression at cooling nor collapse of bubbles during storage. $GL_{\text{remain liq}}$ takes into account the changes in the NMR relaxation times, resulting from temperature decrease and freeze-concentration. It is tempting to directly relate the ice fraction to the intensity of the MRI signal, but from Equation (1) it is clearly not the sole factor affecting the MRI signal during the phase change of water. Despite these combined effects, the gray level in frozen dough is (surprisingly) *linearly* correlated to the ice fraction (Figure 2). This makes MRI a quite perfect ice sensor. The non-negligible effect of the changing NMR relaxation times during freezing [1–3] is evident from the disappearance of the MRI signal at high levels of unfrozen water contents. For the operating conditions of Figure 2, the MRI intensity in dough is hardly distinguished from the signal of the image background at −10.8°C although at such temperature, the ice fraction is only 57 g per 100 g of total water. Sensitivity of the MRI sensor to lower temperatures can be achieved through shorter echo time values [1] or using other sequences [2].

MRI for the Characterization of Heterogeneities in Frozen/Thawed Dough

As the high deformability of dough does not permit an accurate positioning of intrusive sensors, like thermocouples, the non-invasive character of MRI is obviously advantageous for assessing heat transfer. As an ice sensor, MRI will provide information about non-equilibrium states which was not available up to now and which will complement the usual temperature information. Additionally, it is a unique technique to assess the typical multidimensionality of heat transfer in dough [1,2]. As the dough stick is placed on a baking net for freezing, its top surface is in free contact with air, whereas on its flanks the space for air circulation (and consequently the heat transfer exchange) is reduced due to the proximity of the net wall. Hence heat transfer is 2D proceeding along the dough radius, but differing with the angle (Figure 3). Such data will obviously allow a more extensive validation of numerical models in the case of complex product geometries or thermal boundary conditions and help the design of equipments.

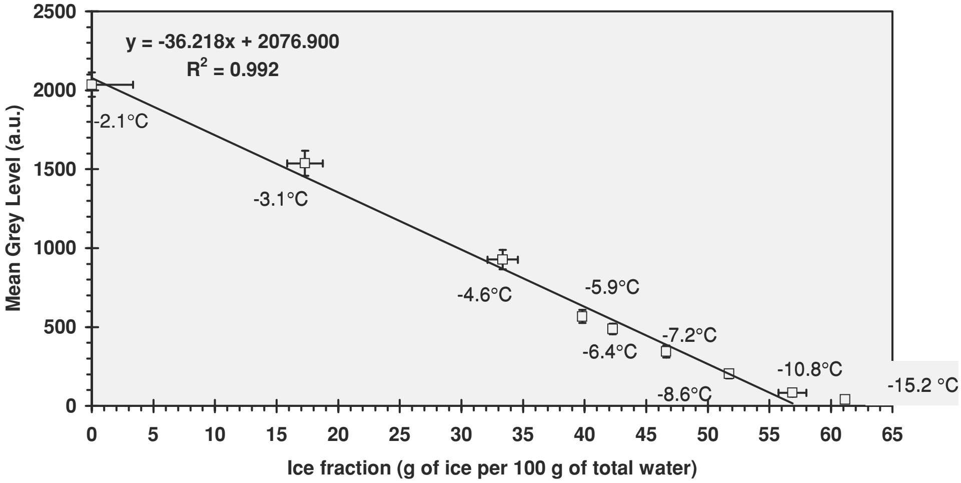

Fig. 2. Mean gray level (Siemens 0.2 T, echo-gradient sequence, TE = 4 ms, TR = 300 ms, slice thickness = 12 mm, FOV = 175 × 175, matrix = 96 × 128, number of scans = 3) as function of ice fraction as measured by NMR. From Ref. [1].

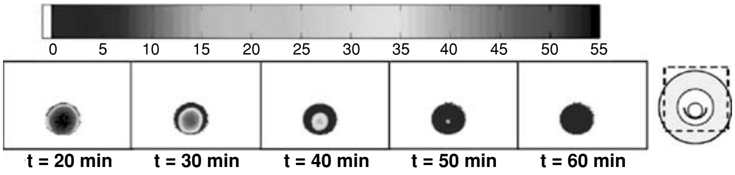

Fig. 3. MRI ice fraction (g of ice per 100 g of total water) maps during the thawing of a dough stick (water content 46.1%, 5 cm in diameter, 30 cm long, initial freezing temperature: –2.1 °C, initial temperature: –27 °C, air temperature: +31.5°C, air velocity: 10 m s^{-1}). Same acquisition conditions as in Figure 2. From Ref. [6]. (See also Plate 136 on page XXVI in the Color Plate Section.)

Changes may also occur under temperature fluctuations during cold storage, leading to micro- and macroscopic redistribution of water. From M_0 maps performed with a 4.7 T SISCO system on dough just after thawing, Esselink *et al.* observed beneath the dough surface, the replacement of low signal levels, attributed to void cells, by high levels attributed to a higher water density and concluded to ice recrystallization in void cells during dough storage [4].

Assessment of Porosity During the Proving Process

Factors Influencing the MRI Signal of Proofed Dough

In a given voxel i, the MRI signal from dough is proportional to:

$$\mathrm{GL}(i,t) \propto (1-\varepsilon(i,t))\mathrm{GL}_{\mathrm{dough}}(i,t), \tag{2}$$

where $\mathrm{GL}_{\mathrm{dough}}$ is the gray level expected from a voxel that would be full of dough (no air bubbles) and t, the processing time. As proving proceeds, dissolved carbon dioxide, ethanol, and water will vaporize into bubbles resulting in increasing bubble size and dough porosity. As only liquid protons give the MRI signal, the increasing gas volume fraction at the voxel scale results in a decreasing intensity of signal. $\mathrm{GL}_{\mathrm{dough}}$ takes into account the variation in the NMR properties of dough (proton density, transversal, and longitudinal relaxation times) resulting from changes in temperature (water), concentration, or composition (enzymatic reaction), which may possibly occur during proving.

Equation (2) assumes the absence of interaction between the gas and the MRI signal, especially no magnetic susceptibility between air and dough (H1), as well as a centered Gaussian distribution of the electronic noise (H2) [5]. It must be emphasized that if the voxel is smaller than a given bubble size (ranging from 100 μm to a few millimeters at the end of proving), its GL will reach the one observed in the image background and "black" holes will be distinguished in the MRI dough object as a result of the presence of gas bubbles. The same applies to cell walls (about 50 μm thickness). Such specific cases will be further detailed in the last sub-section.

The following developments assume that $\mathrm{GL}_{\mathrm{dough}}$ from Equation (2) is constant during proving—no changes in temperature, water concentration, or composition (H3). Under these hypotheses, the local porosity can be deduced from the gray level, provided that the two parameters are known in a reference condition [5]:

$$\frac{\mathrm{GL}(i,t)}{\mathrm{GL}(i,t_{\mathrm{ref}})} = \frac{1-\varepsilon(i,t)}{1-\varepsilon(i,t_{\mathrm{ref}})}, \tag{3}$$

As the dough matter is perpetually moving, Equation (2) cannot be validated easily, if ever, and a volume balance can be applied only at the entire dough scale:

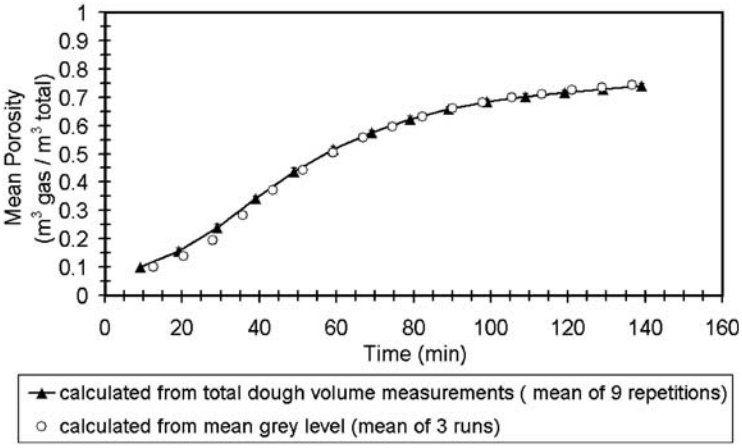
$$\overline{\varepsilon}(t) = \frac{V(t) - V(t_{\mathrm{ref}})[1-\varepsilon(t_{\mathrm{ref}})]}{V(t)}, \tag{4}$$

where $V(t)$ is the total dough volume and $\overline{\varepsilon}(t)$, the mean porosity in dough. The latter can be compared to the mean porosity deduced from the MRI mean gray level ($\overline{GL}$), after generalizing Equation (3) and assuming an uniform initial distribution of porosity (H4) [5]:

$$\overline{\varepsilon}(t) = 1 - (1-\varepsilon(t_{\mathrm{ref}}))\frac{\overline{GL}(t)}{\overline{GL}(t_{\mathrm{ref}})}. \tag{5}$$

For the validation purpose, it was first checked by NMR that changes in composition under enzymatic reactions had no effect on the relaxation signal [5]; this partially validated hypothesis H3. In order to fully verify hypothesis H3, very low water exchange and heat exchange were performed, thanks to the optimization of the experimental device and procedure for proving [5]. The mean porosity calculated from the mean MRI gray level—deduced from Equation (5), was in good agreement with the mean porosity calculated from total dough volume—Equation (4), as illustrated in Figure 4. As heat and mass transfer often take place concomitantly to fermentation at the industrial scale, the estimation of porosity—Equation (2) from MRI images acquired under realistic process conditions should be preceded by a pre-correction step [6].

Fig. 4. Mean porosity estimated from volumetric and MRI measurements during proving (26 °C). (Siemens 0.2 T, spin echo sequence, TE = 11 ms, TR = 300 ms, slice thickness = 12 mm, FOV = 175 × 175, matrix = 96 × 128, number of scans = 2.) From Ref. [5].



The present analysis can be of far-reaching use as it can serve as a validation procedure when testing new MRI sequences or new algorithms for image processing. For instance, echo-gradient sequences are known to be sensitive to the magnetic susceptibility between air and dough, and hypothesis H1 is no longer verified in such case. Applying Equation (2) will then result in overestimated local porosity or bubble size. Such artefact is expected especially at high magnetic field [7], but is also encountered at low magnetic field for long echo times [8]. It would be worth developing test objects dedicated to the same validation purposes, but at the local scale.

Large-Scale Information (Dough Scale)

At any processing time, the specific volume of the dough can be deduced from the area occupied by the dough object in the 2D MRI image [5,9,10]. Such parameter is usually obtained from volumetric measurements—using transparent, graduated containers, or monitoring the displacement of a liquid in a graduated column. However, by inducing additional pressure or frictions to the walls, these methods may be source of bias (e.g. use of a cover disposed on the top of the dough or weight of the liquid column). MRI does not present such inconvenient. Thanks to the possible positioning of multiple slices or even the use of a 3D sequence, it also offers the unique opportunity of dealing with geometries presenting strong anisotropy, e.g. French baguette or croissant compared to sandwich bread. The MRI volume accuracy obviously depends on the facility to detect the dough outlines from the image background. In other words, it relies on the signal-to-noise ratio, the spatial resolution—affecting the partial volume effect, and the type of algorithm retained for image processing.

Intermediate-Scale Information

Dough proving is often thought as a homogeneous process. However, areas of lower or higher densities can be observed from loaf slices [4,9]. Anisotropy may even be evident from the deformed external shape of the proofed dough [10]. These intermediate-scale heterogeneities are likely to happen under stresses. They may be of mechanical nature like the ones induced between sheets or within the roll at moulding [10] or by the outer surface—restraining the expansion [9]. Heat treatments producing intense thermal gradients within dough during previous processing steps [6] may also generate stress on the yeasts or the gluten network.

The scale under concern, ranging from one to a few millimeters, is much larger than the average cell size and parameters like local porosity (ε) or local displacement are more adequate to characterize such heterogeneities. As an illustration, Figure 5 presents the local porosity in dough sticks that have been previously frozen at different rates (at –30 or –40 °C) stored during 2 weeks at –20 °C and thawed before proving at 30 °C [6]. The dough frozen at –40 °C needed longer proving times to produce similar final volume. Additionally, it exhibited a core with porosity lower than the outer layers, even after long proving times whereas the dough frozen at –30 °C had a quite homogeneous porous structure (at a 1-mm scale). In fact, due to the cylindrical geometry of dough, the core freezes at a higher rate and it was found that over a certain threshold—which is over passed in the case of −40 °C at core, the expansion rate—through the survival of yeasts probably, is affected by the freezing rate.

Monitoring preferentially orientated motions of matter is a complementary, rather dynamic, way to characterize

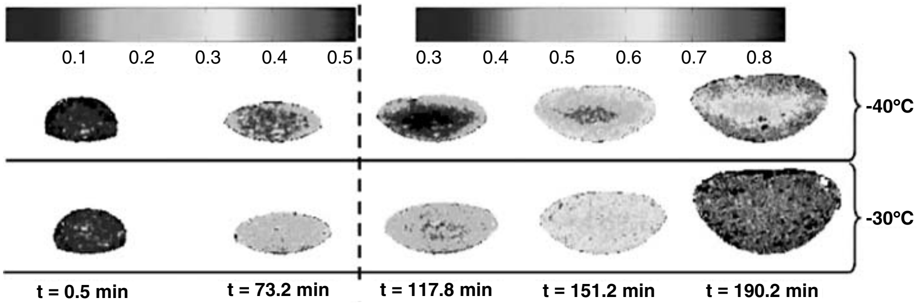


Fig. 5. MRI porosity maps (Siemens 0.2 T, spin echo sequence, TE = 15 ms, TR = 300 ms, slice thickness = 12 mm, FOV = 175 × 175, matrix = 96 × 128, number of scans = 2) of dough sticks previously frozen at −30 and −40 °C. From Ref. [6]. (See also Plate 137 on page XXVII in the Color Plate Section.)

the heterogeneous features of the dough expansion. Surprisingly, this point has received little attention so far [10]. Future investigations in this field would require the development of methods, either at the acquisition step—for instance to "trace" the matter in motion, or at the image processing step, with the adaptation of softwares developed for other applications, e.g. the use of optical flow [10].

Small-Scale Information (Bubble Scale)

Lastly, the distribution in size of cells and of cell walls can be assessed by MRI microscopy. Spatial resolutions that have already been tested [7,10–12] range from 100 to 270 μm, with slice thickness between 0.5 and 3 mm. Optical and electron microscopy [13,14] are more classically used, but these techniques are invasive and less suitable for monitoring dynamic processes in dough during proving. Additionally, the large-sized cells are often omitted because of the small sample slice. The X-ray tomography also offers non-invasive, dynamic monitoring of expansion and may compare with MRI [15–16].

The main challenge with developing MRI microscopy lies on the compromise between spatial and temporal resolutions. Especially, the number of scans (and thus the acquisition time) will tend to increase so to counter-balance the low signal-to-noise ratio resulting from higher spatial resolution. The acquisition durations of the previously tested sequences range from 2 to 8.5 min. Ideally, it should be small relatively to the (linear) period of major expansion (about 20 min), otherwise fast movements of the dough will cause blurring in the images.

The final objective is to get quantitative parameters descriptive of the dough cellular structure. Both the MRI sequence and the algorithm for image processing should be carefully chosen so to avoid bias in the way of quantification. The use of sequences sensitive to local inhomogeneities should be avoided, as already mentioned. Methods for estimating the size of holes have already been developed and tested on similar camera images of dough or bread, obtained from either loaf or microscope slices. Only apparent gas cell distributions (estimated from the 2D image of a 3D reality) have been assessed so far with no reconstruction of the true gas cell distribution by mathematical means [17]. With the same idea, MRI data recorded in 3D mode, combined with a time-resolved analysis will be interesting to track the behavior of individual gas bubbles.

Nevertheless, results obtained with 2D microscopy are already promising. Especially, the gas cell distribution observed by MRI on proofed dough is preserved in the crumb structure of the bread after baking [10]. These results confirmed that the crumb structure is already defined at an early stage of the bread-making process and baking is not the sole determining step. Other effects on the dough cellular structure have also been studied, such as: the freeze-sensitivity of yeast [11], the dough formulation [7], a pre-fermentation step before freezing [11], moulding with fast or slow deformations [10], the kneading temperature [10].

MRI in Food Process Engineering

Joachim Götz
Fraunhofer-Institut Chemische Technologie, 76327 Pfinztal, Germany

Introduction

Most foods (initial/final) and food components are disperse multiphase systems (suspensions, foams, emulsions, porous/dry/wet bulk solids). Aspects of the material properties essential for both consumer and producer are the structure (different length-scales) and flow behavior. The flow behavior is important for the design of *process unit operations* and *sensory behavior* of the final food product. The structure is correlated with various macroscopic properties like the storage/ageing behavior, phase separation (syneresis, sedimentation) [1,2], and the filtration/deformation/flow/sensorial behavior. Correlations between the evolution of the stress and porosity, agglomeration, and flow-type are established for flowing foods (starch solutions [3], wheat dough [4]). It is, therefore, plausible to assume that the correlation between the structure and the rheology is generally valid. Materials with volume fractions of the disperse phase higher than 5 vol.% are usually opaque [5]. MRI offers the possibility to perform measurements non-invasively, non-destructively, and highly selective (*in situ*, online) in order to study the structure or trace structural changes or inner transport processes in different phases/states of aggregation (without preparations) during production, storage, transportation, and consumption (temporal, spatial, chemical resolved). Samples may be studied several times under identical or changed conditions, which is a great advantage (time saving, higher accuracy, interior surface) compared to preparative microscopy. The objective of MRI in food process engineering is to develop and check appropriate models and describe the system for a reliable process design, quality control, and process control, in order to forgo time-intensive trial and -error. Foods have often to be built up step by step from simple ingredients to complex systems in order (i) to study effects of single constituents and (ii) to quantify interactions between constituents. On the basis of the knowledge of the involved phenomena, new products/apparatus with improved process conditions can be developed economically [6].

Structure and Changes

The pore structure of solid matrices (spatially resolved volume concentrations of constituents) and the composition have obviously a strong impact on convective/diffusive transport phenomena. In order to model or simulate transport processes in disperse media detailed geometrical data of the matrix are necessary for the discretisation of the region in question and the generation of the grids. Therefore, the analysis of the pore structure is an important prerequisite for a better understanding of transport processes in or of flowing foods [7]. The MRI applications to foods and food components are focused on the analysis of their structure/composition and detection of structural modifications due to processing/conditions. The local intensity $I(\mathbf{r})$ is due to various contrast techniques [8] generally a complex function of the applied method, sequence parameters (T_E, T_R), spin-density, material properties (relaxation, chemical shift, D_S), and velocity. There are sequences available for the quantification of specific material parameters mentioned above. In many investigations, the used sequences and sequence parameters are optimized with regard to maximal contrast. Applications in food technology are

(a) to determine the local fluid/solid concentration (products or apparatus) [7],
(b) to analyze the structure of heterogeneous foods (differentiation of components): fruit [9], vegetables [10,11], cheese [12] (ripening, spoilage), chocolate products [7], pasta [13], ham, meat products [14,15], dough [16,17], crackers [18], bones [19], filter cakes [20,21], and foams [7], and
(c) to quantify spatially resolved structural changes/reactions caused by process unit operations, storage/ageing, transportation [22–24].

The determination of the local concentration of detectable spins (a) and the structure analysis (b) are often different aspects of the same study.

Distribution of Concentration

The structure, quality, and sensorial behavior of many foods depend on the state and distribution of food components (water, oil, hydrocolloids, proteins). The components are often distinguished by CSI or relaxation times weighted imaging [8,25–30]. NMR provides an approach to characterize the food structure, interactions between

Graham A. Webb (ed.), Modern Magnetic Resonance, 1813–1818.
© 2008 *Springer.*

food components, possible induced structural changes, and monitors the spreading of water and oil. Hydrocolloids are used for the production of many food products in order to modify the textural properties (thickening, gelling, stabilizing). It is possible to determine the local hydrocolloid concentration by T_2 [31,32].

The comparison of extruded pastes shows that the moisture distribution changes dramatically using cellulose [33]. The regions with the highest moisture are without cellulose at the surface. After adding cellulose the maximum of the moisture is in the middle. MRI allows one to optimize the extrusion varying composition, pretreatment, die-geometry, and process parameters. By studying the processes in the interior of the extruder (including die) evolving cracks are observable. Analogous experiments are imaginable to determine the local moisture in extruded pasta (macaroni) for optimization of the production. The flow of pastes around an installed stick in the die leads to increased moisture in volume elements having passed internal fittings [33]. Depending on the local moisture these regions may tend toward spoilage.

Analysis of the Structure

There are principally two possibilities to study the pore system/structure of porous materials:

- direct imaging of the matrix, and
- indirect imaging of the pore system, when it is/has been saturated with a fluid which contains protons, revealing the inverse inner structure.

Direct Imaging

MRI provides 3D representations of foams [34], whereas SEM is only capable of monitoring the surface structure. In order to study the interior of foams by SEM the sample has to be destroyed. MRI allows to image the foam again after or even during the deformation. Thus, the evolution of the pore system [possible breaking of matrices (bars, cells)] can be monitored online. Direct imaging was applied to aerated countlines [7] with a dense layer at the surface and an inhomogeneous poresize distribution. This causes spatial varying firmness and, therefore, sensorial behavior. Two zones can be differentiated in chocolate bars [7]: the inner zone (peanuts: mobile oil) and the outer with pure chocolate (low signal). Nuts and fat fillings produce good contrast, whereas dried fruit and biscuit can hardly be observed [35]. MRI can, furthermore, be used to determine the distribution of fat concentration and polymorphic states of cocoa-butter [36]. This allows one to quantify the influence of heat treatments on the composition/conformations of fat phases and detect water/fat migration during storing, like the migration of triacylglycerol in composite confectionary [37,38]. The evolution of the profiles depend on the storage temperature [39]. Thus, fat bloom can be detected before its visible recrystallization at the surface. MRI provides a rapid test for studying fat bloom (process, recipe, storage conditions). It is also conceivable to use MRI indicators for measuring pH and redox [40]. In several cheese types holes, cracks, and seams of mould were localized (production, storage) and the local grade of ripening was differentiated [12,41]. Short relaxation times in solids cause problems for MRI with echo times longer than 1 ms. The signal decays, before it can be detected. With the help of SPI a signal can already be recorded at 50 μs [19]. A great disadvantage of SPI is the long measuring times (several hours: spatial resolution) [42].

MRI was also applied to study packaging materials or foods in packages (structure, composition, delamination [43]). Commercial food products are online characterized concerning spoilage without removal of the packages [44–46] (correlation of the degree of bacterial spoilage and T_2). The patterns in T_2-weighted MRI of the same matrix are characteristic for bacteria contaminating the sample [44]. The content in plastic-, paper-, or glass-packages and polypropylene cartons with an aluminum foil-top are imaged without any significant artifact [47]. Papers with aluminum foil and ferrous metal-tops (shielded RF, modified B_0) cause problems.

Indirect Imaging

A prerequisite for the indirect method is that (i) all pores can be filled with the proton containing fluid [48] and (ii) the pore system is not changed due to the hydration (swelling). MRI is used to characterize the porosity distribution in water saturated bulk solids/filter cakes and their evolution during mechanical thermic dewatering (filtration, expression) [49–54] and in salt-water ice-systems using decane as pore fluid [55,56]. Indirect MRI was used for tablets filled with Gd-doped oil [57]. The structure was studied for optimizing the agglomeration (parameters, recipe) with regard to the tablet design (coating) and the release of ingredients. MRI enables one to determine the density/porosity of tablets, characterize the homogeneity (±3%), and detect cracks. The structure determines the kinetics of dissolving and drug release (c). The indirect MRI can essentially be improved by hyperpolarized gases (^{3}He, ^{129}Xe) [58–59] due to an enhanced saturation. Ceramics in the green state can often be studied directly [33]. After sintering, ceramics have to be impregnated with detectable fluids/gases. This method is presumably appropriate for porous foods with low content of detectable spins.

Structural Changes and Reactions

Dynamic processes (changes slow compared to the measuring time) can be studied by serial MRI. Presently, the measuring time of one image (64×32 pixels) cannot be decreased below 60 ms/image despite newly developed hardware and sequences (Snapshot-FLASH [60,61], EPI [62], Turbo-RARE [63]). MRI was used to characterize the texture of foods due to storage/ageing (ripening, pathogen infection), damage (bruising), and processing, without peeling [64,65]. Water- and oil-distribution were studied in emulsions (phase separation: creaming) [25,66,67]. The stability of foams (cream, egg-white, beer) was analyzed [68]. Drainage and collapse were observed without process disturbation/preparation. Reviews of MRI applied to foods in mechanical (flow, separation), thermal (drying/baking, heating [69], freezing [70], melting/thawing/solidifying/crystallization, extraction/distillation), and chemical processing (kinetics) are given in Refs. [10,18,71–77].

Serial MRI was used in order to track solvent-diffusion phenomena (water, fat, solutes, solids) in heterogeneous materials [78]. Most of the applied methods for analyzing transport processes are based on integral experiments [79] (total weight). These techniques enable, in many cases, an effective process control. Integral data are not sufficient for modeling and deriving product/process parameters necessary for an effective process design. MRI allows one to observe the solvent concentration, detect heterogeneities (defects, cracks, voids) [80,81] and determine D_S or further NMR quantities [78] (spatial/temporally resolved). Inhomogeneities are observed directly by MRI or indirectly by serial MRI mapping the penetrant-uptake [82]. Assuming a material law for the diffusion the corresponding material parameters (D_S as a function of solvent concentration) can be derived from the monitored profiles. The knowledge of the network and modifications of the network dependent on the local concentration of the diffusing substances are used to improve the modeling. MRI of dewatering/filtration processes reveals the evolution of the structure of filter cakes [20,21,49,50]. Serial MRI could, furthermore, be applied to study the evolution of filter cakes or sediments (centrifugation) and the structure effect of mechanical deformation (shear, ultrasonic) or additives (flocculating/dispersing). The determined porosity profiles are required for an appropriate modeling and design of solid/liquid separation [7,83].

MRI of freezing/thawing of carrageenan gels revealed two-phase changes and at least three phases [67]. A rapid MRI method to study the freezing of raw potatoes did not show a sharply defined processing front, but a region with several water/ice-phases [84]. The extension of this region increases faster than linearly with time. The effect of freezing/thawing and storing of pork can be authenticated by MRI of T_1, T_2, and D_S [85]. Especially T_2 is sensitive to damaging effects of thermal cycles. Drying processes are studied with MRI: corn and cellulose/agar gels (contact-drying) [86], model gel [10,87], and carrots or apples (microwaves) [88,89]. The moisture distribution is homogeneous in gels during drying [86], in corn inhomogeneous (corn morphology). The decreasing integral moisture is usually combined with shrinkage. The extension of cracks correlates with the moisture gradients [90]. The distribution of the moisture and temperature is determined in a model gel [91]. The pore structure strongly influences the drying process. Aim was to characterize the pore system and structure changes, discriminate drying mechanisms (moisture mobility), and analyze the crack behavior during drying. Further applications could be the drying of multicomponent systems (evolution of swelling [92], shrinkage, crack formation). The effect of freeze–thawing on the structure (moisture distribution) of meat, poultry, fish [93], or vegetables [94] is quantified by MRI. The change of relaxation times after thermal treatments is caused by protein denaturation, aggregation, or cross-linking [93]. The signal patterns in vegetables alter dramatically after freezing. The changes of the tissue morphology are caused by the rupture of cell walls, subsequent decreasing turgor, and decreasing firmness. MRI reveals the kinetics of melting/crystallization of fat (liquid-to-solid ratio) [95].

Textural structural changes in lasagne for various cooking/holding-times were recorded [96]. With the cooking time, the moisture increases inducing swelling. The firmness decreases caused by moisture redistribution during holding. MRI allows one to determine the optimal holding conditions (temperature, relative humidity) and modify the composition and process for lengthened holding with constant properties. In boiled grains a front of moisture progresses toward the center, steamed grains show a homogeneous moisture distribution [97]. The understanding and hence the design of baking processes (plus fermentation) is rather difficult due to combined heat/mass transfer (water, gas, fat), chemical/biological reactions, and changing pore structures (shrinkage/expansion). The final pore structure is related to the sensorial behavior of the baked product. Therefore, a deeper insight into the processes during fermentation/baking are required in order to optimize the production process (sensory/ageing behavior, energy demand, production costs, output) [29,66]. Localized spectroscopy was combined with MRI to study void formation, lipid/water migration/loss during baking [98,99]. MRI was also used to characterize the architecture of baked breads [100]. The baked samples were acetone saturated. The fermentation in yeasted wheat doughs was monitored by serial MRI (effect of handling on dough properties) [101]. The increase of the loaf volume was clearly demonstrated, but an exact measurement was not carried out. In order to monitor the fermentation without preparations/interruptions online, dough samples were placed in PTFE tubes (decreased wall friction) [17]. The MRI results correlate well with non-NMR volumetric measurements. MRI clearly reveals slices of higher mass density and, therefore, lower gas permeability at the surface during the fermentation [17]. Dough with baking powder was observed during baking [16].

During the gelation of Na-alginate (Ca^{2+}-induced) a sol/gel-boundary migrates through the sample [31,32,97,102]. The Ca^{2+} progress depends on the initial ion concentration, ionic strength of the sol, and the developing pore system. The data correlate in the short-time behavior with known reaction diffusion models. Deviations for long times are probably caused by syneresis, which describes the progress of phase separation in disperse foods (cheese, yoghurt). For syneresis, serum was detected at the outside of the skim-milk samples, using CSI [29]. The molecular processes causing syneresis are not completely clarified [7].

Many dried food products (pasta, legumes, puree powder, milk powder) are rehydrated before consuming. The rehydration is possibly combined with dissolution, swelling or gelling after mixing, homogenization, and heating or cooling [66]. As mentioned above (b), the structure of a tablet determines the kinetics of dissolving [103] and drug release [7,104–106]. Liquid diffuses into the tablet matrix, polymers hydrate, and build up a gel layer (barrier for liquid ingress and drug release).

Diffusive processes are the migration of brine into meat (^{23}Na [107]), water diffusion into polyamide (O_2-barrier in dry plastic-packages) [108], and water imbibition in cork [109]. A reliable prediction of the evolution of the drying is still impossible. In order to find suitable dryers, practical drying experiments still cannot be forgone. The main reason is that the distribution of water or other fluids and the character of the mass/heat transport cannot be derived from the total vaporized amount of fluid [110]. Examples of combinations between NMR data and modeling are given for freezing [111], rehydration [112], and drying. Characteristic parameters for pore systems (fractal dimension, correlation length, percolation probability [113]) can be derived by conventional MRI (saturated pore system). MRI can be used as a basis for the generation of grids for simulations, e.g. to model the microscopic deformation behavior of disperse foods. The comparison of simulation and MRI results might help to verify and improve the understanding of microstructures and microprocesses in disperse foods undergoing a macroscopic deformation. Structural changes due to transport processes and the possibility of NMR to characterize transport processes are reviewed in Ref. [7].

[2]Bruker BioSpin GmbH, Am Silberstreifen, 76287 Rheinstetten, Germany

Introduction

In food process engineering, the handling, pumping, extrusion, or mixing of highly concentrated disperse systems is of importance for initial, intermediate, or final products. Examples are suspensions (beer mashes, chocolate, dough), foams (protein-, carbohydrate-based), emulsions, porous solids (baked products), and dry/wet bulk solids (malt, sugar). Although plenty of information concerning the rheology of multiphase system is available, the modeling of the flow behavior, structure of the produced system, and its stability cannot be considered as totally completed. In spite of its great importance, the determination of viscosities of disperse systems is difficult in principle [1,2]. Defined velocity profiles in rheometers (so-called viscometric flows), the homogeneity of the sample during the experiment, and applicability of continuous mechanics are usually prerequisites for rheometric studies. In disperse multiphase systems, demixing (phase separation: sedimentation, creaming, wall layers), scale effects [3], preparation, time effects (crushing, de-/agglomeration), tearing apart (fat, ointments), and wall slip cause problems when studying the flow behavior and determining flow functions of disperse systems with conventional rheometric methods.

Materials with volume fractions of the disperse phase higher than 5 vol.% are usually opaque [4]. NMR offers the possibility to perform measurements non-invasively, non-destructively, and highly selective (*in situ*, *online*) in order to study the structure, structural changes, or inner transport processes (without preparations) in flowing materials. The objective of this contribution is to demonstrate the potential of various NMR techniques in monitoring flow processes and the structure of disperse systems. The relevance of NMR for engineering is based on the following possibilities and applications of non-invasive and non-destructive spectroscopic/tomographic sequences with possible temporal, spatial, and chemical resolution:

- The *composition* and *inner structure* of static and dynamic systems and processes are accessible for quantitative characterization.
- *Process and quality control* can be realized without preparing or disturbing the corresponding product or process.
- *Micromodels* and *physically established, phenomenological constitutive laws* may be derived from the microscopic data. These models are required for the professional design of industrial processing units and products. The corresponding material functions can be derived by fitting the experimental data.
- By means of the microscopic non-destructive and non-invasive access, the development and *validation of models* concerning the flow behavior, boundary/initial conditions, and the critical *verification of predictions* for technical solutions is possible by comparison with NMR results.

The flow behavior is specially important in process engineering: (i) it can be used for process and quality control, (ii) it is required for the design of production plants, and (iii) it has an obvious impact on the structure of materials (sensory behavior). According to the definition used for the scope of this contribution, Rheo-NMR encloses all NMR applications dealing with the combination of flow behavior, flow induced structural changes, and NMR data. Thus, it is possible:

(a) to realize *flow experiments* [5,6] (*viscometric* flows: tube flow, Couette flow, plane shear flow, plate/plate, cone/plate) in NMR devices in order to determine the corresponding velocity profiles. By means of additional information (tube flow: pressure drop, Couette: tormentum) assuming constitutive laws it is possible to derive the corresponding *viscosity*- and *wall slip functions*.
(b) to study and quantify *flow induced structural changes* by means of appropriate NMR experiments [7–9].
(c) to derive *correlations* between microscopic NMR data and macroscopic rheological material parameters. These correlations could be very helpful for an effective process and quality control by an online determination of practice relevant quantities (viscosity, molar mass) [1,10] in order to control the assumed

Graham A. Webb (ed.), Modern Magnetic Resonance, 1819–1824.
© 2008 *Springer.*

or required process conditions and increase the efficiency of production units.

(d) to realize experimental conditions (concentration/velocity fields) which simulate the *practice relevant test conditions* in apparatus or processes in food technology. The corresponding materials or phenomena evolve differently without mixing. Therefore, it is impossible to perform these experiments using conventional NMR techniques.

NMR applications analyzing the impact of structure of solid systems on the convective/diffusive flow processes [1] are not taken into consideration.

Applications of Rheo-NMR

Flow of Disperse Multiphase/Complex Materials

In contrast to most other techniques even the flow inside of complex structures and disperse, opaque materials can be analyzed. For a homogeneous sample its velocity profile can be obtained. For specific samples with several phases the velocity profiles of the single components can be determined [11–14]. Flow experiments provide model-free velocity data, especially phase encoding methods, in arbitrary directions. Flow experiments with disperse multiphase materials or of other complex liquid systems [15,16] in viscometric flows [plate/plate, cone/plate, tube flow, extruder (capillary rheometer), Couette] offer the possibility to characterize (quantitatively) the flow behavior or the mixing/demixing behavior (with the help of the evolution of the volume concentrations or the corresponding dispersion coefficient [11]) of the present phases in the tested material. The application of MRI to determine material functions, i.e. flow- and wall slip- functions, was proposed and described in Refs. [17–19]. For this application, NMR flow experiments are combined with further measurements like the differential pressure (tube flow, capillary rheometry) or the torque (Couette flow). Advantages of flow experiments are the possibility to detect possible separation processes (homogeneity with regard to the moisture, hollow spaces or cracks), to control the supposed flow pattern, e.g. shear flow [6,20], or the degree of filling in the test device [21]. For heterogeneous multiphase systems it does not seem to make sense to realize viscometric flows in rheometers where the homogeneity of the material is assumed for the evaluation without any control [21]. Flow- and wall slip functions of homogeneous and quasi-homogeneous materials, i.e. one-phase fluids in good approximation can be determined in one single experiment [14]. Flow experiments have already been applied to study the flow in several set ups. Not only suspensions or pastes have been studied, but also water and solutions of sugars, polysaccharides and hydrocolloids [22–28], tomato juice [29], butter and margarine [30], egg-white and polymer solutions [31–33], suspensions [26,34–37], fibrous suspensions [38,39], blood [40], and wet bulk solids [41,42].

Tube Flow

Assuming appropriate material laws the corresponding material functions can be derived from the velocity profiles in a tube flow determined with MRI. The flow of polymer solutions, particle dispersions, and aqueous polysaccharide solutions was already analyzed with MRI velocimetry [13,14,26,36,43–47] in order to characterize the flow behavior and detect apparent wall slip for these materials in Poiseuille flow. MRI was used to study the flow of PSPB-water pastes (polystyrene–polybutadiene copolymer) in steady state flows [17]. The velocity profiles and volume concentrations of free water and the solid matrix of flowing pastes could be mutually independently determined via MRI flow experiments. This supplies direct proof of the relative displacement of free water in flowing pastes. It was possible to measure the wall slip of the two phases and, therefore, to differentiate between the shear and slip shares of the total volumetric flow. The flow in tubes with various geometric structures, e.g. a tube with constant circular cross-section [48], tubes with contraction and expansion [48], a tube with one or more cylinders [11], or with a U-bend [14] were studied. The measurement of the time-averaged velocity offers, in a technological view, the possibility to study the influence of material characteristics (ratio of the fluid and solid, type and concentration of additives, general formulation) and process parameter (pretreatment of the sample, process and store temperature, convey distance) on the flow behavior and structure of dispersions.

Couette

Ultrafast MRI techniques were presented to visualize steady and unsteady Couette flows of water [49–51]. In several papers [29,52–55], the velocity profiles of the Couette flow for homogeneous Newtonian and Non-Newtonian fluids were visualized by MRI and, thus, shear rate distributions could be derived. The aim was to evaluate standard rheometric methods for one-phase fluids by means of MRI. Like in the case of the tube flow, viscosity functions can be derived from the velocity profiles determined with MRI [21]. The shear induced diffusion and structure in concentrated density matched suspensions undergoing Couette flow was monitored [41,42]. MRI reveals that PMMA suspensions demix during the shear experiment. The fluid fraction increases at the rotating inner cylinder and decreases monotonously from the inner shaft to the outer cylinder. The flow behavior of PTFE pastes and other highly viscous fluids was analyzed in a new Couette shear device, developed especially for pastes [21]. The results prove that Couette shear experiments are generally not suitable for all pastes or concentrated suspensions. It cannot be guaranteed, without additional experiments, that the assumed constitutive law and corresponding viscosity functions can be transferred to model the velocity profile in any 3D problem. Flow experiments in extruders or other test devices are described in [1,56,57].

Analysis of Flow Induced Structural Changes

Nakatani *et al*. proposed the so-called Rheo-NMR to record the microscopic structural changes (e.g. shear-induced phase transitions) in polymer melts and solutions as a function of the shear rate, time (energy input), and temperature both in transient and steady state flow [7]. Conventional rheometer designs (e.g. cone/plate, plate/plate, Couette) are integrated into standard NMR probes. The use of isotopic labeling enables one to differentiate the "mechanical" behavior of chain ends from internal segments of the sheared molecules. Applications to polymeric systems and food systems in shear and extensional flow are given in Refs. [8,9,15,54,58–63]. Carrageenan sol and gels can be distinguished by means of flow experiments [16]. If a flowing sol is cooled down slowly beneath the sol–gel temperature, which holds for materials at rest, only partial gelation can be observed. The sol state (65°C), the gel state (30°C), and the shear induced sol state (30°C) exhibit clearly distinguishable spectra. (i) Polymer sites with reduced segmental mobility (junction zones) caused by intermolecular interactions and (ii) molecules or molecule groups, which are not or less influenced by these interactions and thus reveal higher T_2, can be observed by means of T_2 distributions. Shearing causes a reduction of junction zones [see (i)]. Shear flow and extension flow induced structural changes were studied in dough and its components [65].

Correlation Between Flow Behavior and T_1- or T_2-Relaxation Times

For pure fluids (e.g. water, glycerine, ethyl alcohol, acetic acid), which are rheologically simple Newtonian fluids, theoretically and experimentally a correlation between the NMR relaxation times T_1 and T_2, respectively, and the dynamic viscosity η was found, which is valid independently of temperature and pressure [68,69]. This correlation also holds for aqueous solutions like aqueous sugar solutions, fruit juices, beer, and wine [70]. Further studies on silicone oil/glass sphere suspensions and beer mashes demonstrated that the T_2–η correlation which was originally exclusively derived for Newtonian fluids can also be applied to suspensions [2,71]. In contrast to aqueous sugar solutions, there is not a simple potential dependence in suspensions between the viscosity and the corresponding relaxation times. The correlation between characteristic viscosities such as the zero-shear rate viscosity η_0 or the viscosity at high shear rates κ η_∞ can, nevertheless, be used to determine viscosities by means of the corresponding T_1 or T_2. In other words, the viscosities η are a function of the relaxation times T_1 and T_2: $\eta = \eta(T_1, T_2)$. For the modified four-parameter Carreau model holds [72]

$$\eta(\kappa) = \frac{\eta_0 - \eta_\infty}{[1 + (\kappa/\kappa_1)^a]^{0.5}} + \eta_\infty \qquad (1)$$

κ:shear rate, η_0: zero-shear rate viscosity, η_∞: viscosity at high shear rates, a, κ_1: parameters.

Only finely ground malt can be tested in conventional rheometers, as due to scale effects [3] with respect to the maximum particle size suspensions containing particles with diameters in the order of the characteristic dimensions of the rheometer do not fulfill the prerequisites of continuum mechanics. Continuum mechanics is, however, one of the main prerequisites of conventional rheometry. For silicone oils with different molecular weights, it is possible to determine the viscosity and molecular mass by using a correlation with the corresponding T_2 [10]. Similar correlations between T_1 or T_2 and η have been found for *cis*-polyisoprene solutions [73], solutions and suspensions of carbohydrates and sugars of corn [74], milk during acidification with yoghurt culture with and without stabilizers (storage and loss moduli G' and G'' [75]), paper pulps [76], industrial sauces containing starch with different cooking time (G', G'' [77]), model cheese samples (compression and stress relaxation measurements [78]), emulsions (phase diagrams, shear flow [79]), and chocolate masses (microscopy, shear flow [80]). Besides scale effects, homogeneity is another prerequisite for simple rheological constitutive laws. This is a crucial aspect in process engineering, as many products are multiphase systems. Phenomena causing heterogeneity (phase separation: sedimentation, creaming) and tearing apart (fats, ointments) are usually difficult to detect and quantify in conventional rheometry. Flow experiments combined with spatially resolved spectroscopy or possibly MRI will allow to observe heterogeneity causing flow induced effects and wall slip. Appropriate spectroscopic methods enable to characterize flow induced time effects caused by the energy input or due to special preparation techniques like de-/agglomeration or crushing [66].

Due to the great importance of the viscosity, especially for process and quality control, viscometric methods were developed which allow an online determination of the viscosity [81]. Besides the possibility of combining velocity or, furthermore, concentration profiles with the corresponding stress distribution (assuming constitutive laws) [see (a)] flow- and wall slip-functions can be derived by fitting the velocity frequency distributions [35,82]: (i) direct 2D imaging of the tube cross-section and subsequent determination of the velocity frequency distribution, (ii) radial velocity profiles from 1D projections and subsequent determination of the velocity frequency distribution, and (iii) velocity spectra [38]. Principally, it is possible to derive the flow functions (assuming constitutive laws) and information concerning the pore radius distribution from the velocity frequency distribution and an additional single-point measurement of the shear stress [38].

Realization of Practice Simulating Test Conditions

Rheo-NMR probes enable one, as shown above, to monitor flow induced structural changes in complex fluids undergoing well-defined flow types and mechanical treatments (stress, deformation, deformation velocity tensor and derivatives). They could, furthermore, be used to guarantee homogeneity as mixing devices with known shear rate distributions during arbitrary NMR experiments. Mixtures of substances are (i) miscible on molecular level or (ii) only miscible on a non-molecular level [83]. In many industrial disperse mixtures, constituents are present which dissolve partially during the processing. Furthermore, the system may tend to phase separation. Thus, the mixture is not stabile and separates, if the mixing process has been stopped. Examples for this combination of mixture (i) and (ii) behavior (dissolving and sedimentation/ascending) are beer mashes or starch/water mixtures. In order to develop reliable online process and quality controls and analyze efficiently the evolution of possible concentration dependent reactions in food systems [protein denaturation, starch plasticization or gelling, degradation of polysaccharides (beer: β-glucan)] at practice similar conditions, homogenize composition patterns have to be realized during processing and simultaneous NMR experiments.

The corresponding materials or phenomena evolve differently without mixing. As a consequence the corresponding processes achieve a minor efficiency and quality. The same holds for ceramic masses which require sufficient mechanical energy input by shearing or kneading [66] or ultra-sonification [67] in order to obtain and maintain structural homogeneity for time periods sufficient for a reliable handling during processing. Comparable materials are problematic to study by non-localized NMR spectroscopy without continuous mixing. Thus Rheo-NMR probes enable one to characterize online reacting, eventually phase separating disperse systems, to identify occurring processes, and to derive relevant kinetic parameters.

NMR studies of reacting or non-reacting disperse food systems can be performed in adapted Rheo-NMR devices. Besides the thermally or enzymically induced reactions/structural changes the corresponding velocity profiles have been derived in beer mashes, starch solutions, and water as reference. Thus, using triggered NMR sequences it is possible to detect sediments (possibly causing fouling, spoilage, undesired reactions due to overheating at the vessel walls) and, at the same time, evaluate the mixing potential of stirring vessel and stirrers in combination with the applied process conditions for a given material [84].

Relevance of NMR for Process Engineering

If a material in a specific production process (extrusion, pumping, or mixing) has certain advantages and disadavantages, it naturally to enhance the advantages and simultaneously reduce the disadvantages by a simple treatment. Therefore, measuring techniques (empirical plus advanced, if necessary) are required to identify the relevant microprocesses and microstructures in the flowing material. If the microprocesses are known, the material can be modified by an appropriate adaption process (additives, coating, ultrasonification [67], kneading [66]), to meet the requirements of the customers. To summarize the findings, NMR enables one to study many food products and processes in food processing which are often inaccessible by other measuring techniques. The flow behavior is especially important in process engineering: (i) it can be used for process and quality control, (ii) it is required for the design of production plants, and (iii) it has an obvious impact on the structure of foods (sensory behavior). Reviews on spectroscopic/tomographic methods applied in process engineering are given in Refs. [1,85–87]. The advantages of NMR applications in engineering in order to study combined flow- and NMR-phenomena are

- None or only minor preparation (dilution for optical techniques) is necessary.
- Tracers do not have to be added in general. Detectable spins themselves can act as tracers.
- NMR measurements are non-destructive and non-invasive.
- Processes can be studied completely by means of NMR using one single sample, thus reducing systematic measuring errors resulting from compositional/experimental variations.
- Using other techniques without spatial resolution, effects are averaged, e.g. in systems tending to phase separating, and might be misinterpreted or added possibly to measuring errors.
- An online determination of practice relevant quantities (viscosity, water-holding capacity, denaturation fraction) is possible in order to control the assumed or required process conditions (temperature, concentration, velocity distributions).
- Demixing can be prevented (ultra-sonification or Rheo-NMR probe).

Temperature Measurements by Magnetic Resonance

Kevin P. Nott and Laurance D. Hall
University of Cambridge School of Clinical Medicine, Robinson Way, Cambridge, CB2 2PZ, UK

Introduction

Most of the Magnetic Resonance (MR) parameters of water are temperature dependent, and each has their own advantages and disadvantages as the basis for specific applications in terms of the interplay between spatial- and temporal-resolution, as well as the accuracy of the temperatures measured. Although by far the most widely used application for *MR thermometry* is for interventional thermal therapy procedures on muscles in the human body [1,2] such measurements are increasingly being applied to thermal processing of foods. Although temperature is an important variable for such studies, its role is often complicated by interrelated heat- and mass-transfer processes, as well as the structural-changes that accompany cooking; this poses an array of problems owing to the wide variety of foodstuffs. Nevertheless, the unique power of Magnetic Resonance Imaging (MRI) is not only that it can be used to measure temperature distributions non-invasively in three dimensions, but also other relevant parameters including thermal-convection, moisture-loss, and -redistribution, starch-gelatinization, protein-denaturation, and other phase transitions which can occur either during, or after, the heating process.

Although, much research has involved Computational Fluid Dynamics (CFD) modeling of the often interrelated heat- and mass-transfer processes associated with thermal processing [3], as well as the moving boundaries associated with structural- and phase-changes [4], the limited processing power of computers often requires simplifying assumptions to decrease otherwise excessive calculation times. Therefore, there is a need for measurement techniques that can acquire data for processes that are too complicated to model, as well as to validate the models themselves. This article will describe the MR parameters and protocols that have been used to rapidly map temperature in a variety of model and real foodstuffs (Table 1).

T_1 and T_2 Relaxation Times

Although both the spin-lattice (T_1) and spin-spin (T_2) relaxation times of the protons of water are dependent on water mobility and, as a consequence, are sensitive to temperature, quantitation of both parameters using spin echo imaging can be time consuming. Also T_2 relaxation is very sensitive to structure hence has not been used to measure temperature of foods; however, it has been used on solid polymers which are homogeneous and have very short relaxation times [5]. In contrast, T_1-weighted spin echo images are acquired more rapidly by shortening the time allowed for recovery of the magnetization between the initial 180° pulse and the next phase encoding step, and then calibrating the resultant images against temperature. Hulbert *et al.* quantified the temperature sensitivity of T_1, then compared T_1-weighted images acquired with different repetition times (acquired in 24 and 33 sec) to map the temperature distribution in a pre-cooked carrot [6]. T_1-weighted images (acquired in 12 sec) were subsequently used to map temperature across a carrot piece heated in a stream of hot water; a trial and error modeling procedure was used to calculate the fluid-to-particle convective heat transfer coefficient [7].

Ruan *et al.* used a Turbo FLASH gradient echo sequence with an inversion recovery preparation [8] to acquire in 25 sec a set of seven images used to calculate a T_1 map, which in turn was calibrated to temperature [9]; the MRI results compared favorably with numerical simulations of heat transfer during cooling of cheese [10]. Whereas the acquisition time is similar to that of a T_1-weighted spin echo image, it is faster than acquiring a T_1 image from a set of spin echo images, which can take 10–20 min. In addition, the advantage of acquiring more than one image in order to calculate T_1 is thatthe system error is reduced and therefore the accuracy is believed to be higher. Ruan *et al.* used similar methodology to map temperature during an ohmic heating process [11]; the T_1 relaxation data (acquired in 14 sec) was subsequently fitted to a bi-exponential model, the longer component of which was used to map temperature across potato, beef, and carrot particles in a starch carrier medium.

Diffusion Coefficient

The effect of molecular diffusion in the presence of a magnetic field gradient on MR signals was first described in some of the classical NMR papers [12,13]. Diffusion causes an attenuation of the amplitude of the MR signal due to a loss of phase coherence between precessing spins that move randomly along the direction of a magnetic field gradient; the extent of the amplitude attenuation depends

Table 1: Sensitivity and accuracy of the MRI parameters of water used to measure temperature in real and model food systems (Taken from 2D slice images unless otherwise stated)

Sample	Measurement	Temperature range (°C)	Spatial-resolution	Temporal-resolution	Sensitivity	Error	Reference
Model food gel	Diffusion*	18–42	1.5 mm^2	30 s	13%/°C	<1.26°C	[15]
Potato	Diffusion*	20–50	0.75 mm^2	10 s	13.5%/°C	0.5 °C	[16]
Carrot	T_1	19–80	Bulk	—	3 %/°C	—	[6]
Potato	$T_1^{\dagger}$	22–95	—	14 s	1.9%/°C	—	[11]
Beef					1.2%/°C		
Carrot					1.0%/°C		
Water	Chemical shift	0–100	Bulk	—	0.01 ppm/°C	—	[17]
1% NaCl solution	Chemical shift	35–51	0.36 mm^2	15 s	0.0098 ppm/°C	1 °C	[19]
Agar gel					0.0103 ppm/°C		
Boiled egg white					0.0091 ppm/°C		
Chicken muscle					0.0114 ppm/°C		
Gel	Chemical shift	20–60	0.88 mm^2	8 s	0.0098 ppm/°C	<5°C	[20]
Raw potato					0.0104 ppm/°C		
Cooked potato					0.0107 ppm/°C		
0.01% NaCl solution	Chemical shift	—	0.88 mm^2	0.64 s	0.0096 ppm/°C	2 °C	(Ruan *et al.*, 2003)
0.3% NaCl solution					0.0102 ppm/°C	2 °C	
Gel + 1.5% NaCl					0.0098 ppm/°C	1 °C	

*Pseudo self-diffusion coefficient.
†Long component of bi-exponential fit.

on the values of the diffusion coefficient and the gradient. The diffusion coefficient can be measured by varying the gradient strengths during a Pulsed Gradient Spin Echo (PGSE) experiment [14]. Molecular transport in liquids is governed by the temperature dependence of their viscosity. Using the Stokes–Einstein relationship between viscosity and the translational self-diffusion coefficient, the temperature dependence can be described by the relation

$$D \propto \exp(-E_a/kT) \tag{1}$$

Sun *et al.* acquired an "effective" self-diffusion coefficient in 30 sec to produce 2D temperature maps of a model food gel [15]; subsequent experiments on potato used a half Fourier transform technique to shorten the acquisition time to 10 sec[16].

Chemical Shift

Background

Theory

Chemical shift refers to the variations in resonance frequency caused by different chemical environments; for example, that between protons of water (–OH) and fat (–CH). It is known that the chemical shift of water protons has a linear dependence with temperature from 0° to 100°C, with a sensitivity of 0.01 ppm/°C [17]. The major advantage of chemical shift is that it is the only parameter which has the potential to be independent of changes which accompany cooking, since its temperature sensitivity is based on the changing fraction and nature of hydrogen bonds with vicinal water molecules, rather than the mobility of water in the food matrix. In contrast, since the T_1, T_2, and diffusion coefficient methods are based on the magnitude of the NMR signal they are dependent on moisture content, which frequently changes during thermal processing.

Chemical shift resolved imaging has been used to separate regions with different temperatures [18]; however, it is time consuming to acquire information for a range of temperatures. Instead, phase mapping is employed which is sensitive to changes in the local magnetic field (B_{loc}) and, as a consequence, chemical shift to which it is related by the equation,

$$B_{\mathrm{loc}} = (1 - \sigma_{\mathrm{tot}})B_0 \tag{2}$$

Since the phase image is also sensitive to magnetic field inhomogeneity, changes of phase have to be measured relative to a reference phase image at a known temperature.

Hence, the temperature dependence of phase (ϕ) in a gradient echo sequence is related to both the field strength and the echo time by the equation,

$$\Delta\phi = C\gamma T_{\mathrm{E}} B_0 \Delta T \qquad (3)$$

where $\Delta\phi$ is the phase shift over a corresponding temperature change ΔT; γ is the magnetogyric ratio of the hydrogen nucleus; T_{E} is the echo time; B_0 is the macroscopic magnetic induction; and C is the proportionality constant. Figure 1 is a schematic diagram which shows the procedure for processing of the temperature maps (in 2D, and 3D volume rendered), in this example induced by microwave heating a jar containing a starch sauce with mushroom particulates.

Temporal changes in the magnetic field need to be accounted for by measuring the phase-changes in a model system at a known, preferably constant, temperature within the same field-of-view as the heated sample. Since the temperature measurement depends on the value of B_{loc}, the accuracy of the temperature measurement will also be affected by the magnetic field homogeneity, particularly at higher temperatures.

In Practice

It is known that for water in a range of foodstuffs, the temperature sensitivity of the phase of its MR signal is close to that of pure water [19,20]. However, although it is possible that chemical shift is insensitive to structural-changes, the phase images will be sensitive to changes of magnetic susceptibility, i.e. the effect that the material has on the magnetic field. Most food materials are diamagnetic; however, large differences in susceptibility, such as at an air/water interface, lead to distortions in the magnetic field that cannot be corrected for. This is particularly problematic for foods which contain air bubbles that change location between acquisition of the reference- and heated-images.

The chemical shift of fat does not change significantly with temperature; hence, unless its contribution is removed from the measured MRI signal, it will introduce error into temperatures measured by phase-changes. Fortuitously, the magnetic susceptibility changes in fat are similar to those of water; hence the phase difference between the water and fat contributions remains constant, leaving the phase-changes due to the temperature dependent chemical shift of water as the unique dependency [21–23]. Unfortunately, since the signal-to-noise and sensitivity of the fat signal is poor, its use as an internal reference is frequently impossible and in most cases it is only feasible to provide a bulk temperature measurement by that method [24].

As with all MRI methods, the accuracy of temperature measurement is a function of water content, and thus is best for water-rich foods; however, the accuracy may be impaired by volume susceptibility changes caused by thermal expansion, and motion associated with liquid flow or convection. Bows *et al*. showed that it was feasible to map temperature across mushroom and meat particulates in a starch-based sauce [25,26], the high viscosity of which ensured there were no visible convection or particulate movement during heating.

Applications

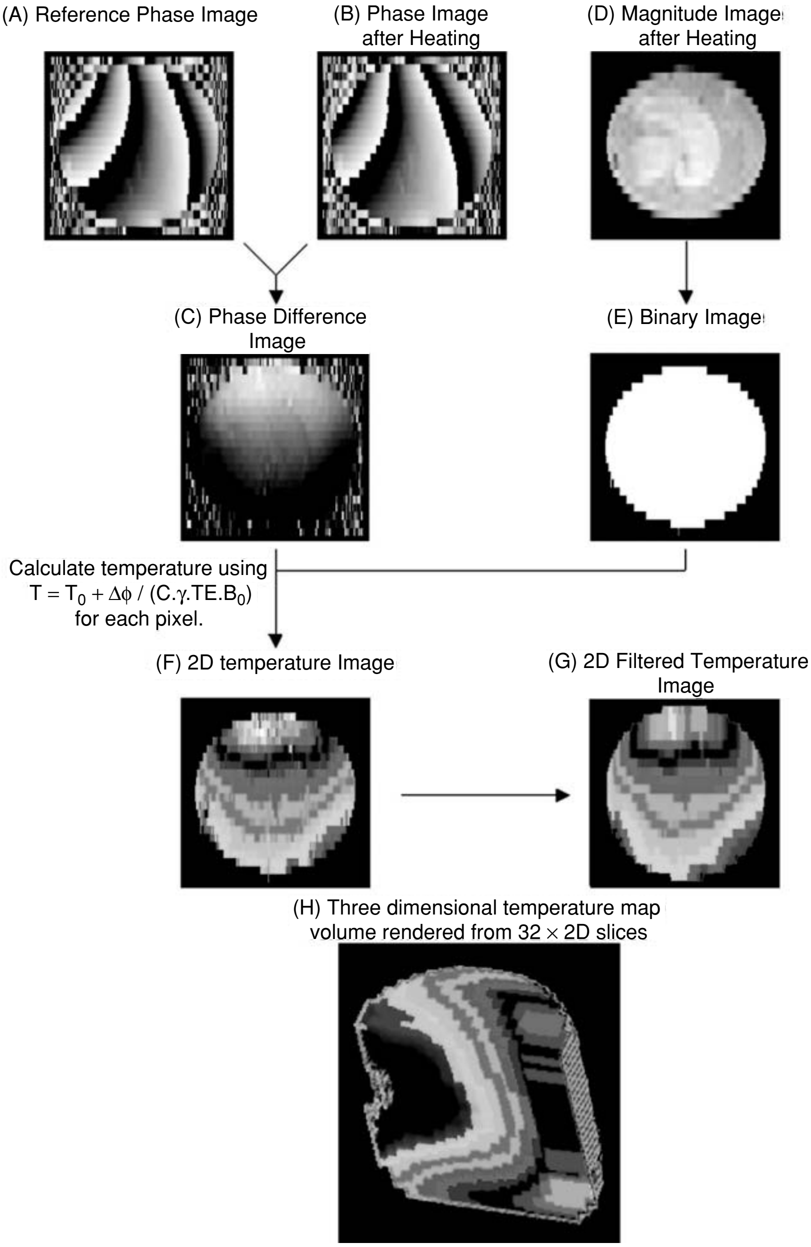
Convective Heating

Kantt *et al*. used phase mapping to measure the temperature distribution across potato particles during an aseptic process [27]; their approach was to syphon off the flow of a starch carrier containing potatoes pieces (1.1–6.9 cm^3) into the MR scanner, then stop the flow for imaging (1.2 mm^2 resolution with a 3mm slice). The MRI temperature maps were used in combination with ANSYS (Canonsburg, PA, USA.) finite element modeling software to calculate the fluid-to-particle convective heat transfer coefficient during aseptic processing of food particulates [7,27]. Since flow can produce artifacts in an MRI image unless it is coherent (or non-turbulent) the fluid has to be either stopped during, or siphoned off for, acquisition.

Sun *et al*. developed a thermostatted glass tube rheometer (essentially a simple heat exchanger) which was optimized for use in an MRI scanner [28]; it allowed flow- and temperature-equilibria to be established in the complete system before the tube was inserted in the scanner without disruption of the fluid flow. Since the fluid flow was coherent, temperature maps could be calculated using the isothermal flowing fluid for the reference phase image. Thus, the phase of the MRI signal was used for measurement of both temperature and velocity through the tube [29], and both those compared well with CFD modeling by FIDAP (Fluent Inc., East Hartford, USA). Such combined measurements are industrially important since determination of residence time, as well as temperature, is important for optimizing thermal processing of fluids flowing through heat exchangers.

Microwave Heating

Phase mapping has also been used to capture with scan times of less than 1 min the 3D heating patterns induced by microwave heating before their dissipation through thermal conduction [30]. Most domestic and industrial food applications involve microwave cavities made of metal which cannot be studied inside a MRI magnet. As a consequence, it is necessary to place the sample in the magnet for acquisition of a “constant temperature” reference phase image, remove it for heating, and then return it to



(A) Reference Phase Image

(C) Phase Difference Image
(E) Binary Image
Calculate temperature using T = T0 + Δϕ / (C.γ.TE.B0) for each pixel.
(F) 2D temperature Image
(G) 2D Filtered Temperature Image
(H) Three dimensional temperature map volume rendered from 32 × 2D slices

Fig. 1. Schematic diagram showing the calculation and processing of the temperature maps from the raw phase data. The "wrapping" of the phase in the reference image of the sample measured at a known temperature (A) represents the magnetic field inhomogeneity across the sample; this is subtracted from the phase of the co-registered image (B) of the heated sample to give the temperature dependent phase change (C). The spatially co-registered magnitude image (D) is thresholded to provide a binary image (E) used "cut out" the phase data from the phase noise, and the temperature for each pixel (T) calculated using the known linear temperature sensitivity of phase ($1/(\mathrm{C}.\gamma.T\mathrm{E}.B_0)$) and temperature of the sample when the reference image was acquired (T_0). A 16-bit scale is applied (F) and the data median filtered to provide contour plots (G) which enable comparisons to be made with CFD. The experimental data shown are taken from a jar containing 100 cm^3 of a mushroom sauce that had been heated without rotation using a prototype industrial microwave applicator (see Ref. [30] for details). The 3D volume rendered image (H) shows not only that the heating is mainly from one side but also that there is a hot spot at the bottom where the curvature of the jar allows the radiation to penetrate from more than one direction. (See also Plate 138 on page XXVII in the Color Plate Section.)

the magnet for acquisition of the heated phase image. This is feasible for objects with a defined geometry, such as a jar, which can be relocated accurately without altering the magnetic field homogeneity to ensure that all measured phase-changes are due to changes in temperature [31]. However, this method cannot be used be foods that shrink due to moisture-loss, such as a potato [32].

Although phase mapping has advantages in terms of signal-to-noise (especially for high temperatures), and of the achievable spatial- and temporal-resolution, its major disadvantage is the necessity for a reference phase image taken at a known temperature and which is spatially co-registered with the heated image.

Ohmic Heating

Phase mapping has been used to map temperature of an ohmically heated whey gel in brine solution [33] to provide better temporal-resolution than for T_1-weighted images [11]. Salt was added to both the gel and fluid to alter their electrical conductivities without significantly changing the temperature sensitivities of water proton chemical shift (Table 1). The heating and cooling regressions were found to be the same indicating the reversibility of the chemical shift method; the electric current was turned off during measurements to avoid interference.

The same protocol was used to map temperature across an ohmically heated potato cylinder immersed in an aqueous solution of NaCl and sodium carboxymethylcellulose (CMC) in order to calculate the time-dependent interface heat transfer coefficients [34]. The images in that study were acquired with the electrical current on as it was found that the stripe artifacts it induced were removed by the phase mapping method; since that approach calculates the relative temperature from the phase difference, the artifacts were cancelled by subtracting the subsequent phase image. The same potato/CMC system was simulated in three dimensions using FEMLAB (Comsol Inc., Burlington, MA, USA) and the temperature maps compared against those obtained by MRI [35]; although there was good overall agreement between them, there were obvious discrepancies due to the heterogeneity of the real foods, to bubble formation and to fluid leakage, all of which are difficult to model.

Summary

MRI temperature mapping has already been applied to a wide variety of foods and thermal processes and, although there are individual complications associated with each specific application, there is no alternative to the acquisition by MRI of temperature data in one, two, or three dimensions. Those same data can also be used either to validate existing CFD models which would otherwise have to be based on assumptions, or to aid the development of new computer models.

Statistical Methods

Part III

Chemometric Analysis of NMR Data

Nanna Viereck, Lars Nørgaard, Rasmus Bro, and Søren B. Engelsen
Quality & Technology, Department of Food Science, The Royal Veterinary and Agricultural University,
Rolighedsvej 30, DK-1958 Frederiksberg C, DK

Introduction

NMR is one of the most successful and versatile analytical techniques of our time, and it is directly applicable to amorphous, heterogeneous, and opaque systems such as food and foodstuffs. NMR is capable of probing both physical and chemical phenomena which allow food engineers and scientists to obtain a unique fingerprint of the protons (nuclei) in a sample. Sometimes the NMR fingerprint of a complicated food matrix is much too complex for simple interpretation for which reason pattern recognition techniques are required for full evaluation of the data.

The quantitative aspect of NMR data analysis has been and still is suffering from oversimplified data analysis, mainly because the complexity of the data is too great for a deterministic approach and because it is conceptually difficult to cope with a high number of variables. This simplifying tradition has resulted in the widespread normative use of NMR: If you keep only the part of the data that you think is relevant, you will confirm what you already know is important and thus reduce your chances of innovation.

There is no doubt that NMR scientists in industry and academia can learn from the successful progress of near-infrared (NIR) spectroscopy, which in the last decade has revolutionized quality control in practically all areas of primary food and feed production. NIR spectroscopy has been implemented for monitoring quality of millions of samples of cereals, milk, and meat with unprecedented precision and speed. The key to this success is the extraordinary synergy that lies in the merging of a rapid non-invasive NIR spectroscopic sensor and the data technology called chemometrics.

Generally speaking, NMR data comes in two forms: time domain relaxation data probing the physical information and frequency domain chemical shift data primarily probing the chemical information (Figure 1). In general, frequency domain data are obtained from high-resolution spectrometers with superconducting magnets, while time domain data are obtained from low-resolution relaxometers using permanent magnets.

Frequency domain chemical shift data are normally characterized by the fact that molecules, even conformations, give individual chemical shift fingerprints and that the intensity at a given band is proportional to the concentration of the substance giving rise to the band. That concentration is proportional to signal intensity and that signals from a given substance remain stable on the frequency axis are exactly the requirements of bilinear multivariate quantifications. A number of exceptions to this rule exist, including molecular size (i.e. more intense peaks from smaller polymeric molecules than from larger polymeric molecules due to their longer T_1 times), chemical shift changes according to pH, temperature, etc.

Time domain relaxation data are characterized by lack of structure and selectivity, normally being composite exponential decay functions. In contrast to frequency domain chemical shift data, time domain data are direct functions of the mobility of the molecular systems under study. Time domain relaxation data have the property that all measured substances contribute to the intensity at all times but with different exponential weights. At a given time the NMR relaxation signal intensity is proportional to the contributions from the measured substances that are exponentially weighted, i.e. a slow relaxing component contributes relatively more than a fast relaxing component. If we assume that we can extrapolate to time zero, the concentrations of the measured compounds are linearly proportional to signal intensity, which is why univariate NMR relaxation measurements can probe proton density (or mass). Difference or ratio calculations, curve fitting or multivariate data analysis is required to extract more detailed quantitative information from such data. Time domain relaxation data have an additional property, namely, that if the time axis is shifted there will remain a linear relation between the individual relaxation components which is actively utilized in the so-called direct exponential curve resolution method (see chapter on “slicing”).

Perhaps because NMR was developed by physicists and chemists, it has primarily been used for identification, authenticity determination, and simple quantification purposes. Its exploratory and quantitative potential has largely remained unexploited. The first report on the use of chemometrics on NMR data appeared in 1983 by Johnels *et al.* [1], but it was not before the early nineties that new developments of applying chemometric data analysis to high-resolution NMR signals occurred, with the impetus being the analysis of complex 1D and 2D

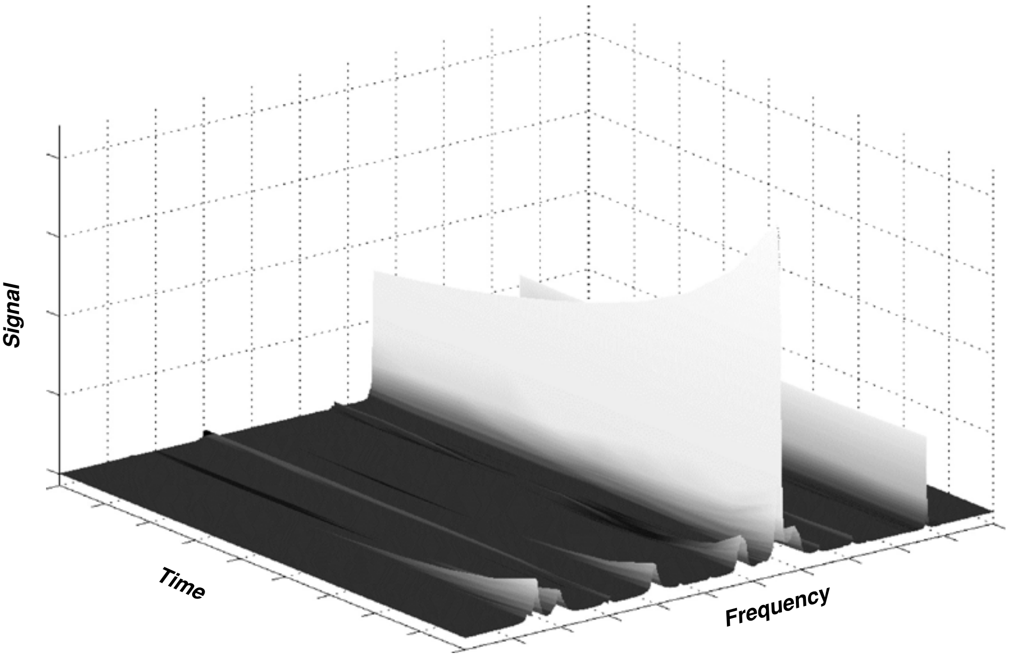

Fig. 1. NMR data comes in two forms: time domain relaxation data and frequency domain chemical shift data.

NMR structures of complex biological and pharmaceutical/therapeutic matrices [2,3]. The use of chemometric data analysis for frequency domain data has now become well-established thanks to the so-called metabonomics approach defined as "Metabolic processes studied by NMR spectroscopy of biofluids" [4], whereas the use of chemometric data analysis for time domain relaxation data is still in its infancy and was first adapted in the late nineties [5–7]. It has been and still is common practice in time domain NMR to design calibration models from univariate signals collected from intrinsically multivariate signals. The most prominent examples are solid-fat determination based on the ratio between the signal at 11 μs and the signal at 70 μs and fat determinations based, for example, on the amplitude of a single gradient-stimulated echo. Such calibrations are, from a data technological point of view, suboptimal approaches.

What is Chemometrics?

The essence of most chemometric methods lies in their construction of common latent factors (or principal components) from underlying latent structures in the original data.

One of the main advantages of chemometric data analysis is the possibility of projecting multivariate data into a few dimensions that can be displayed in a simple graphical representation. Chemometrics is also called "statistics without tears", because it makes it possible to handle large data sets and deal efficiently with real-world multivariate data, taking advantage of the co-linearity of spectral data. In this chapter we will illustrate the application of chemometric data analysis to two different food systems and through them evaluate the current status of the use of two-way chemometrics for the analysis of NMR data.

When using spectroscopic techniques for chemical quantification, traditionally univariate data analytical methods have been used, in which a single response variable is measured or selected from the whole spectrum and only this variable is analyzed. Statistical methods can then be applied for classification, or linear regression can be performed and a regression line can be calculated, indicating how well the measured variables describe the dependent variable in question. However, there are a few problems that should be considered when using univariate methods (Figure 2).

1. *Waste of data.* From a large number of measured variables only one or a few variables are selected for the analysis. Especially for complex samples there is a huge loss of information in using only a few variables from a whole spectrum.

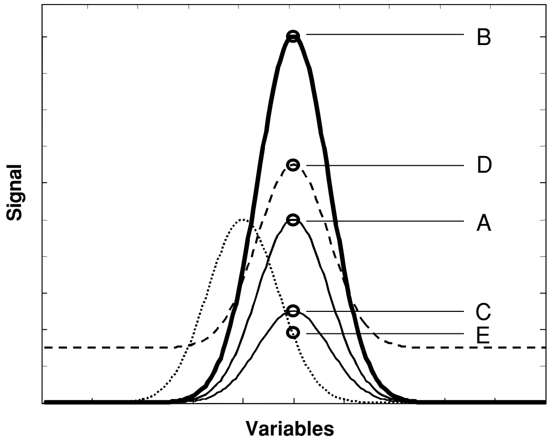

Fig. 2. Examples of problems that arise when univariate analysis is applied to spectral data. Quantitative spectral response of a given analyte in three levels is indicated by spectrum A, B, and C. Spectrum D corresponds to spectrum A with an offset and spectrum E corresponds to spectrum A with a variable shift. The circles indicate readouts in a univariate approach.

2. *A priori knowledge.* Extensive a priori knowledge is required about the sample spectrum in order to choose the right variable and thus a hypothesis about the results to be found is required, which in turn will reduce chances for innovation.
3. *Interference.* Another problem occurs if different components in the sample give signals in the same region as the analyte. In cases of overlapping signals these will be inseparable when only a single variable is measured and the content will be estimated too high due to the several components adding to the signal intensity.
4. *Baseline offset.* From Figure 2 it is seen that if only the variable marked with a dot is recorded, spectrum D will be estimated to have a higher content of the compound in question than spectrum A, even though the two responses have equal amplitude relative to the signal baseline. If the whole spectrum is recorded, the baseline offset of spectrum D is easily detected and the necessary action can be taken to correct for this offset.
5. *Abnormal signals.* Outliers are samples whose spectra do not conform to the majority of samples in a data set and they might have a detrimental effect on the calculated model. An example of this is shown in Figure 2 where one sample has a different spectral signal (spectrum E) than the others. In univariate analysis there is no data analytical way to determine that something is wrong with the sample.

Chemometric data analysis effectively deals with these problems, including handling covariate spectra of complex samples such as foods or biological samples in which the signals are so complex that the signal of a single chemical component cannot be identified, or the property of interest cannot be described by a single peak. The disadvantage of using two-way chemometric models is that it requires data from several samples to be analyzed simultaneously and the qualitative information (e.g. time constants) is lost due to the common practice of extracting orthogonal latent factors.

Several properties are essential for the successful application of chemometrics to spectral data. Firstly, for quantitative spectral analysis, the *intensity axis* must be the same for all samples, as a basic assumption is that the signal intensity is proportional with the concentration and that the signal intensities are additive, analogous to the obedience of Lambert-Beer law in optical spectroscopy. Secondly, chemometric data analysis is based on the extraction of latent components or underlying *common structures* which means that the data should be low-rank bilinear. A practical explanation of the concept of bilinearity is that a given chemical compound gives one and only one spectral signal; hence, this compound will have the same spectral shape in all samples and only vary in intensity from sample to sample. The bilinear chemometric model provides a set of scores and a set of loadings. The loadings describe the spectral shapes needed to describe all the profiles and the scores provide the quantitative information on how much of each loading is present in each sample. In an abstract sense, the loadings can be interpreted as pure spectra and the scores as concentrations. Due to orthogonality constraints, however, the loadings are merely mathematical constructs and therefore, the bilinear components (one loadings vector and its associated scores) are referred to as *latent variables*.

Preparation of Data

While most other types of spectroscopic data can be subjected to chemometric analysis directly from the spectrometer, NMR data often need to be preprocessed in several ways in order to conform to the prerequisites for chemometric data analysis.

1. *Intensity scale.* The data need to have the same intensity scale, which is trivial for most other spectroscopic techniques, but in NMR measurements the data are often scaled in the spectrometer, and this scaling must be removed before chemometric analysis. Secondly, it is often difficult to obtain reproducible shim and sample filling conditions between samples, for which reason normalization is required. This can either be done in the time domain by division by mass or by normalization to the first point (assuming the same proton density and approximately the same proton mobility) or in the

frequency domain by normalization to an internal standard.

2. *Phase errors.* A difficult problem encountered with NMR data is the existence of phase errors. Manual phase correction is usually implemented in the instrument software, but this process is very time consuming, especially for the large data sets that are often analyzed using chemometrics. More importantly, manually phase-correcting a series of spectra will lead to suboptimal results due to the subjective evaluation of the correction necessary for individual spectra. In time domain NMR automatic phase correction is a reality [8], including an algorithm which is built on chemometric grounds [9]. With respect to frequency domain NMR spectroscopy, several methods for automatic phase correction have been suggested; however, none appear to be generally applicable to all types of NMR spectra.
3. *Fourier transformation.* In NMR spectroscopy a Fourier transformation is required to convert the time domain data (free induction decay) to the frequency domain (NMR spectrum). Naturally, quantitative methods require that parameter settings for the Fourier transform (choice of zero-filling and apodization function) are equal for all samples to be evaluated, as they may influence the finer details in the spectra.
4. *Chemical shift variations.* The last preprocessing problem to be mentioned here and which occurs only in high-resolution frequency domain NMR spectroscopy is the chemical shift variations that may occur from sample to sample or even from peak to peak. The overall sample-to-sample variations are due to small variations in spectrometer frequency and the solution is straightforward, as it is a general translation of the entire spectrum either by pattern recognition or by an internal reference peak such as 3-trimethylsilyl-1-[2,2,3,3-$^2H_4$] propionate (TSP). The peak to peak chemical shift variations due to variations in, for example, pH (encountered when analyzing samples such as urine) are much more difficult to handle. Smoothing and/or data reduction in the form called bucketing is a pragmatic solution to the problem, but other more general and elegant methods have been proposed, including Partial Linear Fit [10] and genetic algorithm peak alignment [11]. The so-called warping techniques that have been developed for correction of peak shifts in difficult chromatographic elution profile data [12,13] are also very promising.

Unsupervised Data Exploration by PCA

The basis of most chemometric algorithms is Principal Component Analysis (PCA) which has already celebrated its 100-year anniversary [14] and is still in splendid shape. PCA can be considered as the first amendment in exploratory analysis due to its extraordinarily robust data reduction and data presentation capabilities. In PCA the multivariate (spectral) data set is decomposed into orthogonal components whose linear combinations approximate the original data set in a least squares sense [15]. Common to bilinear models is that an entire matrix, with each row being the measurements on one sample, must be acquired. The model works on this entire data set, instead of on one sample at a time.

The mathematical structure of the PCA model can be described as

$$\mathbf{X} = \mathbf{1} \times \bar{\mathbf{x}}^{\mathrm{T}} + \mathbf{T} \cdot \mathbf{P}^{\mathrm{T}} + \mathbf{E} \tag{1}$$

where $\mathbf{X}$ is the NMR data matrix ($I \times J$; one NMR spectrum/relaxation profile per row), $\mathbf{1}$ is a vector of ones ($Ix1$), $\bar{\mathbf{x}}^{\mathrm{T}}$ is the mean vector of all samples, $\mathbf{P}$ contains underlying profiles ($J \times N$; loadings) and $\mathbf{T}$ is the contributing amplitudes ($I \times N$; scores). The scalar N is the number of factors resolved and $\mathbf{E}$ ($I \times J$) holds residual unexplained variation. For a given N, the mean, scores and loadings are determined in a least square sense. The loadings hold information on which variables are important and which are correlated, and the scores provide information on which samples are grouped, which are extreme etc.

PCA remains the primary tool for initial investigations of large bilinear data structures for the study of trends, grouping and outliers (see below).

Supervised Data Exploration

PLS Regression

Partial Least Squares (PLS) regression [16], essentially based on the PCA concept is its counterpart for regression analysis. While PCA can be compared to shopping (in the data) without a shopping list (i.e. the data analysis is performed without the use of *a priori* knowledge), PLS regression is like shopping *with* a specific shopping list. PLS regression is a predictive two-block regression method based on estimated latent variables and applies to the simultaneous analysis of two data sets for the same objects (e.g. spectra and physical/chemical tests). The latent variables of the spectral data, however, are determined in such a way that only the information needed to predict the physical/chemical data is extracted. The purpose of PLS regression is to build a linear regression model that enables prediction of a desired characteristic from a measured multivariate signal.

Validation

In order to avoid overfit (fitting the noise) in the highly empirical chemometric modeling a suitable validation scheme has to be used. The most optimal situation is to have an independent data set upon which the developed models can be tested to show the true predictive performance of the models. Since this is not always possible due to practical or economical limitations, the method of cross validation [17] can be useful. By excluding some of the samples, modeling the remaining samples and testing the models on the left-out samples, it is possible to obtain a realistic estimate of the significant number of components and the expected prediction error [reported as the root mean square error of cross validation (RMSECV)] [18].

Outlier Detection

An important aspect of chemometric data analysis is the possibility to detect outliers. An outlier is a deviating sample which influences the model incorrectly. The reason can be one of many, such as wrong sample preparation or erroneous handling of the sample, but it can also be due to instrumental artifacts or merely that the sample does not follow the stipulated model. It is important to make an effort to find out why a sample is an outlier before removing it from the data set. Once a sample has been shown to be an outlier, it should be removed from the data set and the calibration model must be recalculated [19].

Variable Selection

There are "fifty ways to leave your lover" and the same statement goes for variable elimination. A multitude of methods exist for the elimination of variables in order to obtain better predictive performance as well as a clearer interpretation of the data. The method of interval PLS (iPLS) [20], based on a simple split of the variables into a number of intervals, is introduced to give an overview of relevant spectral regions in a data set with respect to a given dependent variable. In some cases iPLS also gives rise to models with a better predictive performance compared to the full-spectrum model.

Example I. Chemometric Analysis of NMR Spectra of Apple Juice

As an example of how PLS and PCA can be used to calibrate and classify ^{1}H NMR data, the methods will be demonstrated on ^{1}H NMR spectra of different apple juices with different amounts of added ethanol. Four commercial apple juices (A, B, C, and D) were selected. Apple juices A and B were produced by the same company. Apple juices A, B, and D were produced as an apple concentrate with water added, while C contained pure apple juice. Apple juices A and C contained unfiltered juice, and B contained pure juice from the sort Jonagold. The pH in the four apple juices (A, B, C, and D) was measured to 3.67, 3.62, 3.39, and 3.90, respectively. The NMR data set consists of 48 ^{1}H NMR spectra of the apple juices each with ethanol added in 12 levels [between 0.05 and 10.0% (w/w)] together with four spectra of the pure apple juices. The samples were measured at 293 K on a 400 MHz Bruker Avance NMR spectrometer equipped with an automatic sample changer. Presaturation was applied during the 4 s relaxation delay to suppress the signal from water protons. The spectra were collected into 32K complex data points and 128 scans were acquired for each sample. A spectral window of 8278 Hz was accumulated in an acquisition time of 1.98 s.

The full ^{1}H NMR spectra of the pure apple juices and one of the samples with 0.05% ethanol added are shown in Figure 3. The sugar region between 2.5 and 5.5 ppm contains signals from the major components found in apple juices [21]: glucose (glc), sucrose (suc), fructose (fru), and malic acid (MA). As was also observed by Belton *et al.* [21], the chemical shifts of the methylene protons in MA depend highly on pH within the sample. The region between 1 and 2.5 ppm contains signals from the minor components in apple juice (quinic, lactic, and acetic acids). Noteworthy is the increased region between 1.12 and 1.22 ppm which contains the triplet signal from the CH_3 group of ethanol. Low levels of ethanol can be seen in three of the pure apple juices (A, B, and C). The quartet signal of the CH_2 group of ethanol at 3.6 ppm is hidden below the many signals from the sugars. The other increased region between 6 and 9 ppm contains signals from aromatic compounds which have not been further assigned.

Prior to chemometric data analysis the NMR spectra of the apple juices were aligned spectrally by the dynamic time warping algorithm (DTW) [13]. To investigate the quantitative performance of 400 MHz ^{1}H NMR spectra for measuring ethanol a full-spectrum five-component mean centered PLS model between the spectral data and the ethanol concentration of the juice samples was calculated. The calculations yielded a correlation coefficient of 0.996 and an RMSECV of 0.31 (Figure 4A).

By applying iPLS to these data (Figure 4B) the spectral regions where ethanol gives rise to signals have low RMSECVs when PLS models are calculated on only these intervals. No single interval performs significantly better than the full-spectrum model, but some intervals (44, 60–63) give rise to the same RMSECV as a full-spectrum model.

In order to discriminate between the four apple juices (thirteen) samples of each) an iPLS with a dummy matrix containing the dependent variables was calculated. The dummy matrix consists of four columns, one for each manufacturer, designated by 1s if the juice is from the given manufacturer and 0s if not. A global discriminant

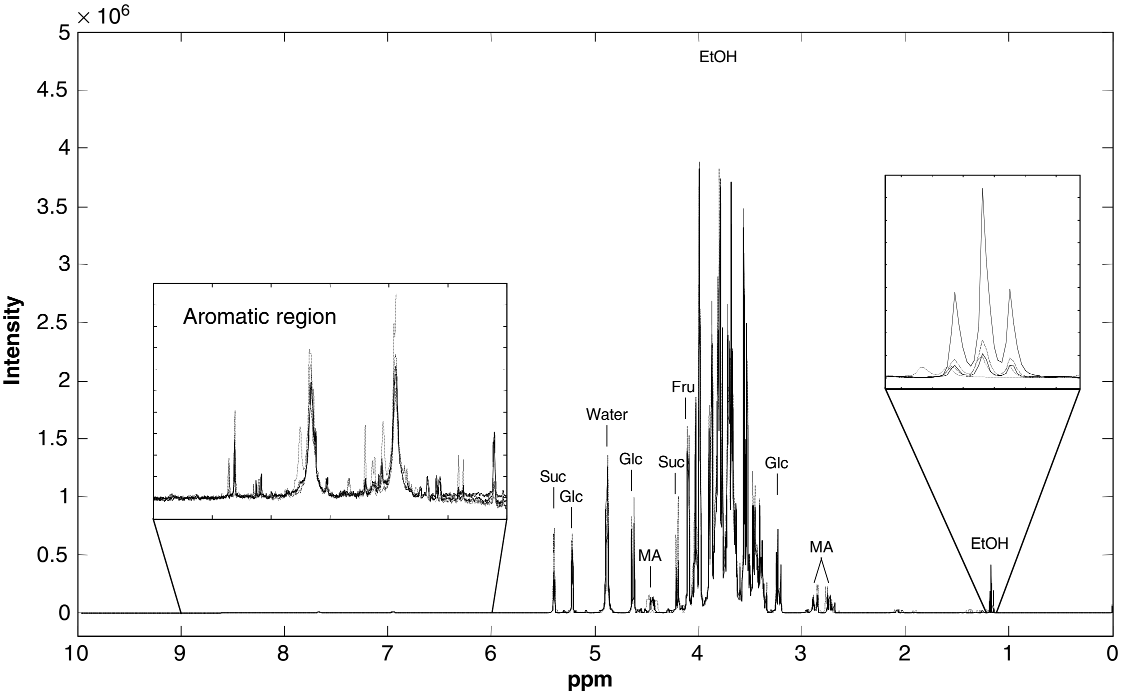

Fig. 3. NMR spectra of the four original apple juice samples (A, B, C, D) and juice sample A spiked with 0.05% ethanol.

PLS model on autoscaled data performs very well on these data and 100% separation is possible using eight PLS components. Thus, using the NMR fingerprint only, it is possible to classify which manufacturer the juice is from. To investigate if specific spectral regions contain the same discriminative ability an iPLS was calculated with the dummy matrix as the dependent matrix. The iPLS plot is shown in Figure 4C and several intervals seem to have discriminative ability. Interval 39 (4.47–4.33 ppm) performs the best and a PCA on this spectral range gives a perfect separation of the juice samples, as seen in Figure 4D. For comparison, a PCA on the full spectrum did not show full separation in any of the score plots (not shown). Furthermore, a mean centered discriminant PLS model on the full spectrum data does not perform well since the ethanol peaks in the spectra dominate the analysis.

Example II. Chemometric Analysis of NMR Relaxation Curves of Minced Meat

Fats are important food constituents and are measured in a number of foodstuffs to assure product quality. Time domain NMR data is sensitive to proton mobility, which is why the technique is useful for solid-fat determinations in the edible oils industry and for swift and accurate measurement of total fat content in dry foods. The established standard NMR approach to measuring total fat in dried food (including meat) is a univariate approach where only one point is acquired from each sample, namely the top-point of a spin-echo [22]. Simple linear regression is used for calibration. This procedure requires that the samples must be dried prior to analysis in order to remove the interfering signal contribution from water protons. Furthermore, the samples are heated to ensure that the entire fat phase is liquid upon NMR analysis to obtain the total fat signal. The second evolution in total fat determination of foods by time domain NMR occurred when pulsed field gradients [23,24] were introduced to suppress the water proton signal, leaving mainly the fat signal and thus rendering the drying step superfluous. In this method normally only one point is acquired, as in the spin-echo experiment, namely the top-point of the gradient-stimulated echo. However it would appear natural to extend the pulse method with an appended CPMG pulse train. In this example we aim to demonstrate how such a simple multivariate upgrade of the gradient-stimulated echo experiment combined with chemometrics can enhance calibration performance for total fat determination in 51 minced meat samples [25].

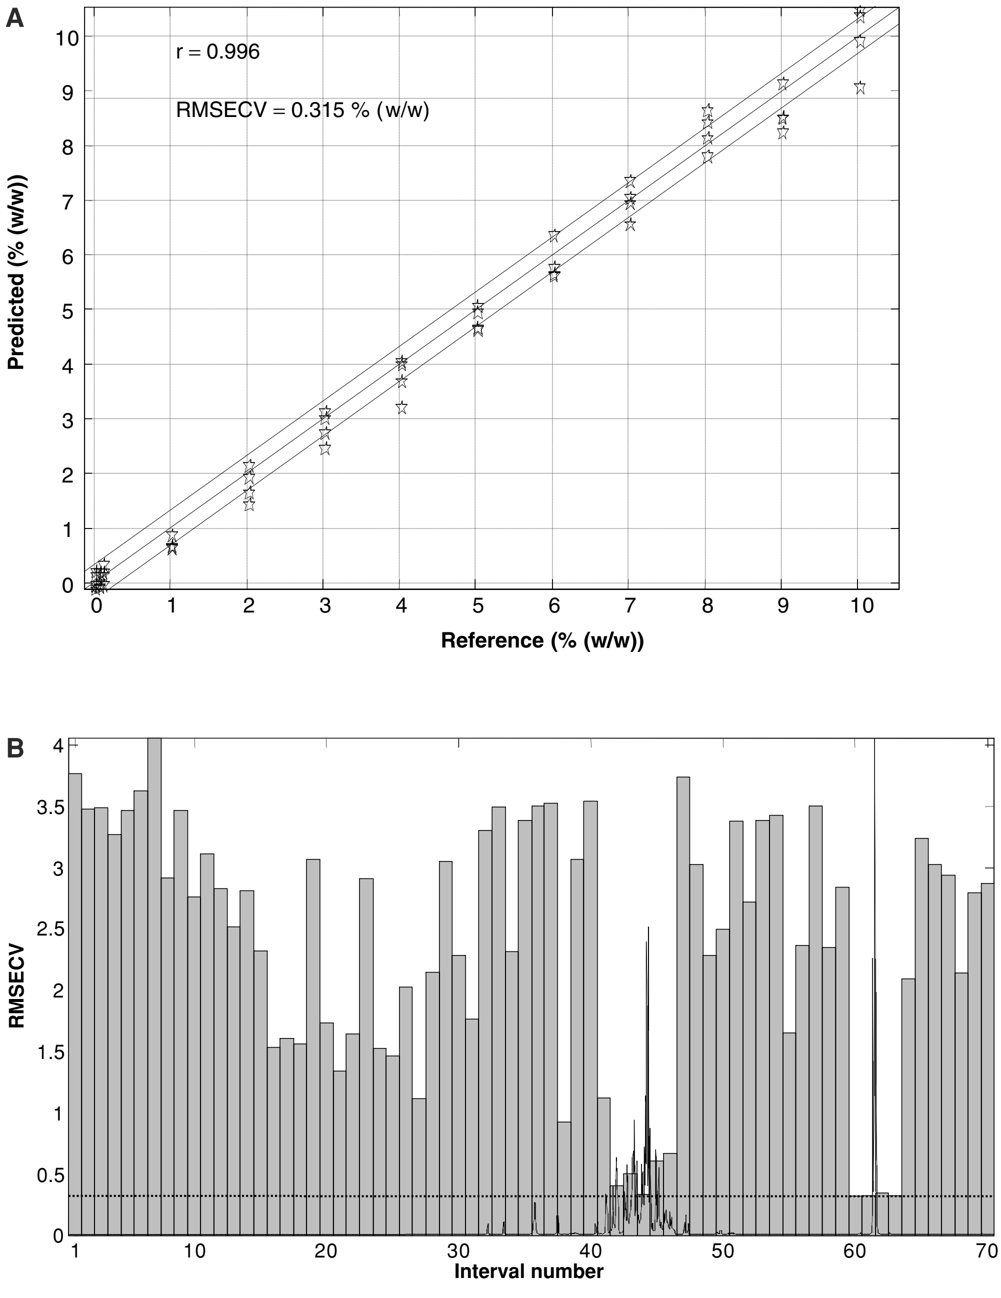

Fig. 4. (A) Predicted vs. measured plot for the ethanol full spectrum model with five PLS components. The middle diagonal line is the model target and the two parallel offset lines indicate limits for +/− RMSECV. (B) Interval PLS plot with 70 intervals and ethanol as the dependent variable. The dotted line is the average error (RMSECV) obtained from a full spectrum model. (C) Interval PLS plot with 70 intervals with a dummy matrix (manufacturer) as the dependent matrix. The dotted line is the RMSECV obtained from a full spectrum model. (D) Score plot from a PCA on interval 39 in the iPLS model (4.47–4.33 ppm). A clear grouping according to the manufacturer is observed.

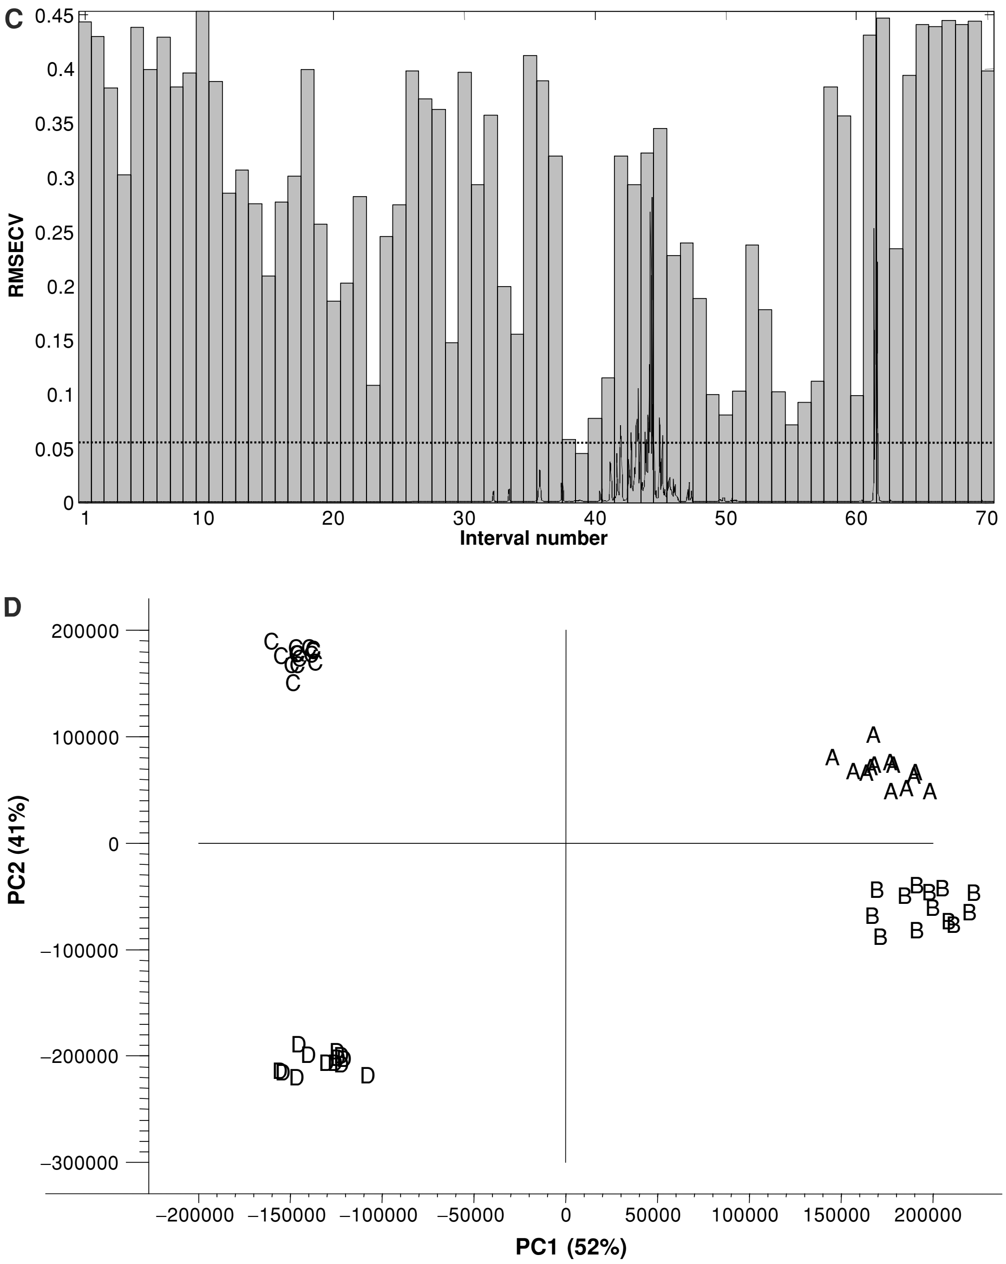

Fig. 4. (*Continued*)

Despite the fact that TD-NMR data rarely satisfies the bilinear condition (underlying latent structures have a tendency to change with concentration), PCA and PLS have proven very robust to this type of data [7]. Figure 5 demonstrates the advantage of the multivariate approach. The relaxation curves of 51 meat samples are given in Figure 5A. In Figure 5B the results of a univariate calibration of the gradient-stimulated echo amplitude of 51 fresh meat samples regressed on the conventional SBR (Schmid, Bondzynski, and Ratzlaff) solvent extraction

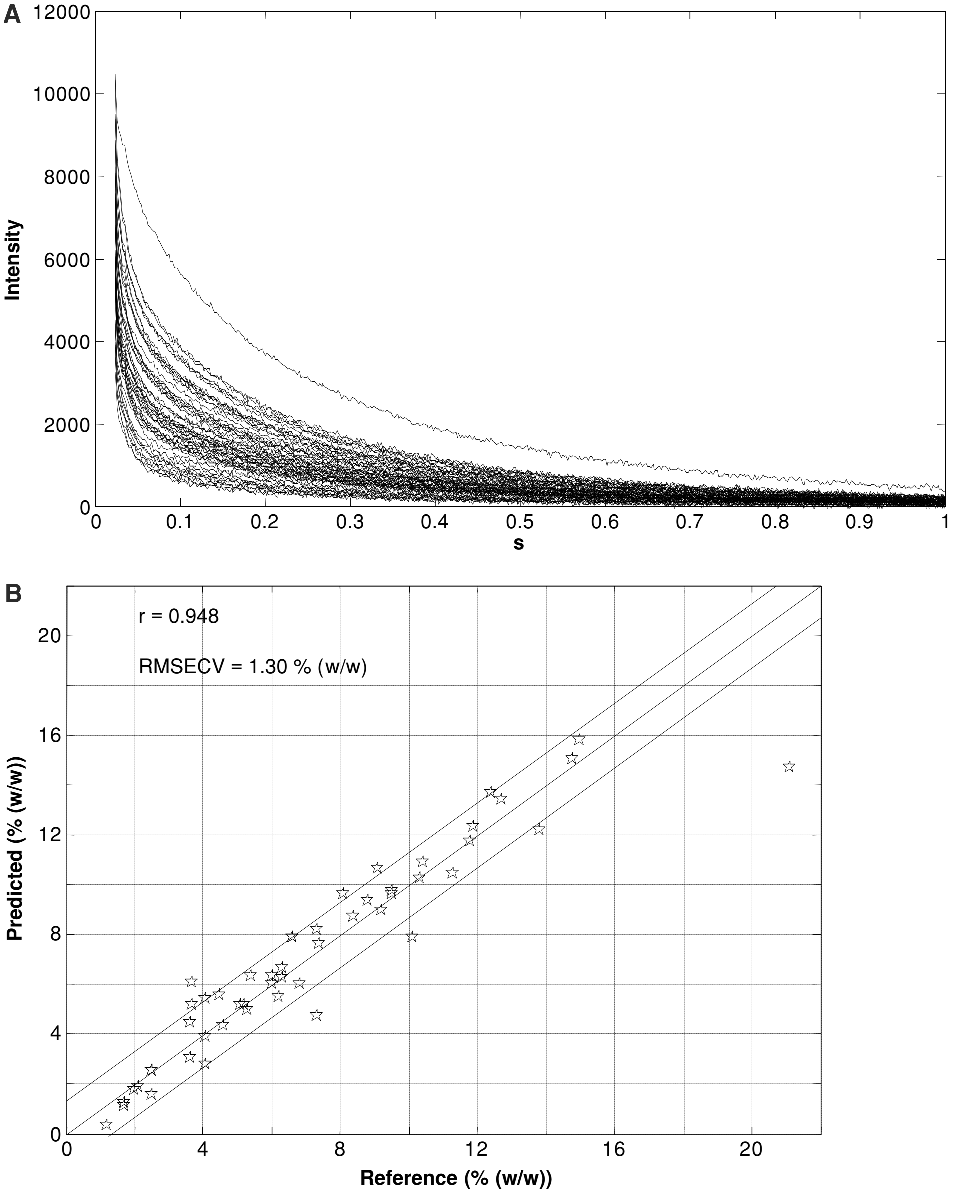

Fig. 5. (A) NMR relaxation spectra of 51 minced meat samples. (B) Predicted vs. measured for a univariate regression model. (C) Regression coefficients from a PLS model with fat as the dependent variable and the NMR relaxation curves as the independent variables. (D) Predicted vs. measured for a multivariate PLS regression model. The middle diagonal line in B and D is the model target and the two parallel offset lines indicate limits for +/− RMSECV.

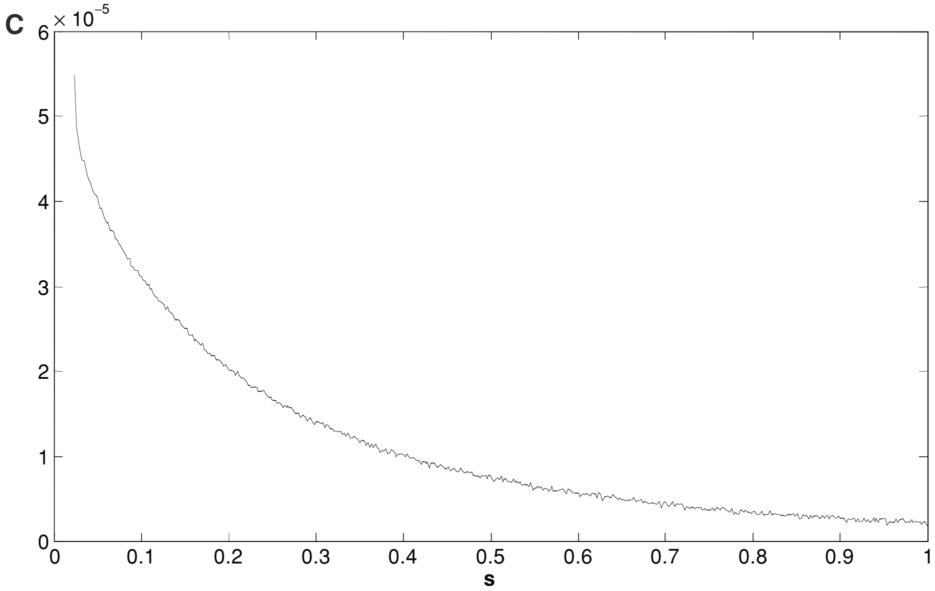
method is shown. The cross-validated calibration results in a correlation of $r = 0.948$ and an RMSECV (average prediction error) of 1.30% (w/w) fat, and it demonstrates that the linear relationship between the echo amplitude and the SBR fat determination is broken above 20% (w/w) fat. In Figure 5C (regression coefficients) and Figure 5D (predicted vs. measured) the corresponding multivariate calibration results are shown for a multivariate upgrade of the gradient-stimulated echo pulse experiment in which the gradient echo is simply followed by a 180° pulse



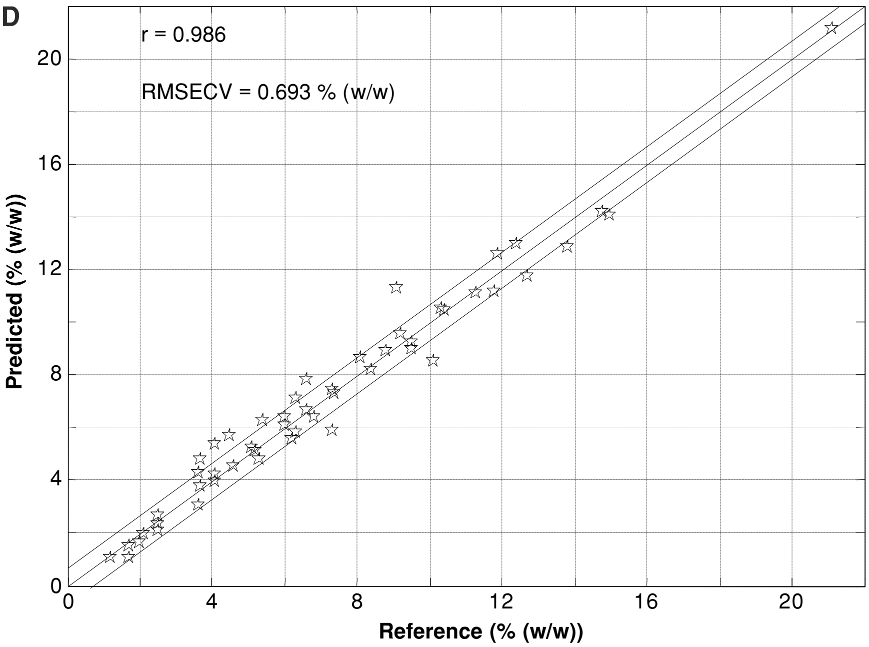


Fig. 5. (*Continued*)

train. The cross-validated calibration based on only one PLS component has now improved the calibration performance to half the error of the traditional approach with $r = 0.986$ and RMSECV = 0.69% (w/w) fat. Moreover, this simple PLS regression model is now able to linearly extrapolate measurements above 20% (w/w) fat. This type of performance enhancement is the rule rather than the exception when comparing univariate or oligovariate approaches with multivariate approaches. For this reason it is intriguing that official standard methods for fat determination are still based on univariate reasoning—we can predict that these dinosaurs soon will be overtaken by new improved company standards, as has been the case with NIR models.

Conclusion

Quantitative NMR spectroscopy has recently been promoted by the metabonomics community. With tremendous challenges and potential for applying quantitative NMR for measuring functional factors in complex food systems, this area of research is still in its infancy.

The challenges, problems, and advantages of extracting quantitative information from NMR data by chemometric methods have been demonstrated. It has been shown that NMR data in both time domain and frequency domain have to be preprocessed in order to comply with chemometric methods. Two examples including time domain NMR data (fat in minced meat) and frequency NMR (ethanol in apple juice) data are given and it has been illustrated that the combination of NMR and chemometrics outperforms univariate approaches with respect to quantitative performance.

Direct Exponential Curve Resolution by SLICING

Søren B. Engelsen[1], Henrik T. Pedersen[2], and Rasmus Bro[1]

[2] *Protein Structure and Biophysics, Novo Nordisk A/S, 2760 Måløv, Denmark*

Several types of NMR experiments result in data that may be described as a sum of exponential functions (T_1 weighted signals, T_2 weighted signals, and gradient weighted signals). In order to be able to understand and interpret these data, it is imperative to be able to model these with a robust and precise method which is why the numerical scientists have worked for centuries with iterative non-linear least squares curve fitting methods for resolving underlying mono-exponential functions. Recently, a new non-iterative method was proposed by Windig and Antalek [1] called direct exponential curve resolution algorithm (DECRA). The new method has several potential advantages, but first of all it is non-iterative, accurate, and rapid. In this chapter, a more general version of the DECRA method called SLICING is outlined and applied to a simple test case measuring fat in meat by NMR relaxometry.

T_2 weighted low-field pulsed NMR (LF-NMR) is a useful and direct technology for probing proton mobility in, for example, food and feed. The physical state of the two major proton-carrying components in food—fat and water—has fundamental impact on the quality and LF-NMR is therefore an important probe for food quality. The overall water compartmentalization and mobility will often mirror the basic food structure and thus indirectly or directly reflect rheological and sensory quality attributes, as well as many oxidation processes. LF-NMR has the potential not only to measure all of these important food quality attributes but also to perform the task as a non-invasive volumetric measure that potentially holds the promise of being able to facilitate real time process control with product control for 100% of the batch. LF-NMR suffers from a crude resolution and is normally only analyzed in the time domain. The most commonly recorded data is the transverse LF-NMR relaxation data (CPMG) which normally is described as a sum of decaying exponentials:

$$M(t) = \sum_{n=1}^{N} M_{0n} \cdot \exp\left(\frac{-t}{T_{2n}}\right) + \mathrm{e}(t), \tag{1}$$

where $M(t)$ is the intensity of the magnetization in the transverse plane at time t, N is the number of (discrete) exponential functions or components in the sample, M_{0n} is the initial equilibrium magnetization of the nth exponentials, and T_{2n} is the corresponding relaxation time constants. While the T_2 values provide a qualitative description of the spin–spin relaxation, the M_{0n} holds the quantitative description. There exists a number of physical sample effects as described by Diegel and Pintar [2] as well as instrumental effects that may give rise to non-exponential line shapes, but normally exponentiality is assumed and the resulting relaxation decay curves are analyzed by *discrete exponential curve fitting*. In this approach, a relaxation profile is decomposed into a limited number of pure mono-exponential curves (typically less than 4). This is the classical approach which scientists working in the numerical field have been struggling with and refining for more than 200 years [3]. More recent numerical approaches include quasi-Newton least squares fitting using soft line search and factorization. Despite the ill-conditioning property of the exponential-sum fitting problem, in practice numerical methods have become fairly robust, but unfortunately the iterative methods are rather time- and memory-consuming. More importantly, the final results are often strongly dependent on the number of exponential components extracted for which reason an efficient tool for selecting the right number of exponentials is required. An example of a traditional sequential curve fitting is shown in Figure 1. It is characteristic of numerical multi-exponential curve fitting that the interpretation (T_2 values—vertical lines) is drastically influenced by the number of extracted components.

The new DECRA principle in multi-exponential curve resolution is based on three premises:

(1) That there exists a linear relationship between exponentials:

$$\exp\left(\frac{-t}{T_{2n}}\right) \propto \exp\left(\frac{-t+\Delta t}{T_{2n}}\right). \tag{2}$$

(2) By exploiting the linear relationship, multi-exponential decay function can, by a simple pre-operation which we have termed slicing [4], be upgraded from a simple multi-exponential decay curve to a double decaying exponential landscape.

Graham A. Webb (ed.), Modern Magnetic Resonance, 1845–1852.

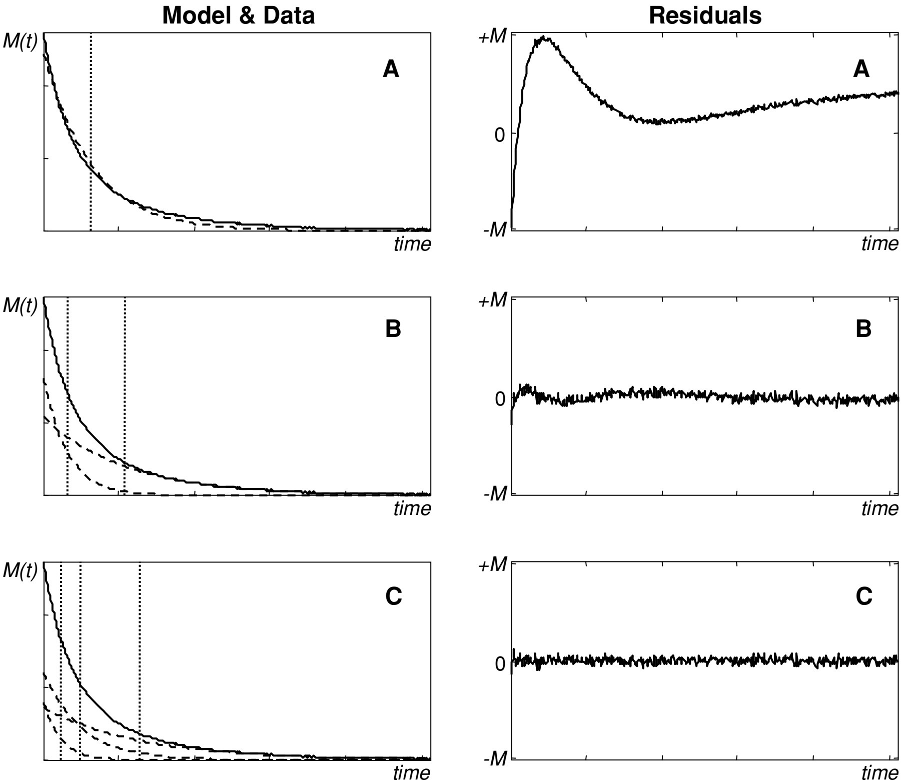

Fig. 1. Numerical curve fitting of a single NMR relaxation profile. (A) The result of fitting a single exponential function. The vertical line indicates the extracted characteristic T_2 time, (B) the result of fitting two exponential functions, and (C) the result of fitting three exponentials.

(3) By the use of a so-called two-dimensional data strategy where several samples are analyzed simultaneously for common underlying phenomena, the sliced data fulfill the criteria of the powerful multi-way algorithms [5] of the general form:

$$x_{ijk} = \sum_{n=1}^{N} a_{in} b_{jn} c_{kn} + e_{ijk}, \quad i = 1, \dots, I; j = 1, \dots, J; \ k = 1, \dots, K. \tag{3}$$

Thus, by rearranging each profile appropriately to a matrix and stacking several such matrices into a three-way data array, the rearranged data can be fitted by a tri-linear model which provides the quantitative (M_0) and qualitative information (T_2).

The principle is applicable in all cases where a sum of exponential functions is analyzed. This also includes spectral time series of chemical reactions displaying simple exponential behavior (first-order kinetics, radioactive decay, etc.). The method is basically built on the fact that a simple translation of a given exponential decay curve leads to a new multi-exponential decay curve that consists of the same underlying features (*quality*: characteristic decay times), but in a new combination of amounts (*quantity*: concentrations or magnitudes), and that the two slices together facilitate the unique advantages offered by tri-linear models. In their first application, Windig and Antalek [1] applied the method to perform exponential curve resolution of first-order reaction kinetics ($C = C_0 e^{-kt}$) monitored by high-resolution NMR at the process line at KODAK (US). Since then, several authors have applied the algorithm in different applications such as multivariate image analysis based on magnetic resonance images [6–9], short-wavelength near infrared analysis [10], UV–VIS [11,12] and solid-state NMR, and mid-infrared [13]. In this chapter, we will describe the technique and illustrate its use on a theoretical data example and an experimental data set.

Tri-Linear Models

While bi-linear chemometric models provide a tremendous advantage to univariate models (see Chemometrics chapter), tri-linear models, Equation (3), offer the additional advantage of unique resolution of underlying components [14]. The "only" assumptions for these multi-order advantages are that several spectra must be analyzed simultaneously, that they share common underlying mono-exponential features (low rank) and that they have tri-linear structure. Several different algorithms are available for tri-linear modeling including *generalized rank annihilation method* (GRAM) [15], *direct tri-linear decomposition* (DTLD) [16], which is a generalization of GRAM, and *parallel factor analysis* (PARAFAC) [17], all essentially fitting Equation (3). With respect to the SLICING problem, we have shown [18] that it is most efficient and adequate to use an algorithm based on the solution of a single generalized eigenvalue problem. While the eigen-based algorithms GRAM and DTLD do not give the least squares solution, they provide fast analytical solutions, and for large data sets with high signal-to-noise ratio and little model error the difference to the least squares solution is often insignificant. As opposed to alternative methods for fitting exponentials, the SLICING algorithm does not require any initial estimates.

Data Slicing

By a simple data pre-transformation, slicing, multi-exponential decay profiles can be upgraded to become bi-linear data structures suitable for tri-linear curve resolution techniques. Different data slicing transformation strategies exist and the simplest possible slicing transformation is as proposed in the original DECRA technique. In this approach, the multi-exponential decay function is copied and then shifted (translated in time) by one variable (see Figure 2A). To keep equal length of the two parts of the multi-exponential decays, the original is shortened by one variable at the end and the copy is shortened by one variable at the beginning. This DECRA-type slicing transformation can be denoted as [1,2]-slicing referring to the indices of the starting variables of each decay curve (slab). The result is a new data structure, a matrix, for each sample/measurement with the dimension $M(t) \times M''(t)$, where the last decay function has the dimension two. Although exponential fitting cannot be performed on two points, it is interesting to note that the underlying time constants for the second decay function $M''(t)$ are identical with those of $M(t)$ since they share the same origin. Furthermore, it is important to remember that the two curves being generated from the same relaxation profile, $M(t)$, share the same underlying time constants according to Equation (2).

It is possible to create more copies (slabs) by shifting the profiles more times. This will make the algorithm more robust, but also requires that the GRAM multi-way algorithm is replaced by either DTLD or PARAFAC. One simple example of such a slicing scheme could be the equally spaced [1,2,3,4,5,6,7,8,9,10]-slicing (Figure 2B) or even better $\log_{10}$-spaced [1,10,100]-slicing (Figure 2C). In our original SLICING method [19], we also investigated a technique to select and optimize slicing parameters (the spacing between slabs and the number of equally spaced slabs). While this technique proved to be very robust, it also meant loss of the speed advantage. An interesting solution to the problem of selecting optimally without prior knowledge of the underlying T_2 values is to select shifts (start variables for new slabs of the three-way array) that are spaced according to the power function 2^x for $x = 0, 1, \ldots, X$ where 2×2^X must be less than or equal to the original number of variables. The algorithm of this slicing scheme is accordingly named as POWERSLICING [18]. In accordance with the transformation terminology above, POWERSLICING gives [1,2,4,8,16,32,64, . . .]-slicing and an example is displayed in Figure 2D (for a sample with 510 time points, i.e. eight slabs). In two dimensions, the resulting landscape of the POWERSLICING transformation in Figure 2D is displayed in Figure 3. This approach, in which the new copies or slabs have exponentially increasing spacing has proven to be a fundamentally feasible strategy for the slicing transformation both in theory and in practice. The shifting scheme is the key to having accurate estimates of the underlying profiles. If the profiles have very fast decays, then small shifts will be beneficial in order to generate adequate variation across the shifting dimension. Small shifts, however, will not provide any accurate variation for more slowly decaying exponential profiles. The POWERSLICING scheme is characterized by providing diverse shifts for both fast, medium, and slow decaying profiles, resulting in a robust and extremely competitive algorithm with respect to speed of calculation.

To test the POWERSLICING technique we applied it to a simulated NMR data set of 30 samples with 2,048 data points containing four underlying exponential components interspaced with a factor of 2. Random noise (0.5% of total sum of squares of the data) was added to the data. This was repeated 3,000 times using different realizations (recalculations) of the noise. Figure 4 compares the performance of (C) POWERSLICING to a traditional two-dimensional numerical approach (D) MatrixFit [19], the previously introduced optimized (B) SLICING [19] and (A) DECRA [1]. From the figure, it is observed that the dispersion of the calculated T_2 estimates by POWERSLICING is comparable and even somewhat narrower than the results from the optimized SLICING; however, POWERSLICING remains a little less accurate in the T_2 estimates compared to the MatrixFit approach. When examining the average

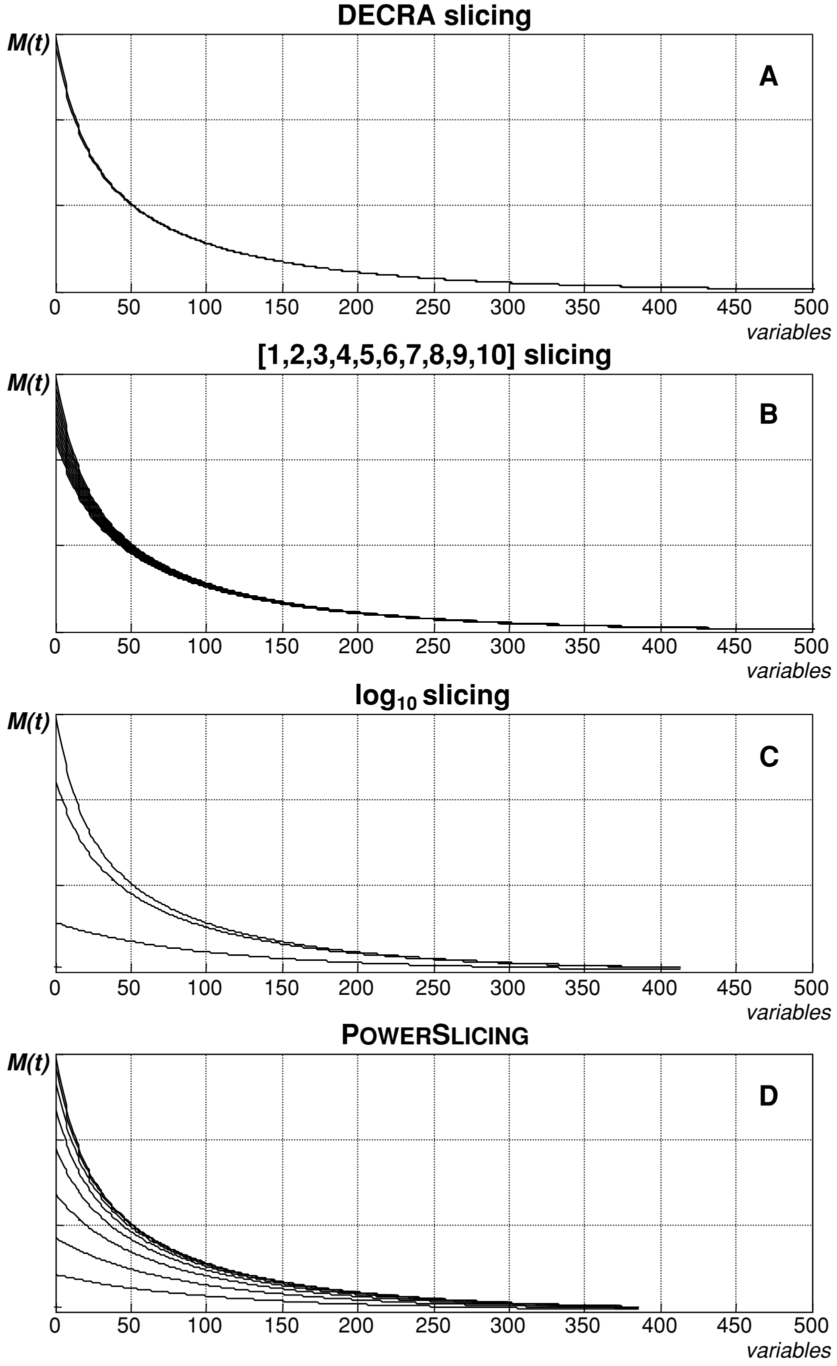

Fig. 2. Examples of different slicing transformations on a single multi-exponential relaxation curve. (A) DECRA or [1,2]-slicing, (B) equidistant [1,2,3,4,5,6,7,8,9,10]-slicing, (C) $\log_{10}$ [1,10,100]-slicing, and (D) PowerSlicing ([1,2,4,8,16,32,64,128]).

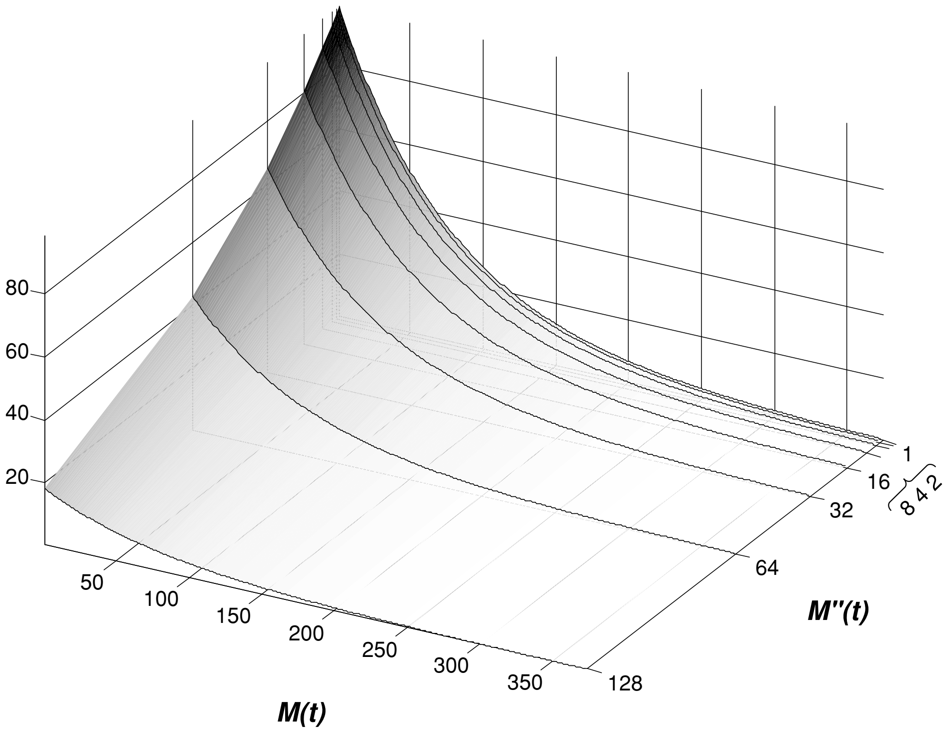

Fig. 3. A double exponential decaying landscape of a single NMR relaxation measurement.

algorithmic speed, PowerSlicing outperforms the optimized Slicing by a factor of approximately 300 and MatrixFit approach by a factor of 8. In terms of resolution, PowerSlicing is substantially better than DECRA which by far offers the poorest resolution, and algorithmic speed is approximately identical.

NMR Relaxometry: An Example

The utility of the Slicing approach will be demonstrated on NMR relaxometry measurements on meat. The data set consists of 47 measurements on minced meat with a total fat content between 1.2 and 15.0% (w/w). The samples were measured at 55 °C to ensure liquid lipid phase and 2,048 even echoes were recorded from a gradient stimulated echo CPMG pulse-sequence with a τ value of 500 μs [20]. A very important aspect of handling LF-NMR data is how the phase correction of the raw quadrature data is performed. Numerical curve fitting algorithms including the new Slicing methods are sensitive to non-optimal phase correction and in particular magnitude transformations should be avoided since this will introduce an artificial (potentially non-constant) offset in data. We have shown that non-optimal phase correction is detrimental to the following analysis and have suggested a simple solution called principal phase correction (PPC) [19] that is able to phase correct without introducing systematic or spurious errors in the corrected data.

Figure 5 shows how the 47 relaxation decays (A) via a two-component Slicing analysis simultaneously is decomposed into two underlying relaxation decays with characteristic T_2 times of 31 and 323 ms, respectively (B). One of the advantages with the underlying tri-linear decomposition of Slicing is that the related scores or concentrations need not to be calibrated to a reference parameter, but only scaled to a single reference. This is possible because the components intrinsically describe physical phenomena directly. Figure 5C shows a scatter plot with the estimated “concentrations” of the slowest relaxing component (323 ms) against a reference analysis of the total fat content in the meat samples (Schmid–Bondzynski–Ratzlaff method). As is observed from the plot, a direct correlation is obtained with a correlation coefficient of $r = 0.988$ (C). It is noteworthy that the high-fat sample apparently is well modeled by the PowerSlicing model in contrast to the simple spin-echo univariate model presented in chapter (see Chemometrics Analysis of NMR Data, page xxx).

Conclusion

By a simple data pre-transformation, slicing, it is possible to upgrade transverse relaxation data to become bilinear. When more samples are available, data can be arranged in a multi-way array to become tri-linear and the slicing pre-transformation facilitates the use of powerful tri-linear mathematical models. When combined, this Slicing method is much faster than traditional methods in extracting characteristic relaxation times and the method has, for example, great potential for mathematical contrasting of MRI images. In an application to NMR

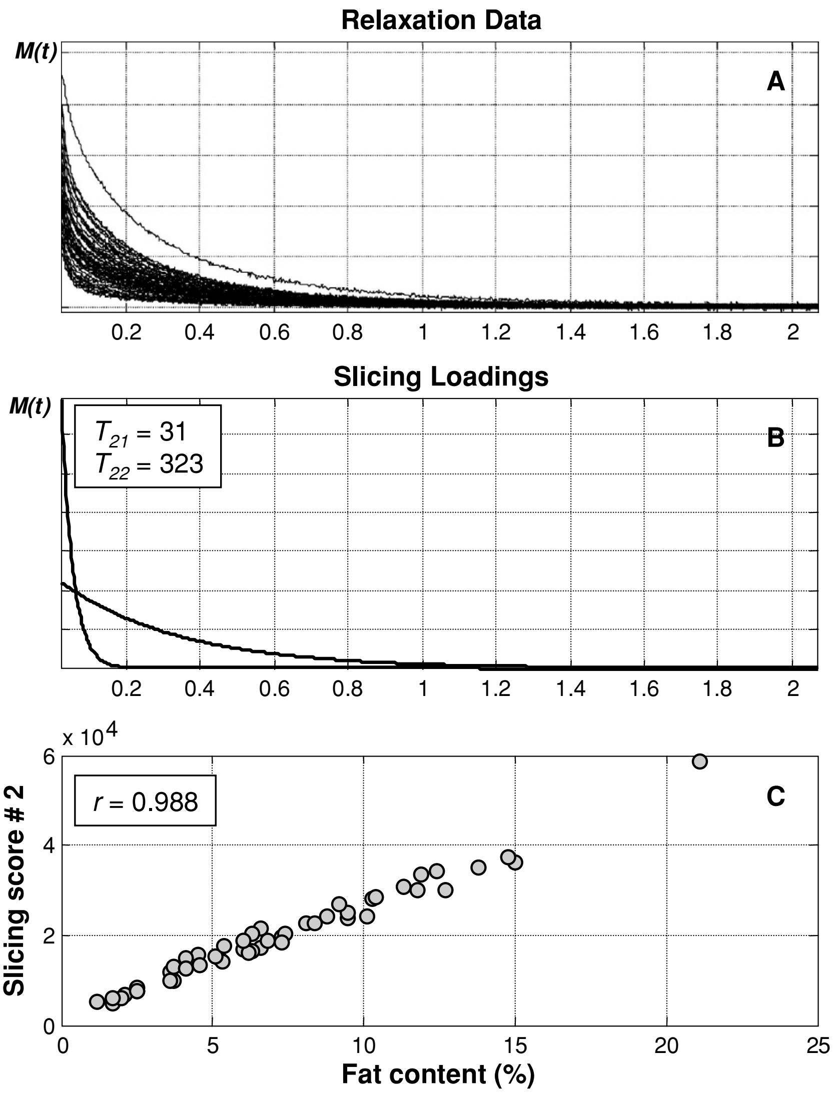

Fig. 5. The PowerSlicing solution to fat-in-meat. (A) Raw data, (B) PowerSlicing loadings, and (C) scatter plot of PowerSlicing score 2 (the slow component) vs. reference value.

relaxometry, we have demonstrated that Slicing provides unique estimates of the underlying profiles.

However, it should be stressed that the result of this procedure will be similar to those of discrete exponential fitting algorithms, fitting common characteristic time constants to a series of samples [19]. Extensive simulations of LF-NMR data revealed that the Slicing approach was comparable, but not superior to a robust classical numerical approach. In practice, it is the dramatically improved speed (largely independent of number of components extracted) and somewhat improved diagnostics of this algorithm, which are attractive. The tremendous speed of the Slicing approach makes it also most qualified for use as pre-processing (super-qualified initial guesses) to traditional numerical curve resolution algorithms.

The consequences of using common characteristic relaxation times in a wider range of quality attribute determinations (i.e. slightly varying time constants from sample to sample) by time domain low-field NMR remain to be investigated. However, it is possible to perform the SLICING pre-transformation twice (or more) and thus from only *a single* relaxation curve generate a tri-linear data cube [21]. This data pre-processing strategy called DOUBLESLICING provides a means to take advantage of tri-linear models when decomposing a single LF-NMR relaxation decay and was rediscovered by Manetti *et al.* [22]. The introduction of DOUBLESLICING leaves one independent of measuring more samples following the same underlying exponential decay functions. In this approach, the number of *slabs* (*pseudo*-samples) must be equal to or larger than the number of components one wishes to extract. This *pseudo*-sample matrix is then sliced again using the SLICING pre-transformation to obtain a *pseudo* tri-linear upgrade of the *pseudo*-sample matrix. Granted, it may appear to be an unnecessary complication to create a three-way data matrix with highly redundant information from a single relaxation curve to solve the simple discrete exponential fitting problem. However, with suitable resampling DOUBLESLICING produces practically the same results as traditional exponential fitting, but with significantly shorter computation times, especially when more than two components are extracted.

ESR Methods

Part III

ESR as a Technique for Food Irradiation Detection

Eric Marchioni

Faculté de Pharmacie, Laboratoire de Chimie Analytique et Sciences de l'Aliment (UMR 7512), Université Louis Pasteur (Strasbourg 1), F-67400 Illkirch, France

Introduction

Known pathogens account for an estimated 14 million cases of food-borne illnesses, resulting in more than 60,000 hospitalizations and 1800 deaths annually in the United States [1]. Important sources of food-borne pathogens include contaminated produce and improperly cooked, handled, or stored food products. Despite important efforts of the food industry, preventable illnesses, and related deaths resulting from the consumption of contaminated foods are still on the rise. Food irradiation is gaining interest in light of this increasing incidence of food-borne diseases in the last decades, as it efficiently reduces the populations of pathogens such as *Salmonella*, *Listeria*, *Campylobacter, E. coli* 0157:H7, and others, but also of parasites and insects [2–4]. The process has been endorsed by the World Health Organization (WHO), the Food and Agriculture Organization (FAO), the Codex Alimentarius Commission, the US Food and Drug Administration (FDA), the US Department of Agriculture (USDA), the American Medical Association, the American Dietetic Association, the American Institute of Food Technologists, and health authorities of approximately 50 countries [5–7]. The list of irradiated products allowed for irradiation varies from one country to another but is often limited to spices, herbs, seasonings, some fresh or dried fruits and vegetables, seafoods, ground beef meat, and poultry [6].

Definition of the Absorbed Dose (kGy)

Ionizing radiations are energy transmitted through space in the form of electromagnetic waves or electrons beams. Food irradiation involves the use of gamma rays generated by radionuclides either ^{60}Co [1.17 and 1.33 MeV ($1\ \text{MeV} = 1.6\times 10^{-13}$ J)] or ^{137}Cs (0.66 MeV), electron beams generated from electric machine sources operated at or below an energy level of 10 MeV or X-rays generated by striking electron beams (energy level at 5 MeV or below) on a metal target of high electronic density [7–10].

The dose of irradiation is measured in units of grays (Gy) or kilograys (kGy). One gray equals the absorption of 1 J of energy in 1 kg of water equivalent food.

Three dose ranges have been defined in food processing according to the effects achieved: between 0.1 and 1.0 kGy (sterilization of insects, destruction of parasites, inhibition of the germination of bulbs and tubers); between 1.0 and 10 kGy (elimination of pathogenic bacteria and increase in the shelf life of food by reduction of the spoilage flora); and more than 10 kGy (sterilization of spices and aromatic herbs) [7]. Doses above 10 kGy are needed for sterilization of generally "ready to eat" foods which require a guaranteed absence of microbes and/or have to sustain long-term unrefrigerated storage [11], e.g. hospital meals, foods for immunocompromised patients, astronauts, soldiers, mountain climbers, or campers.

Labeling

A European Directive, as well as regulations in most countries where food irradiation has been adopted, states that the words "*irradiated*" or "*treated with ionizing radiations*" shall appear on the label of any product sold as items [9]. A specificity of this European Directive is that food products containing irradiated ingredients shall be labeled accordingly. Moreover, the same words shall be required in order to indicate any irradiated ingredients, in whatever amount, used in components of a foodstuff. Labeling legislation and consumers' freedom of choice require that official food control laboratories have at their disposal effective analytical methods enabling them to prove if a food has been subjected to an irradiation treatment or not. This requirement is now fulfilled since the publication of ten standardized protocols, six official methods [12–17], and four screening methods [18–21] for the detection of irradiated foods by the European Committee for Standardization (CEN).

Interactions of Radiation with Matter

While penetrating a food product, high energy electrons, either directly introduced (electrons beams) or induced *in situ* from gamma or X-rays by photoelectric or Compton effect, will lose their energy through electrostatic interactions with atomic valence or molecular binding electrons. Such interactions are not specific and the absorbed dose is distributed according to the relative proportions of

Graham A. Webb (ed.), Modern Magnetic Resonance, 1855–1860.

© 2008 *Springer.*

the various components (water, proteins, lipids, carbohydrates, minerals, etc.) of the irradiated food. The interactions through which primary electrons lose their energy consist in ionization, ejection of one of the electrons out of the target atom or molecule, and formation of a radical cation, but also in excitation and the subsequent passage of an electron of the atom or molecule target in higher energy orbital levels. Ionization and excitation processes occur during very short lapses of time (10^{-18}–10^{-15} s) and lead to a lowering of the energy distribution of the electrons progressing in the food substrate. These electrons of lower energy can better interact with the target atomic or molecular electrons. They can thus lose a very major part of their energy, which makes the interaction very effective, in spite of the observed energy degradation. Then, after 10^{-15}–10^{-13} s, when the energy of the electrons becomes lower than the ionization potential of the food components, the remaining degradations are ascribed only to excitations. If this reduction in energy is such that only excitation of components having a very low excitation energy level is still possible (because of the presence of a ∂ orbital in their electronic structure), these components could be more affected by the radiation treatment than would be expected according to their concentrations in food. After 10^{-13} s, electrons with a much degraded energy will, in the presence of water, lead to the formation of hydrated electrons. The primary and secondary processes of interaction lead to the formation of highly reactive radicals. A great number of them recombine in food, leading to the formation of more or less stable radiolytic products. However, some radicals remain stable for many hours, days, months, and some for probably hundreds of years, according to the degree of mineralization and the relative humidity of the sample. Such very stable radicals can thus be recovered in bones, eggshells, shellfish cuticles, fish scales and teeth, fruit achenes and hulls, dried spices and aromatic herbs, and certain fruits, mostly over the whole commercial storage life of the food.

Food Irradiation Detection

ESR is a spectroscopic method allowing the detection of unpaired electrons, originating from radicals (including those induced by irradiation), or from paramagnetic ions (such as Mn^{2+}). Radicals in food are therefore not specific to irradiation. Nevertheless, ESR can be used as a detection test if the radicals induced by irradiation are stable during the commercial storage life of the food and the corresponding signals are clearly distinguishable from those of the unirradiated material. These radicals occur in the solid and dry components of the food, where the rigid structure of the matrix keeps radicals from reacting with each other or with food components present in the wet portion of the food. The intensity of the signals increases with the concentration of the paramagnetic compounds and thus with the applied dose. Today, particularly three kinds of food components are known to induce stable and specific ESR signals upon irradiation: hydroxyapatite, cellulose, and crystalline mono- and disaccharides.

Hydroxyapatite

Bone tissue is composed of approximately 60% hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$] with most of the remaining fraction as collagen. The characteristic ESR spectrum of irradiated bones corresponds to the $CO^{-\bullet}$ radical [22]. When trapped in the hydroxyapatite lattices, this is an extremely stable radical which is used as an indicator of exposure to ionizing radiations. Measurements of ESR signals induced in animal bones are not really new, having been used for accidental post-irradiation dosimetry [23–25] and for dating bones and

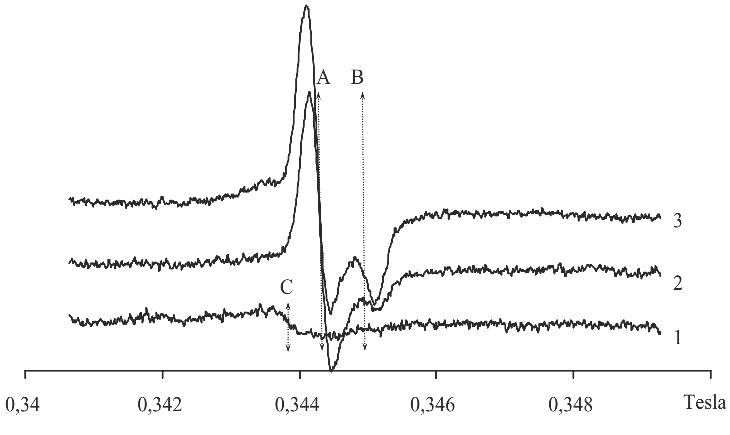

Fig. 1. ESR spectra of chicken bones unirradiated (1) and irradiated at 5 kGy (2 and 3). Dry excised piece of bone (2), bones fragments extracted from MRM (3). Letters A, B, and C show the position of the major ESR lines.

shells [26–28]. As hydroxyapatite is present in bones, scales, teeth, or shells, applications for the detection of irradiated foods containing these items have been widely reported [29–32]. In non-irradiated samples, there is a symmetric absorption with a g-factor $\approx$2.005 and a peak-to-peak line width (ΔH) of $\approx$0.6 mT (Figure 1, spectrum 1, signal C). An asymmetric absorption which is characterized by g-factors $\approx$2.002 and $\approx$1.998 (Figure 1, spectra 2 and 3, signal A and B, respectively) is only observed in irradiated samples containing $CO_2^{-\bullet}$ trapped in hydroxyapatite lattices. Since the signal height for particular bone types can be related to the dose (linearly proportional up to 14 kGy in the case of frog legs), it is possible to obtain a very rough estimate of the dose absorbed by bones using a "standard addition" technique, the ESR signal being recorded after each of several successive re-irradiations [33–35]. Nevertheless, it should be noted that ESR signal strengths depend on several parameters such as irradiation temperature, degree of bone mineralization (age of the animal, type of bone analyzed, etc.), pre- or post-irradiation treatments (cooking or freezing), and preparation of the sample (grinding and drying) [36–38]. In addition, irradiation of whole pieces of meat including bones may yield higher ESR signals than irradiation of dried excised bones alone [39]. It seems therefore very difficult to get, by this method, an accurate estimation of the dose absorbed by the food.

Detection of irradiated fish and meat samples is generally possible above a minimal detectable dose of 0.5 kGy, lower than those used for commercial applications concerning this kind of food product. Moreover, for highly mineralized bones, identification remains possible for lower absorbed doses and is not affected by heating or storage time up to 12 months [14]. For cuticle of crustacea, the ESR signal is much less stable. It may disappear if sample desiccation prior to ESR analysis is performed at temperatures above 40 °C and the intensity of the signals decreases between 44% (claws) and 17% (tail) within 28 days storage at 1 °C depending on the component analyzed [31]. The ESR method was successfully used for the analysis of bones to detect irradiated duck, frog, goose, chicken, rabbit, lamb, turkey, and pork, and in case of fish bones to detect irradiated eel, trout, whiting, sardine, shark, halibut, herring, cod, salmon, and mackerel [14]. Irradiation treatment could also be detected in eggshells [40] and mussel shells [41].

It should be noted that some irradiated food ingredients (mechanically recovered meat) used in the food industry contain very small bone fragments. The use of a specific extraction and purification procedure allows the recovery of these bone fragments and their subsequent ESR analysis for the detection of irradiated ingredients included in culinary preparations (Figure 1, spectrum 3) [42,43].

Cellulose

ESR proved to be one of the techniques that can be used for the identification of irradiated products of plant origin using the paramagnetic species (free radicals) in the cellulose fraction [44,45]. These radicals, first reported by Raffi *et al.* [46] on achenes of irradiated strawberries, were detected by many other authors analyzing the very dry part of most of the irradiated plant products [47–49]. Their ESR spectrum seems to be a hyperfine triplet centered at $g = 2.004$ (Figure 2, signal C). It appears superimposed

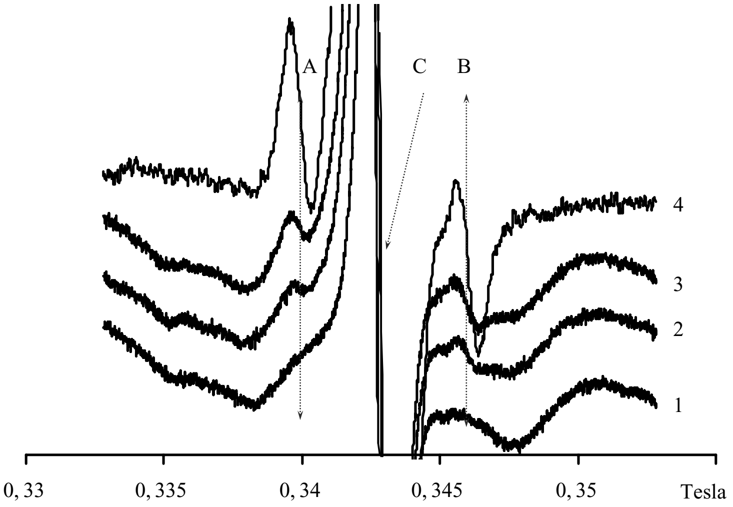

Fig. 2. ESR spectra of dried achenes extracted from unirradiated strawberries (1) and irradiated at 1.5 kGy (2) and 3 kGy (3), and paper irradiated at 5 kGy (4). Letters A, B, and C show the position of the major ESR lines.

on a non-irradiated signal belonging to lignin [50], with a similar g-factor and which is sensitive to radiation, but also to drying processes [51]. From the triplet ESR lines that are induced by irradiation, only the two outermost peaks ($g = 2.020$ and $g = 1.985$, $\Delta H \approx 6$ mT) (Figure 2, signals A and B) can be used in the case of very dry plant products such as paprika powder or dry fruit components, such as achenes, pips, shells, stalks, or stones [47,48,52,53].

In most fruits, the water content is relatively high (80%) and the radicals induced in the pulp were believed unstable and were not observed (in the soft part). Nevertheless, most of the water is free and does not participate in the chemical processes that occur within the cell wall. The active water is about 20–30% which allows radicals induced by radiation to be stable for a period compatible with the shelf life of the product. For the first time, Tabner [54] measured them at doses higher than 2 kGy in the flesh of citrus fruit. After 14 days storage, only the samples irradiated at 10 kGy remained detectable. It has been shown later that the radicals induced by radiation in the pulp of fruits are stable enough to be used as a proof of the irradiation process in the dose interval of 0.1–1 kGy [55–57] even after 3 weeks of storage if the sample dessication, prior to ESR analysis, is performed appropriately [56,57]. One of the benefits of using pulp is its low lignin content which yields much clearer triplet signals than those observed with stalks, skins, or seeds. This also allows a higher signal-to-dose sensitivity that is compatible with dose ranges used in commercial irradiation.

Detection limits and stability are influenced by the crystalline cellulose content and the moisture content of the samples. It is, therefore, important that samples desiccated prior to ESR analysis have not been re-hydrated. As the outermost peaks of the ESR triplet are of very low amplitude compared to the central one, it may be very convenient to use an irradiated sample of paper (cellulose) to get a reference signal for the location of the signals A and B (Figure 2, spectrum 4). Positive identification of the cellulose radicals is evidence of irradiation but the absence of this signal does not constitute evidence that the sample is unirradiated. The minimal detectable dose is about 2 kGy for pistachio nuts (shells) even stored up to 1 year, 5 kGy for paprika powder (live time of the signal depends on the moisture content of the test sample) [15], 1.5 kGy for fresh strawberries (achenes or pulp) stored up to 3 weeks at 1 °C, and 1.0 kGy for fresh papaya (pulp) stored up to 3 weeks at 15 °C [57].

Sugars

Irradiation of pure crystalline sugars induces stable radicals whose ESR spectra may be recorded. When sufficient amounts of crystalline sugars are present in irradiated dried fruits, as figs (Figure 3), mangoes (Figure 4), or raisins, a multicomponent ESR signal may be observed [39]. As different mono- and disaccharides may dominate in fruit samples, different ESR spectra, centered at $g = 2.0035$, may be produced after irradiation (mangoes and papaya $\Delta H = 7.4 - 7.8$ mT, raisins and dehydrated figs $\Delta H = 8.7 - 9.1$ mT) [17]. Irradiated fruits are easily distinguishable from the non-irradiated ones simply because there is no ESR signal (or a little single resonance at $g = 2.004$) in the unirradiated samples (Figures 3 and 4, spectra 1). Nevertheless, if no sugar crystals are present in the sample, irradiation will not produce any specific sugar ESR signals. That is why some irradiated fruits, as have been observed for samples of apricot or prune, do not exhibit any multicomponent ESR signal, even when irradiated at a high dose (10 kGy). On the other hand, as

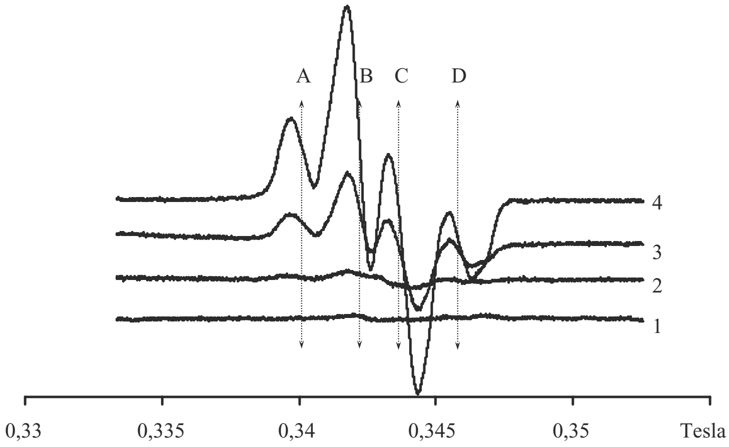

Fig. 3. ESR spectra of dried figs unirradiated (1) and irradiated at 1 kGy (2), 3 kGy (3), and 5 kGy (4). Letters A, B, C, and D show the position of the major multiplet ESR lines.

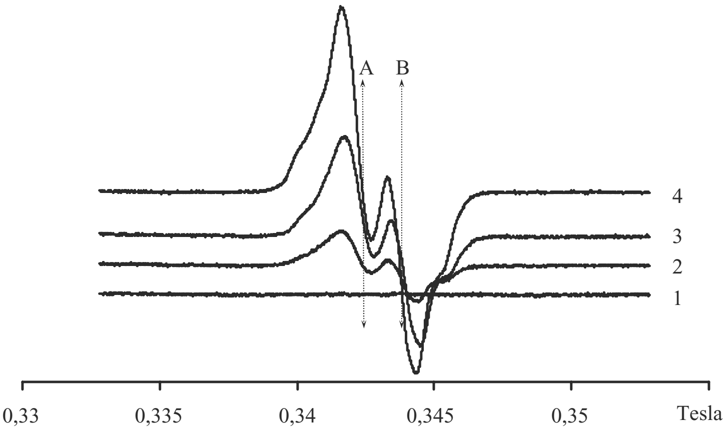

Fig. 4. ESR spectra of dried mangoes unirradiated (1) and irradiated at 1 kGy (2), 3 kGy (3), and 5 kGy (4). Letters A and B show the position of the major multiplet ESR lines.

discussed above for food of plant origin, irradiation can also give rise to the ESR spectrum of the cellulosic material [49]. Multicomponent ESR spectra prove prior irradiation, but the absence of such spectra does not constitute evidence that the sample is unirradiated. The applicability of this method depends on the presence of sufficient quantities of crystalline sugar in the sample at all stages of handling between irradiation and testing. As for the cellulose, radicals are moisture sensitive and it is important that dried samples have not been re-hydrated prior to testing. The minimal detectable dose is of about 1 kGy for dried mangoes, figs, raisins, and papayas.

Conclusion

The complete analytical protocols, including sample preparations and spectrometer settings for the analysis of radicals induced by irradiation in hydroxyapatite, cellulose, and mono- and disaccharides, are described in the official CEN protocols for the detection of irradiated foods [14,15,17]. Using these standard protocols, interlaboratory studies have been successfully carried out with beef bones, trout bones and chicken bones [14], pistachio nut shells, paprika powder and fresh strawberries achenes [15], raisins, dried figs, mangoes, and papayas [17].

Food irradiation detection remains one of the few applications of ESR spectrometry in the field of food analysis. One of its assets is its simplicity which also makes it an inexpensive method compared to other irradiated food detection tests. The realization of such analyses in the food laboratories is now possible since the recent marketing of small, automated, and easy to use benchtop ESR spectrometers at an affordable price. Approximately 1000 analyses of irradiated foods by ESR spectroscopy were carried out in 2002 in the European Union [58].

ESR Spectroscopy for the Study of Oxidative Processes in Food and Beverages

Mogens L. Andersen and Leif H. Skibsted
Food Chemistry, Department of Food Science, The Royal Veterinary and Agricultural University,
Rolighedsvej 30, DK-1958 Frederiksberg C, Denmark

Introduction

Oxidative reactions in food that involve lipids are, together with microbial growth, among the most important causes of spoilage of food and affect both shelf life and the quality of foods. The oxidation of unsaturated lipids in foods is observed as rancidity, while oxidation of proteins may result in other off-flavors and in some cases as a change in texture. The oxidation of vitamins and polyunsaturated fatty acids reduce the nutritional value and form potentially toxic oxidation products, while oxidation of food pigments leads to discoloration. Radicals are intermediates in many of these reactions, and the detection of radicals by electron spin resonance, ESR, provides therefore an excellent way to study early stages of these destructive reactions [1–3]. The study of radicals by ESR can moreover give important mechanistic information, which is useful for designing protective measures against oxidation in food. The detection of radicals by ESR has also recently also been used to predict the oxidative stability of foods, and further to quantify important quality aspects of food.

ESR [also commonly known as electron paramagnetic resonance (EPR) or electron magnetic resonance (EMR)] detects unpaired electrons in atoms and radicals. ESR spectra are characterized by the g-factor that is associated with Zeeman splitting, and which is determined by Equation 1, where h is the Planck constant ($6.6260755 \cdot 10^{-34}$ $\mathrm{J \cdot s}$), ν is the frequency of the applied microwave irradiation, β is the Bohr magneton ($9.2740154 \cdot 10^{-24}$ $\mathrm{J \cdot T^{-1}}$) and B is the magnetic field[4].

$$h\nu = g\beta B \tag{1}$$

Paramagnetic nuclei in radicals can often interact with the unpaired electron causing hyperfine splitting of the ESR lines, which can give useful structural information that allow identification of radicals [4]. Most commercial ESR instruments operate with microwave frequencies around 10 GHz (X-band). Solids and liquids can be studied over a wide temperature range by ESR and samples does not need to be transparent, which makes the technique useful for studies of foods. The very high sensitivity makes the technique useful for detection of radicals at early stages of oxidation in foods. Often ESR is used to compare the relative concentration of radicals in several food samples. In this case it is extremely important that the samples are as similar as possible [5]. It is therefore also important to use reference samples of stable radicals with a known concentration that are as identical as possible to the samples when absolute concentrations of radicals have to be calculated [6].

ESR Detection of Radicals in Foods

Radicals that are formed during oxidative processes in foods are often highly reactive species and are therefore in most cases only encountered as short-lived intermediates with very low steady state concentrations that make direct ESR detection impossible. The lifetime of radicals are often increased dramatically in solid samples, such as dry or frozen foods, where the molecular components are physically trapped, which prevent or slow down chemical reactions that would otherwise quench the radicals rapidly. The direct detection of persistent radicals at room temperature by ESR is therefore often possible in dry foods, where ESR detectable concentrations of physically trapped radicals can accumulate during production and storage. Often only a single line with a g-value in the range 2.003–2.006 and a peak-to-peak line width between 4 and 12 Gauss (Figure 1) is observed in the ESR spectrum of dry foods. However, in many cases also a sextet of lines is observed due to the presence of Mn^{2+}, which is frequently seen in ESR spectra of biological tissues (Figure 1) [7].

The persistence of radicals in dried foods or foods containing solid materials such as bones or shells make it also possible to use ESR for detection and quantification (dosimetry) of irradiation treatments where stable radicals with characteristic ESR spectra are often formed [8].

The origin of the stable radicals in dry foods is unknown and several sources have been suggested including reactions resulting from heat treatment of carbohydrates [9], or oxidation of polyphenols [10] and proteins [2], or formation of Maillard products [11]. However, the stable

© 2008 *Springer.*

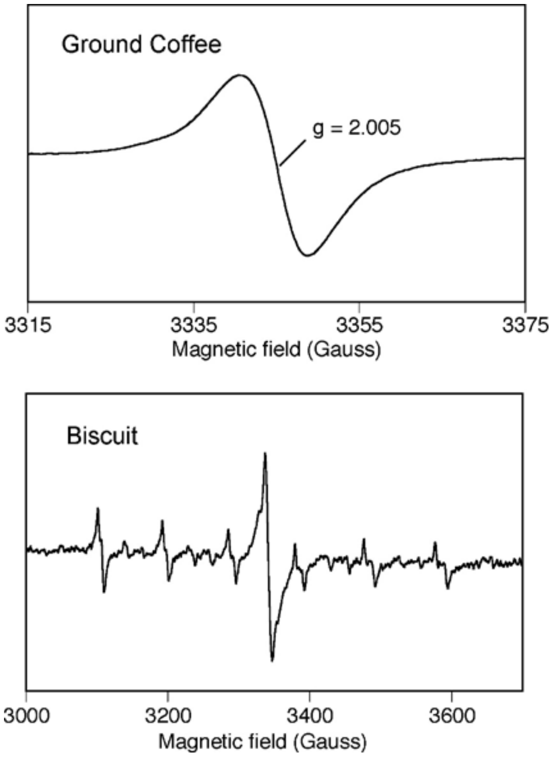

Fig. 1. Typical ESR spectra of persistent radicals detected in dry foods. A single broad signal with g ≈ 2 (presumably due to organic radicals) is often observed. A sextet of lines due to Mn^{2+} is also often observed.

radicals in dry foods have been shown to be good markers of the oxidative status of dry products and several studies have demonstrated that the level of radicals correlate with the extent of lipid oxidation or with external factors such as heat, light and storage time that are likely to induce oxidation (Table 1).

Trapping of radicals in frozen samples has been used together with direct ESR detection for studies of radicals involved in autoxidation of lipids and of light induced formation of lipid radicals in frozen triglycerides at 77 K [24,25]. Radicals that are derived from phenolic compounds have been detected in frozen samples of wine [26].

Spin Trapping

Most foods contain water, which allow the components to diffuse. Radicals in most foods are therefore very short lived with steady state concentrations that are too low to be detected directly by ESR. However, the indirect detection of radicals can under these conditions be carried out by using the spin trapping technique, where a stable radical (called a spin adduct) is formed by the addition of reactive radicals to a spin trap (Figures 2 and 3) [27]. The stability of spin adducts allow the accumulation of ESR detectable concentrations. The spin trapping technique has been used to characterize radicals formed in beverages such as coffee [28] and during oxidative processes in beer [29] (Figure 4).

Spin trapping has also been used to examine the tendency of formation of radicals in mayonnaise and for evaluation of methods for protection of unsaturated lipids in the mayonnaise against oxidation [30,31]. The spin trap PBN was mixed into mayonnaise and the samples were mildly heated at 37 °C for 24–36 h before the amount of radicals were measured by ESR. The amount of radicals could be quantified by comparison with the nitroxyl radical 12-doxylstearic acid that was found to be stable in mayonnaise [32].

Prediction of Oxidative Stability of Foods

Accelerated aging of foods has often been used to predict the long-term stability of foods. Usually the level of oxidation has been followed by measuring the formation of primary or secondary oxidation products. With ESR it is possible to study the radicals that are involved in the oxidative reactions directly, which makes it possible to determine the level of oxidation more directly during forced ageing experiments. The method has been used with great success in the brewing industry to predict the flavor stability of lager beer [33–36]. A spin trap (PBN) is added to the beer after dissolved CO_2 has been removed, and the beer is then heated (50–60 °C) with access to atmospheric oxygen. The presence of antioxidants in the beer will initially inhibit the formation of radicals resulting in a low level of spin adducts in the beginning of the experiment. The antioxidants are consumed as a consequence of their actions, and unhindered formation of radicals will eventually take place when all the active antioxidants are consumed, resulting in a steady increase in the level of spin adducts (Figure 5). The length of the initial lag phase (also called induction period or lag time) is mainly determined by the competition between actions of antioxidants and pro-oxidants, which are also likely to be crucial factors for the oxidative stability under conventional storage of beer. The lag time determined for fresh lager beer has been shown to correlate with the storage stability, making the method suitable for early prediction of the shelf life [34]. The ESR lag time method has also been used for testing the effect of potential antioxidants present in beer on the oxidative stability of beer [37].

The ESR lag time method has been adopted for the prediction of the stability of bulk lipids, although it should

Table 1: ESR detection of radicals in dry foods

Dry product	Observations related to stable radicals detected in foods by ESR	Reference
Plant derived foods		
Coffee-beans	Roasting, water content, and storage affect level of radicals	[12]
Wheat flour and starch	Extrusion, heat, and the presence of oxidizing methyl linoleate increase the level of radicals	[13]
Licorice	Radicals detected in licorice products before and after oral administration	[10]
Dried potato flakes	Level of radicals marker of early oxidation	[14]
Walnut kernels	Heat and air increase level of radicals	[15]
Bread	Heat increase level of radicals	[16]

in principle also be possible to use it for lipids present in more complex systems [3,28]. The lag times determined by the ESR method for lipid oxidation in vegetable oils have been shown to correlate with conventional methods for quantification of lipid stability [39].

The tendency to formation of radicals measured by spin trapping radicals during heat treatment has also been used to evaluate the oxidative stability of raw milk [40], sugar-cane spirits [41], processed pork [42] and dry-cured ham [43]. The meat samples were homogenized in buffer

containing the spin trap POBN, and the slurry was then heated. Samples were taken from the slurry, filtered and subsequently analyzed by ESR.

Other Uses of ESR for Studies of Food Oxidation

ESR has also been used to detect generation of singlet oxygen, $^1O_2$, which can induce lipid oxidation without the involvement of radicals [44,45]. Singlet oxygen can oxidise 2,2,6,6-tetramethyl-4-piperidone to a stable nitroxyl radical, which can be detected by ESR. The technique has been used to study the photogeneration of singlet oxygen by pigments such as chlorophyll and myoglobin. ESR and spin trapping have been used to characterize the role of riboflavin in light induced formation of radicals in beer [46], and to identify intermediates that are formed upon oxidation of isohumulones that are the principle bittering agents in beer [47], while the direct photodegradation of isohumulones has been studied by time resolved ESR (TREPR) [48].

The presence of antioxidants is an important factor that affects the oxidative stability of foods. Many assays for testing the efficiency of antioxidants in foods are based on measuring the ability to quench stable radicals. This approach called spin scavenging has been used with ESR detection of stable radicals such as potassium nitrosodisulfonate, Fremy's salt [49], 1,1-diphenyl-2-picrylhydrazyl radical, DPPH [50], galvinoxyl radical [49,51], and 2,2,6,6-tetramethylpiperidine-1-oxyl radical, TEMPO [20]. ESR spectroscopy has proved to be useful for such studies, since the level of very low concentrations of radicals can be studied in samples that are not optically transparent.

The line widths of ESR lines are dependent on the presence of paramagnetic substances by Heisenberg spin exchange. The concentration of oxygen, which is a very common paramagnetic compound, affects the line width. By recording the line width of a stable radical (a socalled spin probe) one can measure the oxygen concentration. This approach has been used to measure the concentration of oxygen in oil encapsulated in a glassy carbohydrate/protein matrix, and thus to study the ability of oxygen to penetrate barriers of glassy food components at different temperatures [52].

Perspective and Future Developments

ESR is a relatively new analytical method in food science and routine methods needs to be developed further. New generations of low-cost and user-friendly ESR instruments are however becoming available for

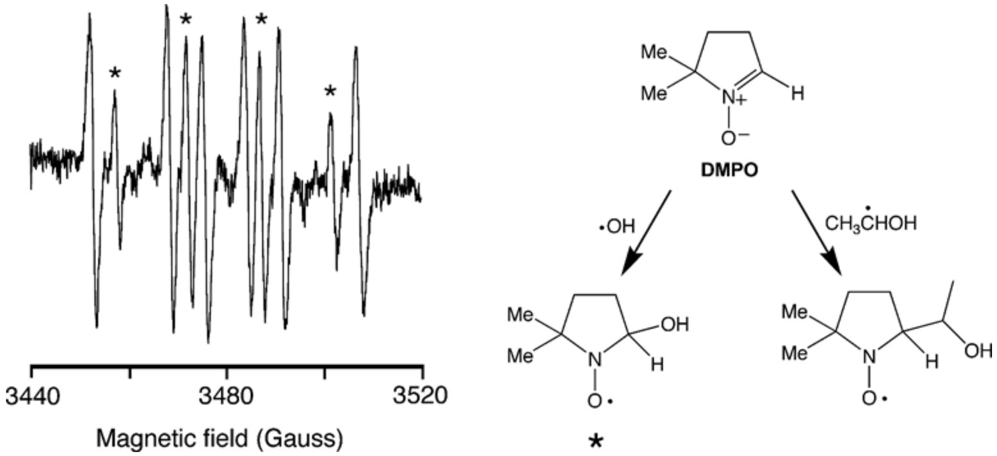

Fig. 4. Spin adducts formed in lager beer by using the spin trap DMPO and generating radicals by the Fenton reaction [29].

introduction in quality control laboratories. Another perspective is development of field gradient ESR-spectroscopy for imaging of radical processes in food systems. Using such techniques, spatial propagation of oxidative processes could be studied in multiphase and cellular systems and prooxidative structures be identified and antioxidant application optimized.

Applications to Food Systems

Magnetic Resonance Studies of Food Freezing

William L. Kerr
Department of Food Science and Technology, University of Georgia, Athens, Georgia 30602, USA

Introduction

Freezing is one of the fundamental operations used for food preservation, as the reduction in temperature reduces the rate of deleterious chemical reactions and microbial growth. In some cases, as with ice cream and sherbet, freezing imparts desirable coolness and texture. Many foods are frozen including fruits, vegetables, muscle foods, eggs, dairy products, and dough, as well as an assortment of frozen entrees.

Freezing is a complex physicochemical process involving the development of crystalline, liquid, and glassy states. Some damage may occur as ice develops and causes migration of water out of cells, or from one region to another. Several questions regarding freezing are of interest to food engineers: How long does it take an item to freeze? What size are the ice crystals that develop? What is the nature of unfrozen water in foods? What effect does freezing have on quality? How are food constituents affected by freezing? How does freezing influence post-thawing processes?

A variety of tools have emerged to study frozen foods, including X-ray diffraction, calorimetry, microscopy, and mechanical spectroscopy. As most foods contain water or oil, the use of ^{1}H NMR seems a natural approach for studying the quantity and dynamics of these components. Proton NMR has also proven useful for studying food structure. Other magnetic nuclei, including ^{31}P, ^{23}Na, and ^{13}C have been monitored to better understand the chemistry of food molecules and biopolymers during freezing.

The study of materials containing ice can prove problematic to NMR spectroscopists. Whereas liquid water has magnetic spin relaxation times up to 1–2 s, or in the millisecond range when inside foods, ice has a spin relaxation time of tens of microseconds. In addition, obtaining field homogeneity can be difficult. This article reviews the several NMR methods for studying frozen systems, and is categorized into relaxometry techniques, pulsed field gradient diffusion techniques, magnetic resonance imaging (MRI), chemical spectroscopy, and solid-state NMR.

Spin Relaxometry

One of the first reports on the use of NMR in frozen biological material was by Wikefeldt in 1971 [1]. Using continuous wave ^{1}H NMR, he tested the hypothesis that the rate of ice growth in small blood-drops was controlled by the translational mobility of water. He used the line width $\Delta\nu_{1/2} = 1/\pi T_2^*$ as the measure of mobility, but recognized that mobility might be influenced, and even dominated by rotational motion in addition to translation. In more recent times, Ablett *et al.* found that recrystallization in frozen sugar solutions is correlated with molecular mobility as measured by time domain NMR. In addition, they found that the glass transition temperature (T_g), and the temperature difference ($T - T_g$), are correlated with ice recrystallization rates [2].

Ice, Unfrozen Water, and Glassy States

The quantity of ice that exists in a frozen food at a given temperature is of great interest to food scientists. Traditionally, this has been determined by adiabatic calorimetry, differential scanning calorimetry (DSC), or differential thermal analysis (DTA). ^{1}H NMR has been investigated as a means for quantifying liquid and solid states in frozen materials, as the solid ice protons have a much shorter decay than the liquid water protons [3,4]. Studies have been conducted on sucrose solutions [4], sucrose–protein solutions [5], NaCl solutions [6], water and oil emulsions [7], porous media [8], food gels [9,10], orange juice [11], and wheat dough [12,13]. Free induction decay (FID) experiments following a 90° pulse have been most useful, as measurement time is short and dynamics in the microsecond range can be captured. The initial post dead time signal, at around 10 μs, is proportional to the number of liquid water, ice, and food constituent protons, while the signal at 70 μs is proportional to the liquid state protons. In some cases, fitting with a series of Gaussian curves has been used to extrapolate to the zero time amplitude [13]. The dependence of the magnetization magnitude on temperature must be accounted for, and

Graham A. Webb (ed.), Modern Magnetic Resonance, 1869–1878.
© 2008 *Springer.*

is described by Curie's law:

$$M_0 = \frac{B_o N \gamma^2 h^2 I(I+1)}{3kT} \tag{1}$$

For sucrose solutions, the proportion of protons in the solid phase was given as[4]

$$F = 1 - \frac{M_{0,F} T_F}{M_{0,L} T_L} \tag{2}$$

where M_0 is the initial signal amplitude, and T is the temperature of the frozen (F) and control liquid (L) samples. For a few sugar solutions, the phase diagrams determined by NMR have been compared with those determined calorimetrically, and these are typically in agreement [4].

FID experiments using both H_2O and D_2O have been used to study the effects of cryoprotectants on the eutectic crystallization of NaCl in frozen solutions [6]. As the temperature of frozen NaCl solutions was increased, a sharp increase in the number of liquid-phase protons occurred, which corresponded with the eutectic temperature as measured by DSC. When cryoprotectant sugars were added to NaCl solutions, the number of liquid protons increased, with no apparent change at the expected eutectic temperature. As a result, they concluded that the addition of sugar inhibits eutectic crystallization of NaCl through formation of an amorphous mixture of NaCl, sugar, and water between ice crystals.

Few NMR measurements of the ice content in semisolid frozen foods have been reported, and there are even fewer cases where concurrent calorimetric data is present. The solid and liquid phases of frozen bread dough have been studied using single pulse techniques. Typically, the FID relaxation curves can be resolved into a single fast component (< 20 μs), and one or two slower components [12,13]. In a previous study, the most dramatic decrease in liquid water occurred between 0 and $-10\,^\circ$C. At $-30\,^\circ$C, a precipitous increase in the solid component, and decrease in the liquid component, was observed and attributed to a glass transition. These results were consistent with CPMG experiments, and were highly correlated with dynamic mechanical thermal analysis (DMTA) and dielectric thermal analysis (DETA) measurements. These authors also found that the liquid signal may increase during frozen storage, which they attributed to the growth of ice crystals and redistribution of water.

Cornillon *et al.* used FID experiments to measure the amount of water in different states of various food gels between -40 and $20\,^\circ$C, then used the data to more accurately predict thermophysical properties of the materials [14]. At $-40\,^\circ$C, they observed some liquid-like signal, and attributed this to unfreezable, or bound, water. The amount of unfreezable water ranged from 0.05 to 0.66 g/g dry matter, depending on the gel type and whether sucrose was incorporated in the gel. They also found that 90% of the water was frozen between 0 and $-10\,^\circ$C. Kim *et al.* [15] studied cornstarch gels prepared with 10 or 30% various sugars and sugar alcohols. They found that for non-sugar gels, the onset of melting (T'_m) occurred at $-10\,^\circ$C, while the addition of sugars decreased the onset of melting to lower temperatures. They also found evidence of the occurrence of non-equilibrium freezing. In particular, sugar addition and rapid cooling promoted the formation of a glassy state, with a concomitant reduction in the amount of ice formed. At high cooling rates, the temperature may decrease such that the water is incorporated in a glassy matrix and prevented from further crystallization [16]. Indeed, many measurements of glass transitions in frozen foods incorporate an annealing process in which the sample is held just above the glass transition temperature (T'_g), thereby allowing the maximum amount of ice to be formed.

In addition to quantifying the amount of unfreezable water, NMR has been used to better understand the glassy state of frozen foods. Glassy materials are amorphous solids with little mobility on everyday time scales. As the temperature of a glassy material is increased, one or more glass transitions occur at characteristic temperatures, corresponding to the onset of coordinated molecular motions in the polymer chains [17]. Such transitions in foods, and particularly in frozen foods, are much more complex. First, foods are usually comprised of a variety of biopolymer carbohydrates, proteins, and a myriad of small and medium molecular weight substances. In addition, ice readily forms in high moisture foods; however, a glassy phase may coexist at temperatures below a characteristic temperature (T'_g). A noticeable change in the spin–spin relaxation time, T_2, often occurs at the glass transition temperature [13]. Several studies have suggested that some mobile water remains, even at very low temperatures. For example, Ullmann *et al.* used spin–spin relaxation to study the effects of freeze-concentration on proteinase-catalyzed peptide synthesis, and found that some mobile water existed even at $-70\,^\circ$C [18]. In a series of malto-oligomer solutions, Ablett *et al.* observed a fast (low mobility) and slow (high mobility) relaxing component of the spin–spin relaxation [19]. As the slow relaxing component disappeared when the experiment was conducted with D_2O, they associated this with water. They found that, upon freezing, there was a significant reduction in the intensity of the slow component down to $-10\,^\circ$C, at which point maximum ice was assumed to have formed. These authors were quick to note, however, that signal intensity was not completely due to mobile water, as chemical exchange with labile protons enhances the apparent signal. At lower temperatures, some portion of the water signal still persists, suggesting that there are mobile water protons in the glassy state. Strictly speaking, this indicates only that proton rotational motion persists, and this was better quantified with spin–lattice (T_1) measurements. They also conducted pulsed field gradient experiments, which suggested that some translational motion of water occurs in the glassy state.

NMR studies have also been conducted to determine the ice and unfrozen water states in model systems. Le Botlan *et al.* measured T_2^* and T_1 relaxation in water-in-oil and oil-in-water emulsions [20]. In emulsions held in the frozen state, up to four phases may be present. At $-13\,^\circ$C, at least 99% of the water existed in the solid state. Several researchers have also studied ice formation in porous media. Rault *et al.* used ^{2}H FID to examine ice formation in porous glass with a variety of pore sizes [21]. They showed that only part of the confined water froze, and that a non-frozen interfacial layer approximately 0.5 nm in thickness existed, which explained why water confined to regions less than 1 nm did not freeze. Morishige and Kawano showed that hysteresis occurred between freezing and melting curves in cylindrical pores, becoming more pronounced in larger pores. They attributed this to size-dependent supercooling of water confined in mesopores [22]. In addition, the melting point of water in small spaces, and with high curvature, is expected to be lower than that for bulk water [23]. Watanabe and Mizoguchi also studied porous media, including glass powder, silty soil, and clay saturated with salt solutions. They found that the amount of unfrozen water increased with increasing solute concentration, in the order $\mathrm{NaCl} = \mathrm{KCl} < \mathrm{MgCl_2}$. In addition, Valiullin and Furo used nuclear magnetic resonance magnetization transfer and NMR cryoporometry to study coexisting liquid and frozen phases in porous glasses [24].

Structural Studies

NMR relaxometry has been used to study a variety of structural features in frozen materials, including ice crystal size, ice and water distribution, pore size, and aspects of cellular structure. Most of these studies rely on the effect of relaxation "sinks" on the apparent relaxation time, and are most often described by the Brownstein–Tarr theory [25]. The sinks may be paramagnetic surface impurities, mechanisms that limit molecular tumbling near the surface, or opportunities for chemical exchange. The rate of change of the magnetic moment per unit volume (ρ) is given by

$$\frac{\partial \rho}{\partial t} = D\nabla^2 \rho - \vartheta \rho \tag{3}$$

where D is the self-diffusion coefficient of water, and ϑ is the volume sink parameter. It can be shown that the measured magnetization is given by

$$M(t) = \int_V \rho(\mathbf{r}, t)\,\mathrm{d}V \tag{4}$$

In general, $M(t)$ is related to a sum of exponential terms that include the relaxation time (T_n). If the diffusion of water is sufficiently rapid, and the size of the pores is relatively small, then water in the pore can diffuse to a surface and interact with a sink in a time much smaller than that characteristic of the relaxation processes. In this case, $M(t)$ is a single-exponential process, with an averaged T_2 (or T_1) less than that of bulk water and dependent upon the size of the pore. Equations relating T_n to pore size depend upon the particular geometry assumed for the system. In general, porous systems are heterogeneous in size; therefore, one expects a distribution in T_n characteristic of the distribution of pore sizes. In general, magnetization relaxation data can be deconvolved into a distribution of exponential decay processes. One common approach is through the CONTIN program of Provencher [26].

The size of ice crystals in frozen materials is a key determinant to the quality of the food. However, *in situ* measurement of ice crystal size is problematic. Conventional microscopy requires fixing, thin-sectioning, and a well-controlled temperature stage or the ability to place the microscope in a cold environment. Indirect spin–spin relaxation techniques have been developed to give a bulk measurement of ice crystal size distribution in some products [27,28]. In frozen starch gels, ice crystals were sublimated by freeze-drying, leaving an intact structure containing spaces where ice crystals once existed. These spaces were filled with acetone, presumably leaving the gel structure unaffected. The starch surface acts as a strong relaxation sink for acetone proton transverse magnetization. Pore sizes were determined by the Brownstein–Tarr theory.

A multitude of NMR studies have been conducted on the structure of porous materials. Much fewer, however, have been conducted on frozen porous materials. Hills and Le Floc'h studied transverse relaxation time distributions in randomly packed beds of Sephadex beads [29]. As these included beads of differing radius and cross-link density, this allowed investigation of a broad range of pore size distributions similar to those that might be found in foods. In addition, the dextran matrix provided hydroxyl groups with substantial proton exchange with water. They found that unfrozen Sephadex contained two water-filled compartments consisting of a region inside the beads characterized by $T_{2\mathrm{in}}$ as well as a bulk water region outside the beads. Furthermore, diffusion of water between the compartments was sufficiently rapid so that an averaged T_2

was observed, which depended on the bead pore size. Ice crystals were found to form inside the Sephadex beads, and with sizes less than the bead diameter. In a series of controlled experiments, they examined the temperature dependence of T_2, and found the existence of two phases, that is, ice surrounded by a concentrated dextran gel.

An interesting twist on the theme is the study of porous materials through cryogenic NMR [30]. This approach relies on the fact that water in small pores has a lower equilibrium freezing point. Prepared samples are frozen, raised stepwise to a variety of subfreezing temperatures, and the FID signal intensity determined after the solid signal has decayed. The pore size (R) distribution is derived from the Gibbs–Thompson relationship. The advantage of the cryogenic NMR approach to pore size distribution is that complex properties such as the magnetization sink strength do not need to be measured or assumed. However, materials that are readily deformed or fractured by the formation of ice would give rise to artifacts using this approach.

States of Water

Although many studies exist on the use of NMR relaxometry to examine water states in solutions of protein, carbohydrates, or other solutes, few exist on the properties of frozen solutions. Lucas *et al.* characterized both spin–spin and spin–lattice relaxations of water in frozen sucrose–protein solutions between -13 and 20 °C [31]. At -13 °C, three relaxation components could be distinguished. A short T_2 (16.2 μs) component was associated with ice, while two longer ones, 8–18 ms and 103–110 ms, were associated with non-exchangeable sucrose protons and cryo-concentrated water protons, respectively. These authors were able to calculate the fraction of ice at each temperature. They also noted that T_1 measurements, as opposed to T_2 measurements, gave more information on the ice molecular structure. For example, they determined that the ice phase in sucrose or casein solutions contained pure water, and speculated that incorporation of ions or small molecules could be detected.

A substantial number of NMR relaxometry studies have focused on the effect of freezing and thawing on structural aspects of cellular materials. Most of these have relied on the observation of distinct multiple relaxation phenomena, which can be associated with magnetic nuclei in different states or regions. As with porous systems, these distinctions cannot be made if molecules of interest rapidly diffuse amongst regions. Cameron *et al.* investigated the use of T_1 as a measure of ice crystal size in rat tissue, tendons, and lens material [32]. They found that the average ice crystal size, as determined by microscopy, had a significant positive correlation with T_1.

When maize was dried at temperatures between -30 and 25 °C, two T_1 components were observed, with minimum values at -20 °C [33]. They concluded that water mobility decreased with temperature. Hills and Le Floc'h [29] used spin–spin relaxation to study non-freezing water in potato tissue. In isolated starch granules, distributed exponential analysis showed two water domains, a slower relaxing one outside the granules and a fast relaxing one inside the granules. The relaxation time of the shorter component decreased with temperature, and it was concluded that most unfreezable water was associated with the granules and cell wall material. In whole tissue at -15 °C, they identified three peaks, and tentatively associated them with non-freezing water in cytoplasmic macromolecules (∼1 ms), water in partly frozen starch granules and cell wall material (3–4 ms), and extracellular or cytoplasmic water or water in vacuoles (10 ms). They also reinforced the idea that unfreezable water protons are still mobile, even when the material is in the glassy state ($T < T_g'$).

Hills and Remigereau used NMR to monitor the subcellular and intercellular redistribution of water in apple tissue during drying and freezing [34]. During freezing at -3 °C, ice first formed in the vacuoles, while the cytoplasmic and cell wall compartments froze at much lower temperatures (<-10 °C). Similar relaxation time distributions were observed upon thawing as were seen upon freezing. However, upon complete thawing, T_2 of vacuole water was 250 ms, as compared to 650 ms of the fresh tissue. In addition, the cell wall and cytoplasmic compartments were less well resolved. These authors concluded that NMR relaxometry is a more useful tool for studying subcellular water distributions than are spatially resolved imaging techniques. Similar observations were found during freezing and thawing of carrot parenchyma cells [35].

In seaweed shoots at -10 °C, two fractions of water were observed [36]. The slow ($T_2 \sim 50$ ms) fraction was attributed to protoplasmic water and cell wall polysaccharides, and was completely frozen at -25 °C. The fast ($T_2 < 10$ ms) fraction was attributed to water-soluble proteins. Freezing of the slow component occurred more rapidly than that of the fast component. Interestingly, some water (∼2%) related to the fast component remained unfrozen at temperatures as low as -40 °C.

Muscle foods have also been studied using NMR relaxometry. Heated, pressure treated, and frozen stored cod was studied using spin–spin relaxation [37]. In this case, however, T_2 data were collected over time for samples held at $-$ 20 and -10 °C, but thawed before analysis. In fresh cod, a single exponential decay was observed, with $T_2 = 65$ ms. In addition, by plotting the relaxation rate ($1/T_2$) vs. the $90^\circ - 180^\circ$ pulse spacing, a dispersion in the relaxation rate was seen. This suggested that, in fact, there was a second short relaxation ($T_2 \sim 1$ ms) process present. After freezing and thawing, an additional longer

T_2 component appeared, and was attributed to the appearance of thaw exudates. Steen and Lambelet investigated NMR as a tool to study the texture of cod mince [38]. The longest T_2 of three components increased with temperature and duration of frozen storage. Changes in this component were correlated with degradation of fish texture, as measured by instrumental and sensory techniques.

Farouk and Swan used spin–lattice (T_1) relaxation to study the combined effects of rigor temperature, electrical stimulation, and frozen storage (1 month at −20 °C) on hot-boned beef [39]. They reaffirmed that most of the water in the muscle cell exists between the thick and thin filaments. They found that T_1 values were shorter for frozen/thawed vs. 24 h *post mortem* beef, which they attributed to changes in muscle proteins as a result of denaturation or aggregation. They also found that T_1 after freezing decreased with initial rigor temperature, and argued that this was related to increased protein denaturation and decreased water holding capacity.

PFGSE Diffusion Measurements

While spin–spin and spin–lattice relaxation are sensitive to rotational movement of paramagnetic nuclei, pulsed field gradient stimulated echo-NMR (PFGSE-NMR) techniques can determine translational motion of nuclei. Only a few studies exist of PFGSE-NMR in frozen systems. Callaghan *et al.* designed an NMR spectrometer that uses the Earth's magnetic field to study restricted diffusion in extracted sea ice cores [40]. At −6 °C, they found diffusion rates greater than that in pure water. For samples oriented with the sea ice axis parallel to the gradient, the echo attenuation was independent of the diffusion time Δ, indicating brine pockets with dimensions along the axis sufficiently large to allow unrestricted diffusion. For samples oriented perpendicular to the gradient, diffusion was restricted at $\Delta = 200$ ms, suggesting pores on the order of 40 μm in the perpendicular direction. These authors concluded that water moves tortuously between connected pores with narrow throats. In order to limit artifacts caused by core extraction, a probe was developed that could be inserted directly into the ice sheet [41]. They confirmed the existence of two diffusive elements, and found that water diffusivity was strongly anisotropic, and on short time scales its rapid motion suggested convective transport. Menzel *et al.* studied salt water ice formed by shock freezing or by slow freezing over several hours [42]. For shock frozen ice, the ice structure contained streak-like porous channels with diameters up to 300 μm, and had unrestricted diffusion along one axis. For slowly grown ice, restricted diffusion was observed on the scale of 30 μm.

NMR diffusion studies have also helped characterize the structure of frozen/thawed gels. Polyvinyl alcohol cryogels, containing bovine serum albumen, were formed by freezing at −20 °C, followed by warming to 20 °C [43]. They found that diffusion of PVA sidechains was higher for the gels compared to PVA solutions, and increased with temperature up to 45 °C, but decreased at higher temperature. In contrast, diffusion of water in the gels increased with temperature but did not show a maximum point. Dimensions of the cryogel were analyzed through the effects on restricted diffusion. The authors determined that the compartmental spaces were determined largely by ice and polymer microcrystallites formed during freezing.

Magnetic Resonance Imaging

While spin relaxation and PFGSE measurements give important information on physical states and structural aspects of frozen systems, they do not provide spatial discrimination of properties. MRI allows the measurement of magnetization intensity, typically at a resolution of 100–500 μm, but in the case of microimaging in the 10–100 μm range. Contrast may be provided by differences in ^{1}H density, spin relaxation rates, diffusion rates, or even chemical shift. MRI is subject to similar constraints as found in other NMR techniques, and in particular the fact proton relaxation in ice is quite rapid, thus making it invisible to imaging. Thus, experiments are conducted on thawed materials, or rely on signals emanating from unfrozen water during freezing, or unfrozen liquid in equilibrium with ice after the material is frozen.

Freeze/Thaw Effects

Gamble used MRI to study the effects of freezing on thawed blueberries [44]. The distribution of "unmodified" water ($T_2 \sim 14$ ms) in fresh and frozen/thawed blueberries was obtained using a slice-selective spin-echo technique. The distribution of sugar and "motion-modified" water ($T_2 \sim 6.6$ ms) was also attained, by including an additional hard 180° pulse to invert the ^{1}H magnetization, then collecting signal at the null point of water. By constructing difference images of blueberries before and after freeze/thawing, Gamble showed that freeze/thaw results in the rupture of water-containing membranes in particular locations in the berry.

Several MRI studies have been done on muscle foods. Guiheneuf *et al.* investigated MRI as a means of authenticating fresh vs. frozen pork [45]. They found that the magnetization transfer (MT) rate increased after freezing/thawing of muscle from the same animal, and attributed this to a decrease in moisture content and denaturation of myofibrillar proteins. Evans *et al.* looked at the effects of freezing and thawing on beef, lamb, and pork placed on 6 × 6 multi-well plates [46]. By this approach, they could simultaneously measure six NMR parameters on 168 meat samples. They found that freeze-thawing caused significant changes in moisture content, MT, and T_1. However, they did note that interanimal variation would make it difficult to use MRI for authentication. Similar experiments were also conducted on trout [47], cod, and mackerel [48]. They were able to clearly resolve anatomical features of the fish, and using a three-point Dixon technique, they were able to highlight either high-water or high-fat containing regions. They found no significant changes in NMR parameters when samples were fast-frozen in liquid nitrogen, then thawed, but did observe differences in MT, T_1, and $T_{1,\mathrm{sat}}$ when slow freezing was used. As repeated freeze-thaw cycles produced less change, the authors felt this could be an avenue to authentication. That is, a sample with unknown history could be subjected to a short freeze-thaw cycle. Changes observed from a "fresh" sample would be greater than those found for a previously frozen sample.

Several studies have used MRI to study changes in the structure of frozen/thawed bread dough. Takano *et al.* prepared dough with freeze-sensitive and freeze-tolerant yeast [49]. Images were collected during fermentation following thawing, with each set of images taking 5 min to measure, with a resolution of 100 μm and a slice thickness of 1 mm. They observed that small gas cells formed during mixing without yeast, and that larger nonuniform pores formed during fermentation. They found that prefermentation before freezing increased bread loaf 10–110% for baked breads made with freeze-tolerant yeast, but decreased bread volume when bread was made with freeze-sensitive yeast. Esselink *et al.* used both MRI and cryoSEM to study structural damage incurred during freezing of bread dough [50]. Time-domain NMR showed two T_2 regions, one they associated with water bound to starch and one associated with water rapidly sampling hydration sites in gluten.They surmised that during freezing, ice crystallization causes separation of water, and that this does not return to its original state upon thawing. T_1 and T_2-weighted MR images showed that water is not equally distributed over the dough slice. After frozen storage, the water-rich regions became thicker, consistent with migration of water.

Transient Freezing

Magnetic resonance imaging has also been used to follow the formation of ice during transient freezing. As the T_2 of ice is quite short, ice is relatively invisible to the spin-echo pulse sequences used in imaging. However, the unfrozen phase absent of ice still provides sufficient signal. Kerr *et al.* mimicked commercial freezing by directing the air from an air-blast freezer into a PVC pipe leading through the bore of the MR imaging system, and which contained the sample [51]. They studied potatoes freezing at − 42 and − 11 °C, at air speeds between 2–10 m/s. Images showed the advance of the asymmetric freezing interface and loss of signal intensity as water turned to ice. Temperature profiles were simultaneously monitored with thermocouples, and the amount of heat removed over time was measured by a differential calorimeter. A numerical model was used to predict temperature profiles and freezing interface over time, and was verified using the temperature, calorimetry, and image data. This approach was patented as a means for on-line prediction of enthalpy changes during food freezing [52].

The dynamics of freezing were also studied in immature kiwifruit [53]. With the conventional spin-echo sequence, images took approximately 4.25 min. Thus, a FLASH sequence was attempted, which gave no significant difference in image quality, and allowed image formation within 25 s. Ice formation commenced at the epidermis and gradually progressed to the core. Freezing was asymmetric, and in some cases ice moved rapidly through the core. Spin–spin relaxation was faster, and translational diffusion coefficients greater, in freeze-thawed compared to fresh fruit. Kerr *et al.* also studied a variety of other foods during freezing, including potatoes, carrots, peas, corn, and chicken legs [54]. Internal structures were distinguished based on water and fat. The ice interface advanced uniformly, but asymmetrically, in all samples except for corn. Freezing in corn seemed to be governed by nucleation, as kernels froze individually. The time required for the total signal to disappear corresponded to the time to reach steady-state enthalpy. Kuo *et al.* studied the effects of freezing on mozzarella cheeses [55]. In addition to monitoring the formation of ice in the product, they found that there was a significant change in T_2 and the water self-diffusion coefficient following freeze-thawing that could be used to determine areas of freeze-damage.

In order to achieve even shorter imaging times, Lee *et al.* applied a single-point ramp imaging with T_1 enhancement (SPRITE) imaging to produce 1- and 2-D images of orange juice, lean ground beef, and bread dough [56]. For samples held between 20 and −40 °C, distribution of the liquid-like components was well resolved. The authors noted that SPRITE images are able to show unfrozen water intermingled with ice, while spin-echo images do not.

While traditional MRI has a resolution on the order of 100 μm, it is possible to acquire MR images at the microscopic level. In theory, this should allow the observation of how freezing proceeds into microscopic entities such as cells and cell organelles. Samples of potato 8 mm in length were studied using fast radial microimaging [57]. They captured cross-sectional projections every 30 s for samples placed at −20 °C. The apparently noisy freezing interface was attributed to heterogeneity in the size and structure of cells. Higher resolution imaging has been used to study non-food systems including wintering leaf buds of Momi fir and Japanese red pine [58], and both leaf and flower buds of fool-moon maple [59]. In-plane resolution of 39 µm was attained with a slice thickness of 0.5 mm. MG images clearly showed internal structures including bark, crown tissue, pith, resin canals, leaf bud scales, vascular tissue, and xylem. Bud scales of Momi fir froze quickly at −7 °C, but supercooling down to −21 °C was found in shoot primordial of March buds. In maple, scales and stem barked froze at −7 °C, primordial inflorescence and terminal primordial shoots remained supercooled to −14 °C, and lateral primordial shoots remained unfrozen at −21 °C.

Liquid Phase Chemical Spectroscopy

Chemical shift spectroscopy has been used to study a variety of frozen materials, with the aim of understanding basic chemical, structural and dynamics features as influenced by freezing. Though few studies have dealt directly with foods, much of the results have direct application to food systems. As frozen foods are not readily studied by conventional NMR spectroscopy, studies have focused on the effects of freezing. Direct studies on frozen materials by solid-state NMR will be discussed in a subsequent section.

Phospholipid Membranes

As all foods of a cellular nature, including meat, fruit, and vegetables, contain phospholipid membranes, the study of the effects of freezing on membranes is of interest. Hsieh and Wu used both ^{2}H and ^{31}P NMR to study six phospholipid bilayers at temperatures between −20 and −70 °C [60]. Three types of interbilayer water were observed: supercooled water in two of the bilayer systems at temperatures between −20 and −35 °C which spontaneously nucleates at −35 °C; "perturbed" water at −20 to −70 °C; and bound water. ^{31}P NMR suggested that rotational motion of phospholipids groups was frozen at −40 °C.

Cellular and Tissue Systems

NMR spectroscopy has also been used to study the state of water and cellular metabolism in plant and animal tissue. Haranczyl *et al.* used ^{1}H NMR spectroscopy to study freezing of lichen thallus at temperatures down to −45 °C [61]. They observed a narrow line, which they associated with "bound" water, and a broader peak associated with free water. A broadening line width and decrease in peak area below 0 °C was associated with freezing. At −20 °C, a rapid decrease in area for low moisture samples occurred and was attributed to freezing of loosely bound water. They also postulated that there was a transfer of water from loosely bound to tightly bound states.

Lockett *et al.* used lactate-edited ^{1}H NMR difference spectra to study lactate production in isolated rat liver held on ice [62]. Water suppressed spectra were observed by an interleaved binomial sequence optimized for lactate. In addition, a spin-echo double resonance technique was used in which the lactate group was decoupled by low-power RF energy on alternate scans. An initial peak at 1.26 ppm was assigned to lactate, and steadily increased in the liver tissue over a 24 h period. An additional peak, assigned to alanine, also increased with time.

Both ^{1}H NMR and ^{31}P NMR were used to measure high energy phosphates in wood frogs frozen at −1.5 °C for 7 days. Decreases in the water peaks were used to assess freezing. While most frogs survived slow freezing, no frogs survived the entire rapid freeze. Frogs maintained ATP and creatine phosphate (CP) levels during slow freeze, while rapidly frozen frogs had up to 80% reductions in ATP and CP. Changes in pH were monitored by slight shifts in ATP spectra. Intracellular pH remained between 7.2 and 7.6 for slowly frozen frogs, but decreased to 6.57 during fast freezing.

NMR spectroscopy has also been used to assess cryopreservation of cells and tissues. Hubel *et al.* examined the influence of preculture on the prefreeze and postthaw characteristics of hepatocytes [63]. Cells were processed in a cryopreservation medium containing 10% DMSO, and frozen in a complicated protocol to a final temperature of −100 °C. NMR spectroscopy of lipids showed that *in vitro* cultivation increased the relative levels of cholesterol as compared to membrane phospholipids, as well as phospholipid interconversion. ^{31}P NMR showed an increase in the net energy charge during culturing. Eugene *et al.* monitored the kinetics of permeation of a variety of cryoprotective agents used to preserve human arteries. They found that equilibration was achieved within 120 mins for DMSO, 2,3-butanediol, and glycerol, while polyethyleneglycol (MW 20,000) reached concentrations between 40 and 50% in extracellular spaces.

Solid-State NMR

As frozen systems contain a high degree of solids, it would seem logical to apply solid-state NMR for their study.

Frozen Solutions

A variety of solutes and biomolecules have been studied by solid-state NMR. Appleyard and Evans used ^{13}C NMR with magic angle sample-spinning to study solutions of glycine under a variety of freezing conditions. To avoid crystallization of water, some samples were fired through a fine nozzle into liquid propane to form an amorphous solid state. Others were subject to slow freezing rates. Although they predicted that the distribution of ice I_h and glycine would become more dispersive as the freezing rate increased, they did not observe differences in the NH_3^+ group rotations between fast and slow frozen samples. They felt that these results were encouraging, in that any formation of ice I_h in rapidly frozen samples should not be detrimental to the solute. In addition, they felt this was a good approach to trapping chemical intermediates from enzymatic reactions.

Volke *et al.* studied solutions of α-chymotrypsin frozen during magic angle spinning at 4000 Hz [64]. A very broad ice peak was observed, spanning a region of 160 ppm. To improve resolution, a sine-bell window function was applied to the FID, but this allowed only a qualitative interpretation of the resulting spectrum. However, resonances from protons of the mobile polypeptide chains could be observed. From the T_2^* values they estimated a non-frozen water content of 0.15 to 0.24 g H_2O/g protein.

Dynamic nuclear polarization (DNP) techniques have proven useful to improving the sensitivity of spectra from frozen aqueous solutions. Here, the high-spin polarization of unpaired electrons is coupled to the nuclear spins through microwave irradiation near the electron paramagnetic resonance frequency, using a nitroxide radical as the paramagnetic polarizing agent. Gerfen *et al.* used this approach to study frozen solutions of water and glycerol [65]. The ^1H and ^{13}C NMR signal strengths were improved by a factor of 185. Hall *et al.* used this approach to study arginine and T4 lysozyme in frozen glycerol-water solutions [66].

Smith *et al.* extended the idea of studying biomolecules trapped in low-energy states by freezing them in a glassy matrix [67], using rotational-echo double resonance (REDOR) spectroscopy. Samples of 2-^{13}C,^{15}N-glycine and ^{13}C-methyl β-D-^{15}N-acetylglucosamine were frozen at −80 °C, and spun at 4.5 kHz. Low energy conformation states were developed for both molecules and corroborated with molecular dynamics computational methods.

Whole Foods

In food systems, Li *et al.* used ^2H and ^1H solid-state NMR to study the mobility of unfreezable and freezable water in waxy corn starch [68]. They found that a large percentage of the unfreezable water was relatively mobile even at −32 °C. Bertram *et al.* used ^{13}C cross-polarization MAS NMR to examine differences in pre-slaughter treatments on rapidly frozen pork longissimus muscle [69]. Resonance peaks from fatty acids, carboxylic groups, and carbons in lactate and glycogen were identified. They found a significant difference in methylene carbons attributed to membrane lipids, suggesting altered membrane properties in the muscles of stressed and electrically stunned animals, as compared to control CO_2-stunned animals.

Antifreeze Glycoproteins

Antifreeze proteins and glycoproteins are found in a variety of fish and insects subject to freezing conditions, and help protect the organisms from freezing. There have been some hopes that these could be used in food systems, particularly as they may affect ice nucleation processes. NMR has been used to study the dynamics of antifreeze glycoproteins (AFGP) in the presence of ice [70]. Solid-state ^{13}C NMR indicated that AFGP adopted similar three-dimensional folding in the presence of ice and in the freeze-dried state. A high number of conformers existed, indicative of a very flexible molecule. AFGP-ice interactions were dominated by fast motions on the nano- to picosecond time scale.

Conclusion

A variety of NMR techniques are available to study frozen foods and food components. These include relatively simple relaxation techniques for measuring solid/liquid ratios, imaging approaches to monitor food during freezing, and chemical spectroscopy to measure unfreezable water and conformations of molecules.

Nuclear Magnetic Resonance Studies on the Glass Transition and Crystallization in Low Moisture Sugars

Bill MacNaughtan

Loughborough, LEICS, LE12 5RD, UK

Introduction

Sugar glasses are suitable materials for mobility studies due to changes in mobility of many orders of magnitude occurring at the glass transition. In addition, these glasses will often crystallize. The idea behind crystallization from a glassy matrix can be summed up very simply, albeit incompletely. A rigid immobile non-equilibrium glass gives way to a mobile material above the glass transition temperature and allows the material to attain equilibrium by crystallizing. The most common method of studying glassy behavior in carbohydrate [1,2,3] as well as inorganic glasses [4], is to use a thermal technique such as differential scanning calorimetry (DSC). A common trace found in polymer, pharmaceutical and food texts is shown on Figure 1. Of course not all materials will exhibit cold crystallization with resultant melting as shown here. When considering experiments designed to investigate motion in such samples, the simplest approach is to carry out measurements in the obvious regions of the trace i.e. "below the glass transition," "above the glass transition but below crystallization," "above crystallization" etc., and ignore all aspects of the temporal component of the respective events. For example, we know that the dynamic glass transition has a frequency dependence [5] and that the glass transition temperature relevant to a storage trial will probably not be the same as that recorded using DSC at 10 K/min. Additionally, crystallization is a kinetic process [6] whose peak temperature on a DSC trace will change with scanning rate, whereas melting, at least for a small molecule such as sucrose, is an equilibrium event.

Line Width and Shape Studies

A free induction decay (FID) signal recorded on a typical low-resolution time domain spectrometer is shown on Figure 2. The rapidly decaying signal is due to the "solid" or immobile component of the sample, whereas the slowly decaying component is due to the "liquid" or mobile component. There are many bench top NMR spectrometers [7,8], which will produce such traces. Other machines have been produced [9] which will give a direct recording of the spectral peak corresponding with these decays. If we think in terms of Fourier transform pairs, the line widths of solids tend to be wide (frequency domain) with corresponding short decay times (time domain). For protons in a solid, line widths can be greater than 50 kHz and the decay times of the order of 10's of microseconds. Sharp lines and long decays are the rule for liquids. For very wide solid lines, the true line width can be often limited by the excitation bandwidth of the pulse.

Often a beat will be observed in the decay. This is not to be confused with a signal which is off resonance in a machine recording both in phase and out of phase signals, and is present after combination of such signals, for instance when the magnitude is taken. There is some discussion as to how to treat such a decay. The interaction between two protons can be treated rigorously and produces the well-known Pake pattern [10]. For interactions between many spins, this problem was originally approached by performing summations in crystals such as fluorite [11]. It was found that a flattened top Gaussian curve was a good description of the line width, with a Sinc function multiplied by a Gaussian being a good approximation to the FID decay, however the decay in the time domain corresponding to the Pake pattern also has an oscillating character (Figure 3). We are left with the complexity of having at least four possible fits to the solid component if we include simple Gaussian or even a Sinc function multiplied by an exponential [12]. See reference [13] for more details.

Fitting using the sinc/Gaussian function is often known as moments analysis because of the description of solid lines in terms of an infinite series of moments [14]. In practice only the 2nd and 4th moments tend to be significant. The moments expansion of lineshape is

$$G_1^{(4)} = 1 + M_2t^2/2! + M_4t^4/4! +$$

Graham A. Webb (ed.), Modern Magnetic Resonance, 1879–1888.

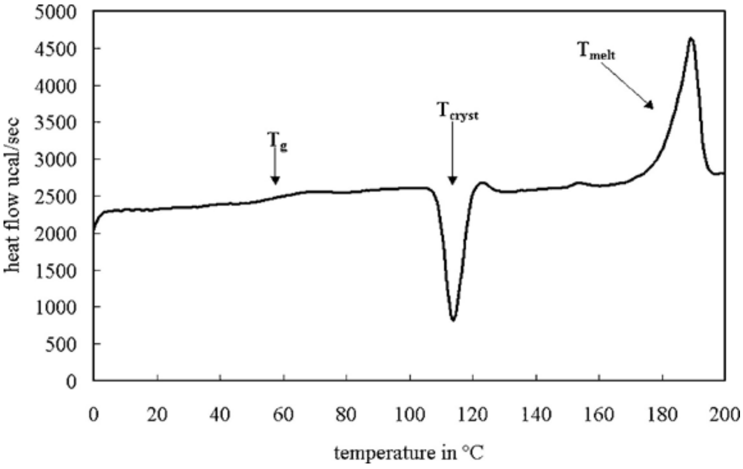

Fig. 1. A DSC thermogram at a scanning rate of 10 K/min, showing glassy, crystallization and melting behavior of amorphous sucrose at a moisture content of 1–2%.

and the series expansion of the function

$$F(t) = \exp(-a^2t^2/2) * \sin \beta t/\beta t$$

$$\text{is } 1 - (a^2 + b^2/3)t^2/2! + (3a^4 + 2a^2b^2 + b^2/5) \times t^4/4! - \text{etc}$$

Therefore the 2nd moment $M_2 = (a^2 + b^2/3)$, and the 4th moment $M_4 = (3a^4 + 2a^2b^2 + b^2/5)$.

It is useful to bear in mind that we are simply describing residual order in the material. In a glassy, apparently totally disordered, material there is still order in the sense that a random mixture of glass balls has nearest, and shells of progressively more disordered, neighbors. Pronounced beats are often observed in glasses (and crystals), which progressively disappear as the material goes through the glass transition. It is an interesting question as to whether amorphous materials and crystals can be distinguished easily solely on the basis of solid line shape. On Figure 4, we can see the results of fitting the solid decay obtained from frozen maltose solutions. It is possible to adjust the recycle delay time so that any signal from the ice, which has a very long T_1, is suppressed. We are effectively examining a maximally freeze concentrated sugar solution, or maltose glass. In the region above 240 K, the approximate T_g' for a maximally concentrated solution of maltose, the fitting using the sinc/Gaussian and Pake functions (both simple and multiple) becomes less good due to motional averaging of the residual order. With increasing temperature the signal is ultimately better fitted to simple functions such as Gaussian and exponentials [15]. However it is interesting to note that the best fit to a solid decay in a

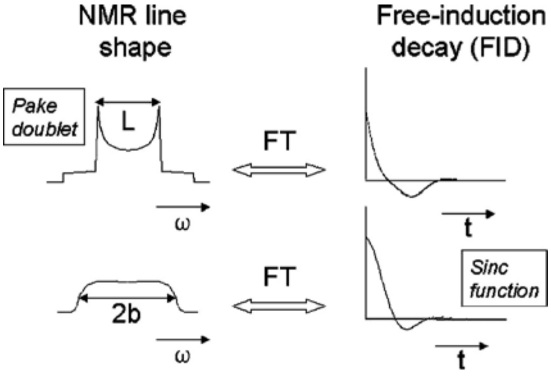

Fig. 3. Two different lineshapes, which will produce similar free induction decays [13].

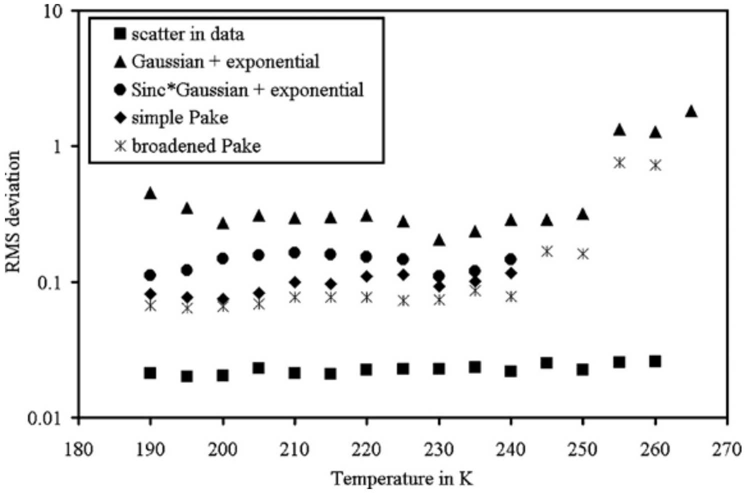

Fig. 4. A series of fits to the free induction decay of a frozen 40% maltose solution.

maltose glass is a decay corresponding to the interactions of a distribution of proton-proton pairs of slightly different separations.

Deuterium Line Shape Studies

That a deuterium powder profile looks similar to the interaction between two proton spins is a consequence of the interaction of a spin 1 particle with an electric field gradient being similar to the interaction between two spin 1/2 particles. The characteristic features of the lineshape will be averaged as the mobility is increased and will ultimately become a single isotropic line. The motion of deuterated glucose was studied in reference [16] where it was found that even above the glass transition temperature, the sample was sufficiently viscous to appear solid-like on the time scale of the measurement and so produce a Pake powder pattern (Figure 5). Interestingly the signature of D_2O in a glass, as opposed to ice, was proposed to be a flat-topped Gaussian, due to a distribution of quadrupolar coupling constants as well as orientations.

Residual orientation of deuterium in say D_2O trapped in interlamellar layers, for example in vanadium pentoxide hydrate, results in incomplete averaging and produces a similar powder pattern with a much reduced spectral width [17]. Hills [12] has used a quadrupolar solid echo measurement to show that D_2O is insensitive to the glass transition in 10% D_2O maltose glasses and is still highly mobile at temperatures well below the glass transition.

Deuterium can of course exchange with exchangeable protons on sugars and can so provide direct information on the state of the sugar [18,19].

Relaxation Studies

In food related work, Relaxation is usually concerned with the mobility of protons and here we will mainly deal with spin-spin or T_2 relaxation. A simple signal has already been shown in the form of the time domain signal of Figure 2. The instrument dead time limits the signal acquisition at short times; the very times where crucial information on the solid is available. This can be overcome by pulse sequences producing solid echoes [20], however information in this region tends to be line shape based rather than the simple decay time. Changes in motion through the glass to rubber transition are typically described by changes in intensity of the solid component and by intensity and time constant of the mobile fraction. Additionally it is difficult to distinguish between a rigid amorphous fraction and any crystals produced by "cold" crystallization above the glass transition, by simple measurements of the solid decay. Information tends to be restricted to indirect changes monitored by the mobile fraction, for example due to a transfer of protons caused by water exclusion from the material which is crystallizing. If this is the case then techniques more suited to the measurement of mobile species, such as the Carr Purcell Meiboom Gill (CPMG) sequence, can be used.

For example, in the case of a commercial product from which sucrose is crystallizing (Figure 6), there is a transfer of water from the sucrose, which contains no water in the unit cell, to the remaining amorphous material, which progressively becomes more mobile. Consequently the immobile to mobile ratio falls. There is an apparent paradox, in that the material appears more mobile with time as an almost completely rigid material is produced. A continuous distribution of T_2 values in the FID shows

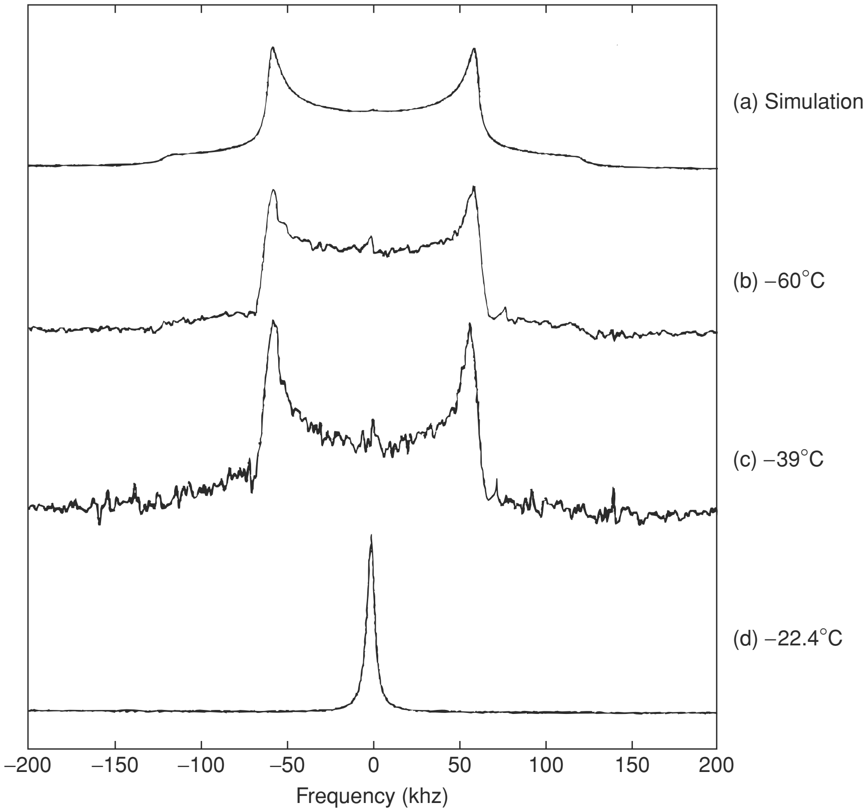

Fig. 5. A series of deuterium lineshapes for deuterated glucose at specified temperatures.

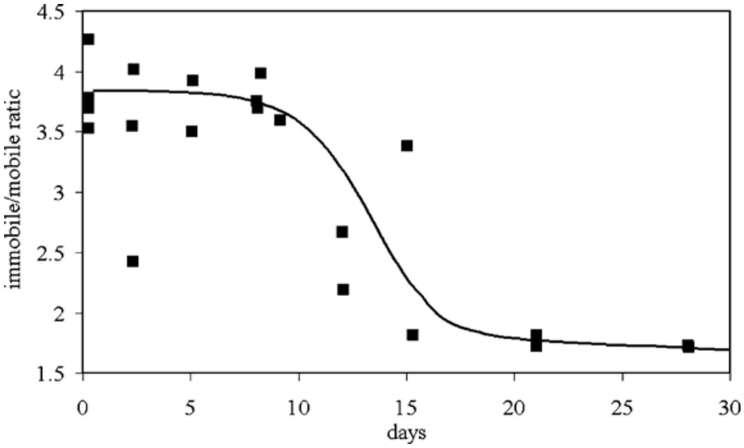

Fig. 6. The change in immobile to mobile ratio as defined by the ratio of the amplitudes of a fitted gaussian (immobile) to exponential (mobile) upon crystallization of sucrose. Notice the significant induction time i.e. time lag at the start of the trace. This is a commercial product with a complex list of ingredients.

these changes clearly, as well as dramatic differences in mobility when the glassy phase is taken above the glass transition temperature. We would see still more complex behavior if a sugar such as lactose, which retains water in the unit cell had crystallized. Changes in the simple decay time of the solid fraction are however small.

Van den Dries *et al.* [18] in a comprehensively argued study of low moisture maltose glasses, demonstrated that the DSC determined glass transition temperature was very close to the temperature of discontinuities in both the mobile T_2 relaxation time and the immobile second moment M_2. By comparison with deuterated samples, where the discontinuity in the second moment was slightly below the T_g, it was concluded that the increased reduction in the second moment above T_g in the protonated sample was due to motion in the exchangeable protons on the maltose. Several other important deductions were convincingly argued. By contrasting Goldman Shen results, which placed an upper limit on chemical exchange, with the transverse relaxation rates which were approximately 2 orders of magnitude greater, it was concluded that chemical exchange could not account for the amplitudes of the mobile and immobile components as the temperature was varied. Rather, below the glass transition there was a contribution of immobilized water protons to the solid maltose proton signal, whereas above T_g there was a contribution of mobile maltose protons to the water signal. Hills [12] has however suggested that increases in the lateral degrees of freedom may be relevant to the observed discontinuity in the mobile fraction.

In addition, by comparing the magnitude of the decrease in viscosity on the formation of a solution from a glass (10^{13}) with the measured reductions in correlation times (10^5) [18], water did not appear to fully sense the glass transition, but was decoupled to a degree dependent on the water content. The lower the water content, the more pronounced was the break (Figure 7). This agreed qualitatively with Ablett *et al.* [21] who observed similar discontinuities in the solid at T_g, however none in the mobile signal. Of particular interest was the observation that the M_2 for crystalline maltose [22] was larger than the glassy value. This may provide an answer to the question in the previous section concerning a way to reliably distinguish between amorphous and crystalline phases by measurements in the solid region. Tang *et al.* [23] have also calculated the second moment for crystalline rhamnose and methyl rhamnose by lattice summation and have carefully argued the contributions to M_2, based on the results of other relaxation measurements, which progressively disappeared as the samples were heated. The absence of a clear structure for glasses meant that rigid lattice M_2's were calculated indirectly.

The arguments in [18] and [23] provide a good rationale for the explanation of many observations in other systems. For instance Farhat *et al.* [24] and Derbyshire [15] have observed discontinuities in the M_2 and the solid T_2 fitted using a Gaussian, of amylose and glucose close to the predicted glass transitions. Kumagai [25] observed discontinuities in M_2close to the predicted glass transition in low moisture sugars containing 1% carrageenan.

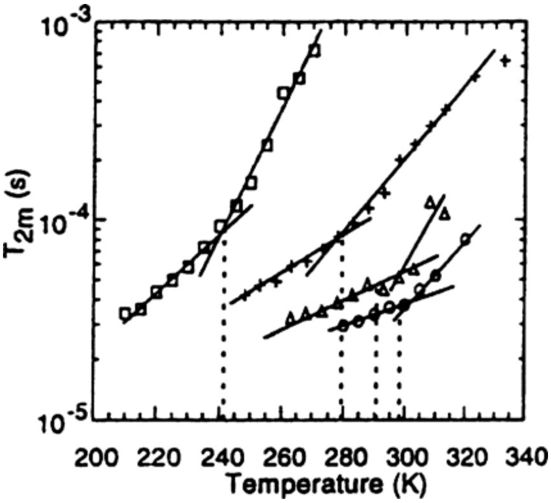

Fig. 7. Typical breaks in the value of the decay time of the mobile component for maltose glasses. Moisture content ○, 5%; △, 7%; +, 10%; □, 20% [18].

Apparent discontinuous behavior in T_1 or longitudinal relaxation has been observed in other materials. Mansfield and Powles [26] carried out some early work on glycerol, measuring T_1 over a wide range of temperature. A dramatic drop in T_1 was observed as the material transformed from a glass to a more mobile state. The estimations of correlation times [27] also proved interesting and this will be returned to in the next section. T_1 discontinuities have also been observed in toluene [28], a molecule not too dissimilar in size to sugars, although glass formation is through Van der Waals bonds rather than H bonding.

Multiple breaks observed in M_2 [25,29] have also raised the interesting possibility of additional "events" above the glass transition. This has been associated with "ball in a cage" or mode-coupling theories of the glass transition [30], where there is an additional breakdown of postulated aggregates at a temperature approximately 20% above T_g. The lateral and orientational time constants are also proposed to separate in this region with the lateral attaining a larger value.

In much of the work presented so far there is the tacit assumption that the T_g determined by rheological and thermal methods and the NMR determined T_g should fall at the same temperature despite the massive difference in frequency of measurement. This is a complex issue. T_1 measurements tend to reflect behavior at high frequencies, whereas T_2 measures contain contributions from both static and high frequencies. $T_{1\rho}$ measurements tend to lie somewhere in between depending on power level used. Clearly there is evidence here that T_1 measurements nevertheless do correspond to low frequency measurements of T_g such as DSC values. This may depend on the degree of coupling between different parts of the molecules. However, work remains to be done on importing ideas from the areas of calorimetry and polymers on the scanning rate and frequency dependence of the glass transition.

High-Resolution Solid-State ^{13}C NMR

Whilst low-resolution relaxation data provide a wealth of information concerning the mobility of entire proton fractions, detailed information on specific protons is obtained indirectly, normally by clever choice of molecules containing for example off-ring methyl or hydroxymethyl groups [23] or deuterium substitution [18]. High-resolution solid-state ^{13}C NMR has the ability to identify, and in addition measure, the relaxation of particular carbons in a molecule. As previously stated, the proton NMR spectrum of a solid often consists of a single wide line as indeed does the carbon spectrum. The main reasons for line broadening in solids are firstly strong dipole–dipole interactions. Each nucleus experiences a different local magnetic field depending on the orientation and distance of the neighboring nuclei. Secondly, Chemical Shift Anisotropy, which reflects the difference in chemical shift according to the orientation of the molecule in the magnetic field, will produce a range of resonance frequencies. This produces inhomogeneous lines which means that each region of the line is distinct from the other regions and can be affected independently, such as by specific irradiation which can "burn" holes in the line [31]. There is a third problem associated with the observation of NMR in solids, namely the long T_1's associated with very immobile samples. A cross polarization stage with high power decoupling whilst spinning at the magic angle (CPMAS NMR), ameliorates all of these problems and in addition provides a rather neat way of distinguishing between mobile and immobile species. Cross polarization relies on species maintaining "magnetic contact" at low frequencies for efficient transfer of magnetic polarization—too much motion—no transfer. Solids are therefore observed. A conventional NMR experiment using a simple 90° pulse will measure all species, however the solid lines will be wide, depending on the decoupling power used, and so only the mobile fraction will be seen. This is often known as a Fourier transform magic angle spinning (FTMAS) or single pulse excitation (SPE) experiment. It is a remarkable fact that using the tricks of the CPMAS method the spectrum of crystalline sucrose, effectively broad and featureless, can be turned into a spectrum with detail comparable to spectra obtained in solution (Figure 8).

The glass in Figure 8 was prepared using a freeze drying method; melt quenching tending to produce colored glasses which, depending on the degree of heating above the melting point, can be upwards of 50% degraded and interestingly exhibit broader peaks. If we have clear chemical shift information available, i.e. we can identify specific carbons in the molecule, we can carry out a series of relaxation measurements, each of which has an associated frequency [32], on individual carbons of the molecule composing the glass.

We therefore have the ability from the experiments shown on Table 1 to construct primitive spectral density maps, from the values of the decay times, i.e. measure the intensity of magnetic fluctuations present at particular frequencies. This is similar to the procedure carried out by Schaefer and Stejskal [33] (see Table 2).

The glass has lower T_1 values, which have less of a spread across the different regions of the molecule compared with the crystal. The hydroxymethyl groups in the sucrose crystal are not completely hydrogen bonded [34] which leaves a certain degree of freedom to rotate. This

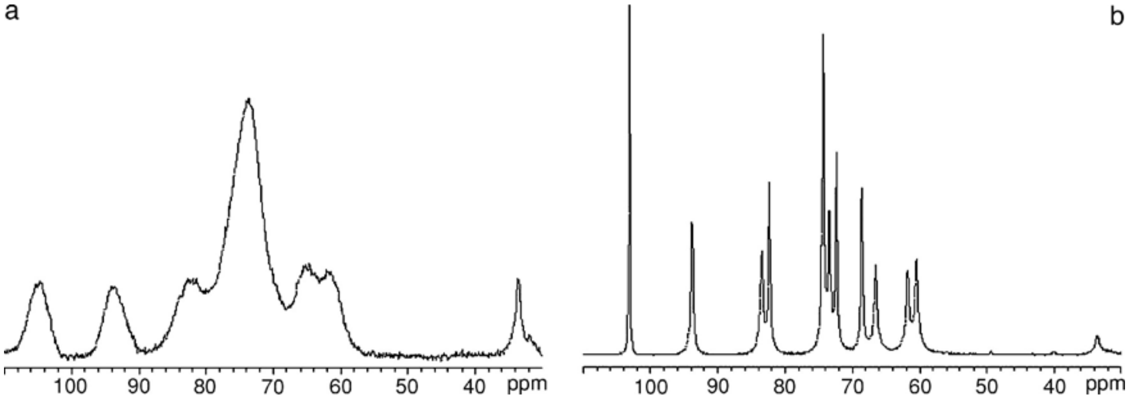

Fig. 8. Typical ^{13}C CPMAS spectra for glassy (left) and crystalline sucrose. The peak at 33 ppm is a polyethylene reference.

Table 1: The frequency of perturbation associated with each experiment

Experiment	Effective motional frequency range
T_1 spin-lattice	Larmor frequency (e.g. 75 MHz for ^{13}C in a > tesla field)
$T_{1\rho}$ spin-lattice	10–50 kHz
T_2 spin-spin	Static to mid-kHz
Cross polarization T_{C-H}	near static

accounts for the large differences in the relaxation parameters, particularly the T_1 values, for these carbons. T_1 was determined here using the sequence described in reference [35]. Similarly the anomeric carbon of the fructose moiety has no directly bound protons, leading to long T_{C-H} time constants.

A simple temperature sweep spanning the DSC determined glass transition, while recording CPMAS spectra can be instructive (Figure 9). A change in T_1 value is seen at the glass transition. Of particular interest is that the discontinuity for the off-ring group is at a lower temperature than the main ring and anomeric groupings. Apparent discontinuities in T_1 and other relaxation parameters have been observed in many systems as outlined in the previous section.

It is interesting to speculate as to the fundamental cause of this type of feature. Connor [36] has generated curves showing the type of T_1 profiles expected for distributions of correlation times based on equations containing terms of the type [37]

$$A\{[\tau/1+\omega_0^2\tau^2]+[4\tau/1+4{\omega_0}^2\tau^2]\}$$

In general a distribution of times leads to a flattened base of the T_1 profile [38]. It is tempting to generate T_1 profiles based on distributions of correlation times for isotropic motion and view these as an explanation for the variation in relaxation parameters with temperature (see Figure 10); apparent linear regions may simply be part of a curve in the distribution if the temperature range is not wide enough. However, increasingly sophisticated techniques, capable of measuring non-isotropic motion, suggest that motion can be fundamentally different in the glassy state and in addition there can be switchovers in particular temperature regions from one form of motion to another [23]. Although strictly belonging to the previous section on relaxation NMR, reference [23] is probably the most thorough approach to correlation times in this area. By careful choice of molecules with off-ring methyl and hydroxymethyl groups the minima in T_1 and $T_{1\rho}$ measurements were fitted accurately by discrete correlation times without recourse to complex distributions.

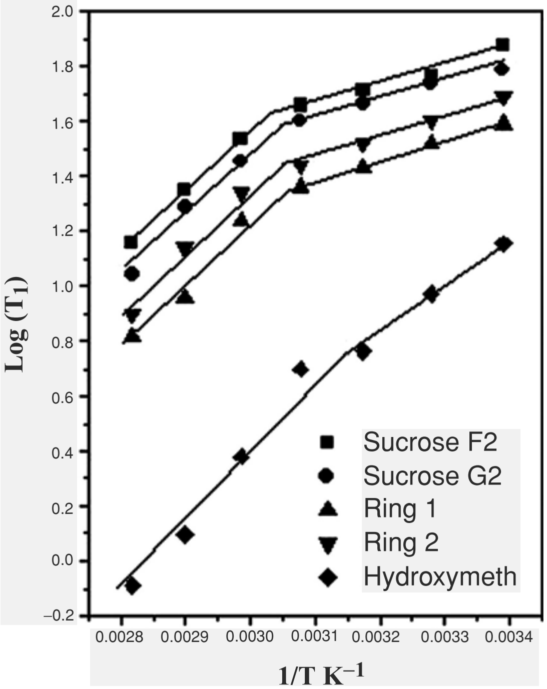

Fig. 9. The Arrhenius variation of the ^{13}C CPMAS determined T_1 in freeze dried sucrose.

Although essentially the same features are observed it we plot other relaxation parameters such as proton or carbon $T_{1\rho,}$ the changes do not approximate two linear regions so closely, at least not in sucrose. This is possibly because there is a more complex spread of correlation

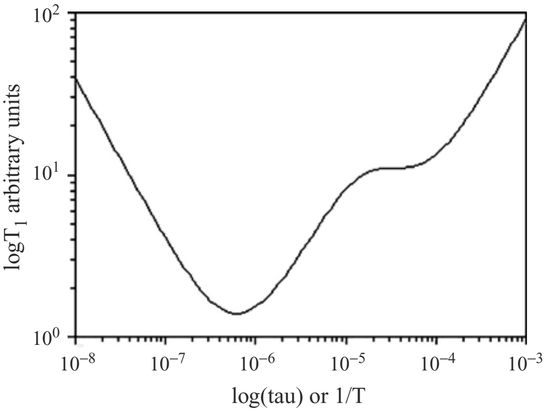

Fig. 10. A theoretical plot showing the effect on T_1 of two distinct correlation times.

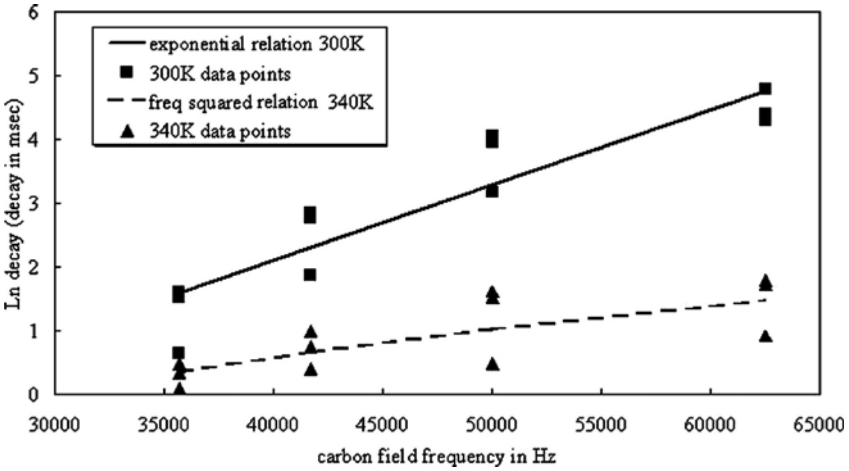

Fig. 11. ^{13}C $T_{1\rho}$ for the ring grouping in freeze dried maltose as a function of the frequency of the spin locking magnetic field.

times at the lower frequency end of the spectrum. Changes in moisture content can also blur apparent sharp features in the graphs. Similar observations have been made in the case of maltose [39] However here at low temperatures there appeared to be an additional reduction in T_1, apparently in disagreement with theory. It was proposed that this was not related to mobility, but may have reflected enhanced spin diffusion in these very rigid systems to efficient relaxation sinks. It has also been proposed that relaxation can be affected by the physical vibrational characteristics of the rotor in CPMAS NMR.

Of great interest both in Figure 9 and in reference [39] is the apparent lower transition temperature of the off-ring hydroxymethyl, when compared with the ring carbons. Moreover the absolute value of T_1 does not reflect the attached number of protons, i.e. is half the value for twice the number of protons, as might be expected. This implies the uncoupling of the motion of certain parts of the molecule from the main glass transition. As in the previous section where water was used as a solvent, the idea of uncoupling was further reinforced by examination of the motion of methanol in maltose methanol solutions [39]. Once again, while the increase in viscosity is of the order 10^{13}, on going from a solution to a glass, the rotational diffusion was only slowed by 4–5 orders of magnitude. This contrasts with other organic glasses measured using deuterium NMR [30], which showed that rotational motion of all components of the mixture tended to the same value as the temperature approached the glass transition. This may reflect the degree of compatibility of the solvent with the glass former.

^{13}C $T_{1\rho}$ measurements have often been cited as particularly relevant to glassy behavior, due to their being sensitive to motions in the mid-kHz region [40,41]. However the unambiguous assignment of ^{13}C $T_{1\rho}$ values to a measure of motion depends on the absence of efficient coupling of the carbon to the proton fraction, which would effectively shunt the magnetization to the lattice. It has been suggested that the variation of ^{13}C $T_{1\rho}$ as a function of frequency of the carbon irradiation is a test of this. If the ^{13}C $T_{1\rho}$ values have an exponential dependence then the $T_{1\rho}$ is tending away from a measure of motion. A squared dependence suggests a closer measure to true motion. This experiment was carried out (Figure 11) on freeze dried maltose and the result obtained, that below the glass transition there was a tight coupling between protons and carbons, whereas above T_g motion began to decouple the carbon/proton transfer of magnetization and $T_{1\rho}$ was a useful motional parameter . This is yet another example of a mobility experiment sensitive to the glass transition.

CPMAS NMR and Crystallization

The experiment described on Figure 9 was terminated at a temperature of 350 K due to the crystallization of the sucrose. As is seen on Table 2 the relaxation parameters for the glass and crystal are quite different. If the glass were to be caught in the act of crystallizing then we would expect a dramatic shift in value of the particular relaxation parameter. Figure 12 shows exactly such an experiment. These experiments can be difficult to reproduce as crystallization parameters such as induction time and rate are affected by shear when the sample is introduced to the CPMAS rotor and subsequently spun at 3–5 kHz.

Table 2: Relaxation times for different carbons in the sucrose molecule, crystal (anhydrous) and glass (1–2% moisture), at ambient temperature (295–305 K). Anomeric data are for the F_2 carbon of sucrose with no attached protons. The G_1 anomeric carbon, having one attached proton, exhibits ring values. Typical or averaged values are shown where several carbons belong to one class. T_1's in seconds, $T_{1\rho}$'s in milliseconds, T_{C-H} in microseconds

Sugar carbon	Anomeric				Ring				Off ring			
experiment	^{13}C T_1	^{13}C $T_{1\rho}$	^{1}H $T_{1\rho}$	T_{C-H}	^{13}C T_1	^{13}C $T_{1\rho}$	^{1}H $T_{1\rho}$	T_{C-H}	^{13}C T_1	^{13}C $T_{1\rho}$	^{1}H $T_{1\rho}$	T_{C-H}
glass	75	70	5	174	44	28	5	42	14	9	5	28
crystal	281	196	>300	248	264	110	>300	46	10	44	>300	26

One can also simply examine CPMAS spectra with time and under suitable conditions of temperature and moisture, observe the emergence of sharp peaks corresponding to crystalline species [42]. A corresponding reduction in the FTMAS trace, which measures the mobile fraction, can also often be seen. The latter depends to a certain extent on the proton decoupling power used in the FTMAS experiment. Large powers enable the rigid amorphous fraction to be seen whilst low powers render visible only the most mobile of species.

In conclusion, the CPMAS method detects glass transitions via a variety of relaxation methods and can measure the rate of crystallization and identify crystallizing species. This latter property distinguishes it from other relaxation methods.

Other NMR Techniques As Monitors of the Glass Transition

Two-dimensional exchange spectroscopy and its time domain echo decay equivalent are capable of providing a more detailed view of motion in glasses than has been presented thus far. In an adaptation of deuterium stimulated echo methods [43,44] which examined reorientation in ortho-terphenyl and glycerol, van Dusschoten *et al.* [45] used glucose, enriched in the 1 and 6 positions with ^{13}C, and examined the motion of the complete molecule and the off-ring hydroxymethyl.

Essentially, the orientation of a nucleus in the external magnetic field determines the frequency of evolution during the first time period. The magnetization is then stored in the *z* direction for a second time period during which rotational motions of the molecule, which change the orientation, will cause evolution at a different frequency in a third time period. Motion will therefore tend to decrease the subsequent echo. A ^{13}C cross polarization stage was incorporated to enhance sensitivity. Deuterium NMR could not be used here because of the relaxation properties in this system. It was found by comparison of experiment with computer simulation that echo decays were well described by a bimodal distribution of jump angles (75% 1–2° and 25% 7–8°) with the off-ring group having a higher value for the larger jump angle. However the motion of the ring and the off-ring group were strongly correlated, with no evidence for substantial rotational freedom. This has also been observed in glucose

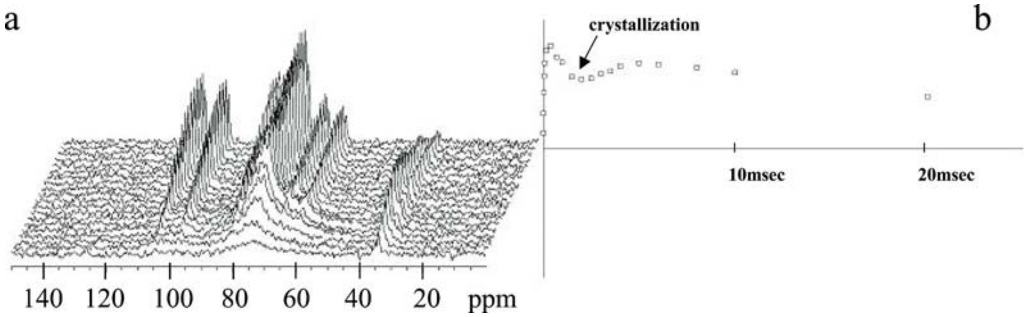

Fig. 12. A variable contact time experiment for freeze-dried 3/1 maltose pullulan at a moisture content of 11%. The emergence of sharp features (back) from the broad amorphous peaks (front) shows the progressive crystallization of maltose. Each trace took approximately 20 min to record. Figure 12b shows the integrated ring peak (75–85 ppm) in Figure 12A as a function of contact time. The normally smooth decay at times greater than about 1 msec is punctuated by a sudden increase in intensity corresponding to the shift in the value of the ^{1}H $T_{1\rho}$.

using CPMAS NMR, however, there are substantial differences in the freedom of off-ring groups amongst sugars. These studies suggest that in the glass and glassy region, isotropic motion or continuous rotational diffusion is no longer a good description of mobility.

Imaging in the Study of Glasses

The use of conventional NMR imaging is usually restricted to mobile systems with the sensitivity and noise being limited by the interplay between T_1 and T_2 values [46]. However the advent of pulse sequences designed specifically for more solid like materials, such as single point or constant time imaging [47], may provide macroscopic and functional information on glassy carbohydrate matrices including sugars, such as the ingress of moisture, although they would appear unlikely ever to give the detailed motional information provided by the previously considered methods.

Probing the Sensory Properties of Food Materials with Nuclear Magnetic Resonance Spectroscopy and Imaging

Youngsoo Lee, Soo-Yeun Lee, and Shelly J. Schmidt
Department of Food Science and Human Nutrition, University of Illinois at Urbana-Champaign, Urbana, IL 61801, USA

Introduction

Consumers are becoming increasingly interested in the nutrition, science, and safety of the foods they consume. They want high quality, economically priced, healthy, and convenient food that satisfies their sensory expectations. To meet the consumers' needs and expectations, a thorough understanding of the chemical, biological, physical, and sensory aspects of foods is essential. The most innate consumer need and expectation is for the food to provide an acceptable (e.g. a quick lunch) to grand (e.g. Belgium chocolate) sensory experience. If the food possesses several desirable attributes (i.e. low cost, nutritious, and convenient), yet does not "taste good," the consumer will not likely purchase the food again [1]. The five major sensory properties of food materials—appearance, texture, aroma,[1] taste,[1] and irritation—are perceived by the primary human senses—visual (sight), tactile (touch), olfactory (smell), gustatory (taste), auditory (hearing), and chemesthesis[2] (common chemical sense). Figure 1 illustrates the connection between how these six primary human senses (left column) can be used to probe the five major sensory properties of food materials (center column)—the visual system for appearance, tactile, and auditory systems for texture, the olfactory system for aroma, the gustatory system for taste, and the chemethesis system for irritation.

Sensory scientists use well-designed and controlled objective sensory tests with trained human subjects to measure, analyze, and interpret reactions to food materials, as they are perceived by the senses, with the intention of formulating food products with desirable sensory properties. In addition to sensory methods, various instrumental methods have been used to investigate the sensory properties of foods. For example, gas- and liquid-chromatography have been developed to characterize numerous flavor compounds, such as the flavor compounds in roasted coffee beans [5]; texture analysis methods have been used to measure firmness in processed diced tomatoes [6]; and viscometer methods have been used to investigate mouthfeel attributes of beer [7]. Instrumental methods can provide rapid, reproducible, on-line, data that complements and correlates with sensory data. Instrumental methods can evaluate discrete sensory properties of foods and probe their underlying chemical and/or physical causes, however, they lack the integrative powers and sensitivity of the human sensing system. Thus, sensory and instrumental methods can be used in a complementary fashion to both assess the sensory properties of foods and to design foods with desirable sensory properties.

Nuclear magnetic resonance (NMR) spectroscopy and magnetic resonance imaging (MRI) are very versatile, non-invasive, non-destructive molecular level techniques that have been applied to investigate the sensory properties of food materials [8,9,10,11], as well as the activity of the brain while engaged in sensory evaluation [12,13,14,15]. In order to use NMR and MRI to probe the sensory properties of food materials (or brain activity) a relationship (either direct or indirect) between the NMR or MRI observables [16] and the sensory property of interest must be established. The association between the NMR or MRI observable and sensory property is based on a series of connections between fundamental spectroscopic events and molecular, microscopic, and macroscopic properties of the food sample. Figure 1 gives four examples of how various NMR and MRI observables and their associated molecular, sample, or brain activity properties (right column) can be used to probe the five major sensory properties of food materials (center column). In example one, the NMR observables of relaxation time [longitudinal (T_1, sec) and transverse (T_2, sec)] and spin diffusion coefficient (D, m^2/sec) can be used to measure rotational and translational molecular mobility, respectively, which in turn can be correlated to texture (e.g. firmness and crunchiness) and taste (e.g. sweetness

---

[1] "Flavor" is an attribute of foods that is a composite of the smell and taste sensations.

[2] Chemesthesis is defined as the sense mediating irritation aroused by the action of noxious chemicals on exposed or semi exposed mucosal membranes [2,3]. Examples of chemical sensibility humans possess toward irritant compounds are capsaicin in red chili pepper, piperine in black pepper, zingerone in ginger, isothiocyanate in mustard and horse radish and 1-propenyl sulfenic acid in onion and garlic [4].

and saltiness). In example two, the NMR observables of chemical shift, j-coupling, peak intensity, Nuclear Overhauser Enhancement (NOE), and multidimensional NMR can be used to determine the molecular structure of various color additives (appearance), aroma compounds, taste compounds, and irritants. In example three, the MRI observables of pixel (2-D) or voxel (3-D) intensity can be used to measure spatially resolved sample concentration and/or component molecular mobility, which in turn can be correlated to internal sample appearance and texture sensory properties. In example four, the functional MRI (fMRI) observables of pixel or voxel intensity (typically proton density for measuring changes in blood flow over time) can be used to measure brain activity of a subject while engaged in sensory evaluation. These examples were designed to illustrate the general usefulness of NMR and MRI for probing the five major sensory properties of food materials. The remaining of this article is devoted to the use of magnetic resonance techniques for specifically probing texture and taste properties of food materials.

Texture

The texture of food, in most cases, is measured and expressed by its rheological and structural characteristics [17]. When the texture of food is perceived, one or more of the visual, tactile, and auditory senses are engaged. When a consumer is in the process of choosing a food product, the first level of textural evaluation usually involves the visual and tactile (hand) assessment of the product, especially in the case of fresh produce, meat, fish, and poultry. Subsequent post-purchase textural evaluation of the product involves mastication, also known as chewing, which directly involves the tactile (mouth) and auditory senses, and may be indirectly influenced by the simultaneous activities of the olfactory and gustatory senses. The perception of texture in the mouth is often a critical quality factor for many types of foods, such as the crunchiness of snack foods, the creaminess of puddings and mousses, and the astringency of red wines.[3] Magnetic resonance techniques have been employed to evaluate food texture, along with other instrumental methods, such as texture analysis and viscosity measurements [22]. Food texture studies using magnetic resonance can be categorized into three main types: water mobility, image analysis (MRI), and functional brain imaging (fMRI). Recent research studies that have been done to better understand and evaluate food texture using magnetic resonance are discussed below.

Water Mobility

Water mobility as measured by NMR has been related to the texture of solid and semi-solid food systems [23,24,25,26,27,28,29]. For solid and semi-solid foods, the mobility of water, as measured by free induction decay (FID), longitudinal relaxation time (T_1), or transverse relaxation time (T_2) of the water, has been correlated to instrumental and/or sensory texture measurements. In general, decreasing water mobility (i.e. shorter FID, T_1, and T_2 values) is linked to increasing food texture parameters, such as crispness, firmness, hardness, and elasticity. For example, Chen *et al.* (1997) studied the NMR mobility of water [20 MHz ^{1}H NMR T_1 saturation recovery sequence and T_2 Carr-Purcel-Meiboom-Gill (CPMG)] in bread during storage (5 and 22 °C) and found that several NMR parameters correlated with the firming process in the bread crumb (staling) as measured by the TA.XT2 Texture Analyzer [23]. In another study, Thygesen *et al.* (2001) explored the correlation of low-field ^{1}H NMR parameters extracted from CPMG relaxation curves of raw potatoes and the chemical and sensory analysis of cooked potatoes [28]. The purpose of their study was to understand the underlying chemical connection between the sensory predictive NMR parameters and sensory texture. They tested several potato varieties and two growing methods (organic and non-organic). Overall, it was found that predication of sensory texture quality of boiled potatoes from relaxation curves of raw potatoes is possibly because NMR relaxation curves contain information on water content, which, in turn, is inversely correlated to starch content. It was also reported that NMR is able to probe adhesiveness and springiness mouthfeel attributes slightly better than chemical descriptors due to its sensitivity to the state of the water (bulk or associated with solids) in the sample, a parameter that is uniquely determined by NMR. These studies illustrate the utility and the potential of using NMR for examining the texture of food materials.

Image Analysis

While NMR can measure the spatially averaged water content and mobility of a sample, MRI can measure the spatial distribution of water content and mobility across the sample. In turn, this spatial information has been correlated to the internal textural properties of the sample [30,31,32]. For example, Gonzalez *et al.* (2000) studied the effects of cooking time (9.5, 11, and 15 min) and holding time of lasagna pasta after cooking (4–185 min) on sample textural properties (mechanical testing using the texture analyzer) and internal moisture distribution (*via* MRI at 300 MHz using a spin-echo based imaging sequence) [30]. They reported that changes in MRI moisture distribution correlated well with changes in textural properties. For example, migration of water, as measured by MRI, to the sample center coincided with a significant decrease in peak force required to cut the lasagna pasta during both cooking and holding times.

Functional Brain Imaging

Functional MRI can be used to understand how the human brain responds to the presence of different tactile stimuli [14,15,33]. For example, de Araujo *et al.* (2004) used fMRI (3T Vaian/Siemans whole body scanner) to investigate the representation of food texture and oral fat in the human brain, using carboxymethyl cellulose (CMC) and vegetable oil [33]. The choice of fluid foods minimized the movement of the subjects during imaging, since no chewing was required. It was found that viscosity of tasteless and odorless CMC was represented in the (primary) taste cortex in the anterior insular and that the level of activation was proportional to the log of the CMC viscosity. The ventral anterior cingulated cortex was activated by oral fat independently of its viscosity, and was also activated by sucrose. This study is the first investigation of the oral sensory representation of food texture and fat in the human brain. The results begin to reveal brain mechanisms that may be important in texture-related sensory properties of food that make them palatable, and in turn may be related to the control of food intake and obesity. Even though fMRI is complicated by the problem of movement during chewing, it has great potential for understanding the perception of food texture by the human brain.

---

[3] Astringency is a chemically induced multifaceted oral tactile sensation that is described as a puckering or drying sensation in the mouth. Astringency is thought to result from the interaction between polyphenols and proline-rich salivary proteins, which form a complex that precipitates, and in turn reduces the lubrication effect of saliva on the tongue and the surface of the oral cavity [18]. NMR has been used to characterize the structure and dynamics of the tannin-saliva protein complex [19,20,21].

Taste

The gustatory sense is one of the most common and fundamental senses in life. It is the direct detection of a relatively few specific chemical compounds (compared to the sense of olfaction) on the sensory organs called taste buds or gustatory calyculi, which are concentrated on the upper surface of the tongue [34]. There are currently thought to be five basic tastes: (1) salty, mainly produced by the presence of sodium chloride and to a lesser degree by other salts, such as potassium chloride, (2) sweet, produced by simple carbohydrates, such as sucrose and fructose, as well as high intensity sweeteners, such aspartame and sucralose, (3) bitter, produced by alkaloids and other chemicals, (4) sour, produced by acids, and (5) umami or savory, produced by the salts of glutamic acid, such as monosodium glutamate (MSG), a flavor enhancer. Taste transduction for salty and sour stimuli is thought to be *via* the ion channel mechanism, while sweet, bitter, and umami stimuli are thought to be induced *via* the receptor protein binding mechanism [35,36]. NMR spectroscopy has been used to identify the chemical structure, conformation, and dynamics of the molecules responsible for these taste sensations (taste stimuli or tastants), as well as tastant–receptor interactions. The NMR methods used to investigate the five tastes described above are discussed below by taste category.

Salty

Interest in better understanding the molecular level role of table salt (NaCl), as well as the salt substitute potassium chloride (KCl), in the processability, stability, and salty taste perception of food systems has led to using NMR techniques [37,38,39,40,41]. Ayya (1988) and Rosett *et al.* (1994) used sodium-23 (^{23}Na) NMR to investigate the relationship between perceived saltiness and the binding of Na^+ in aqueous ionic and non-ionic gum systems. In both studies it was observed that ionic gum solutions (carboxymethylcellulose, xanthan, and carrageenan) received lower saltiness intensity ratings compared to non-ionic gum solutions (methylcellulose, guar, and locust bean) with equivalent added Na^+ contents. The lower intensity ratings of the ionic gum solutions were attributed to the interaction of Na^+ and the negatively charged groups of the ionic gums. The Na^+–gum interaction was investigated by measuring the ^{23}Na NMR transverse relaxation rate (R_2*) of the gum systems. Again, in both studies, the ionic gum solutions had higher R_2* values (lower rotational mobility) compared to the non-ionic gum solutions, in the same Na^+ concentration range, indicating that the Na^+ in the ionic gum solutions was slowed down by interacting with the negatively charged groups of the ionic gums.

Rosett *et al.* (1995) examined the competitive binding between K^+ and Na^+ ions to elucidate a mechanism by which the addition of other cations may enhance saltiness perception of processed foods using ^{23}Na NMR relaxation measurements [40]. They reported that the ^{23}Na NMR R_2* values increased with the addition of K^+ to the NaCl ionic xanthan gum system, corresponding to an increase in the average Na^+ mobility. Correspondingly, they found that salty taste increased with the addition of KCl to the NaCl ionic xanthan gum system, as determined by Decision Boundary modeling of subject identification data. They concluded that enhancement of the salty taste of a food system containing NaCl by KCl can be explained, at least in part, by competitive binding of Na^+ and K^+. The K^+ displaces the Na^+ on large negatively charges macromolecules, allowing more Na^+ to remain free for saltiness perception.

Nagata *et al.* (2000) used ^{23}Na and chloride-35 (^{35}Cl) NMR to study the mobility of Na^+ and Cl^- in crab meats cooked by traditional boiling in salt water for 10 min at 100 °C in the case of fresh crab meat and autoclaving with salt water for 90 min at 110 °C in the case of canned crab meat [41]. It was known that traditional boiling produced better tasting crab meat, but the question was why. The researchers measured T_1 by inversion recovery and found that both Na^+ and Cl^- mobility in the crab meat decreased significantly with autoclaving. They hypothesized that the poorer taste of canned crab meat compared to fresh meat was due to the observed reduction in Na^+ and Cl^- mobility.

Sweet

Two areas of sweet taste that have been readily explored using NMR are, (1) the chemical structure of sweet molecules and their solid and solution conformation and, (2) the role of sweet molecule–water interactions and physical properties on sweet taste perception. An example of the first area is the recent research aimed at elucidating the structure-taste relationships of sweet proteins (e.g. brazzein, monellin, and thaumatin) [42,43]. Kohmura *et al.* (2002) used a suite of NMR techniques, including two-dimensional nuclear Overhauser enhancement spectroscopy (NOESY), total correlation spectroscopy (COSY), and double quantum filtered correlation spectroscopy (DQF-COSY), to study the relationship between structure and taste of the sweet protein monellin (4000 times as sweet as sucrose) and thirty-seven synthesized monellin analogs [42]. The results suggest that it is the free β-caroxyl group of the Asp^{B7} residue that binds to the receptor site through ionic bonding and triggers the sensation of intense sweet taste.

In the second area, researchers have enlisted a number of techniques and physical parameters, including NMR, to examine the role of water in sweet taste perception [35,44,45,46,47,48,49]. For example, Aroulmoji *et al.* (2001) investigated the effects of sucrose, caffeine and their mixture on water mobility using both physicochemical properties (intrinsic viscosity, apparent specific volume, and surface tension) and ^{1}H NMR relaxation rate (R_1 and R_2) measurements [35]. NMR data together with physicochemical properties data helped explain the role of water in sweet and bitter taste perception.

Recently, Mahawanich and Schmidt (2004) explored the relationship between the molecular mobility of water and the perceived sweetness of three simple sugars, sucrose, fructose, and glucose solutions (0.15 mol/l to saturation) [49]. The rotational mobility of water was measured by ^{1}H-decoupled oxygen-17 (^{17}O) NMR 500 MHz R_1 (inversion recovery), R_2 (CPMG), and R_2* (line width at half-height). The translational mobility of water was measured using ^{1}H NMR pulse-field spin-echo (PGSE) method. The rotational and translational mobility of the sugar molecules were measured using ^{1}H NMR 500 MHz R_1 (inversion recovery) and translational mobility (PGSE), respectively. In general, as sugar concentration increased the rotational and translational mobility of both the water and sugar molecules decreased, while the maximum sweetness intensity increased. However, the researchers concluded that there appeared to be no direct correlation between the perceived sweetness and the NMR molecular mobility parameters measured in the study. The lack of direct correlation between the perceived sweetness and the NMR molecular mobility parameters was attributed to the complex nature of sweet taste perception and the challenges associated with correlating molecular level parameters with macroscopic sensory data.

Bitter

Bitterness in some foods and beverages are tolerable or to some even desirable, like the bitterness imparted to beer by alpha-acids, or the bitterness imparted to broccoli by glucosinolates, or the bitterness imparted to coffee by caffeine. However, there are a number of bitter compounds found in raw foods or produced by processing or senescence that are undesirable in foods. Hofmann and his lab group, for example, have used NMR techniques to aid in the structural determination of bitter off-tasting compounds in cold-stored and commercial carrot puree and those formed during thermal food processing from Maillard-type reactions [50,51].

Sour

The structure of sour tastants has been determined using NMR. For example, Shima *et al.* (1998) used mass spectrometry, ^{1}H NMR, and ^{13}C NMR to identify the structure of a novel compound [N-(1-methyl-4-hydroxy-3-imidazolin-2,2-ylidene) alanine] that is thought to be responsible for the sour taste aspect of beef broth [52].

Umami

An example of the use of magnetic resonance to explore the relatively new taste of umami is the research by de Araujo *et al.* (2003), which used fMRI (3T Varian/Siemens whole body scanner) to determine the representation of umami in the human brain [36]. The regions in the brain activated by MSG were found to be very similar to the regions activated by glucose. The authors concluded that this similarity in brain activation provides additional evidence that umami is indeed a "fifth taste."

Summary and Future Applications

Sensory evaluation and magnetic resonance are complementary techniques for probing the fundamental nature of the sensory properties of food materials. Their combined use is leading to a deeper understand of the basis of food material properties, with sensory science contributing an integrated macroscopic perspective and magnetic resonance providing a physical-chemical molecular viewpoint. As far as future applications of magnetic resonance, NMR will continue to be used as the method of choice for uncovering the molecular structure, conformation, and dynamics of molecules of importance to sensory science. MRI could be used for monitoring deformation of foods using an artificial mouth to simulate the mastication process, opening up the door for a new generation of texture and flavor release studies. fMRI could be used to develop a map of sensory perceptions in the human brain, which could provide critical information necessary for the development of foods with optimal sensory attributes, functional properties, and nutritional benefits. The future is bright for innovate uses of NMR and MRI in sensory science.

Introduction

A relatively new approach in NMR is the relaxing of restrictions on the magnetic field homogeneity for the static field B_0 as well as for the radio frequency field B_1, known as single-sided or unilateral NMR. This realization of an NMR device implies cost reduction of the equipment as well as the possibility to non-destructively apply NMR techniques to samples larger than the probe. However, this approach has also physical consequences. The magnetic field gradients are in an order of magnitude where almost every pulse becomes selective thus leading to spatial selectivity which is given by the Larmor frequency and the bandwidth of the tank circuit. In addition, these single-sided NMR devices have an inherent sensitivity to diffusive or convective processes as the field gradients are large. For example, the device used for the measurements presented here exhibits B_0 field gradients in the order of 10–20 T/m, leading to an full width at half maximum, FWHM slice thickness of about 2 mm with a quality factor of the circuit of about 70. The $B_1(r)$ can be constructed such that shape and size of the sensitive volume corresponds to the sample to be measured and is therefore to be tailored to the desired properties. In case of homogeneous food samples, the sensitive volume should be chosen as large as possible, whereas small and sharp volumes are preferred in examinations of local properties. Examples are the investigations of skin cancer and of fat content in living salmon [1].

The Bruker Single-Sided NMR Device

Starting from the NMR-MOUSE® [2–5], a trademark of the RWTH Aachen, a single-sided NMR device was constructed especially for the needs in an industrial environment. The device is small and equipped with exchangeable rf parts for allowing fast and easy change of measurement depth (Figure 1), i.e. tailoring to the application problem. Currently, three measurement depth are available, which are surface, 3 mm, and 5 mm. Moreover, the probe design was chosen such that detuning due to the dielectric constant of the sample was minimized. This lead to an increased reproducibility without any re-tuning of the circuit. Furthermore, the dead time of the probes was reduced to about 11 μs which opened application of the Bruker single-sided NMR device to hard materials like plastics. As the measurements take place in the stray fields of B_0 and B_1, the inherent sensitivity is smaller compared to a conventional NMR spectrometer using homogeneous magnetic fields. Therefore, special attention was given to an optimized signal to noise (S/N) ratio under these circumstances.

Experimental Approaches in Fat and Water Determination

As already discussed in part B (Time-Domain NMR in Quality Control: Advanced Applications in Food), the determination of fat and water content in food is an important application in food analysis. Using Time-Domain (TD-) NMR or even single-sided NMR implies that the chemical shift resolution is usually not high enough to allow a reliable determination of both contents. Therefore the physical parameters NMR relaxation and diffusion have to be exploited. These approaches work for the single-sided NMR devices also.

Diffusion Weighted Approach

As the single-sided NMR devices exhibit strong B_0 and B_1 gradients, it is quite natural to think about the use of the B_0 gradient for selective suppression of the water signal. The difference in the diffusion coefficient, D, can be exploited to create sufficient contrast between water and fat compartments. Several NMR methods are known: (1) The conventional Hahn echo sequence exhibits a dependence on D proportional to $\exp(-D\tau^3)$, where τ is the echo time. Consequently, at large echo times the influence of diffusion is more pronounced. (2) In contrast to the Hahn echo sequence, in multi echo sequences [6] the dependence on the decay time t is proportional to

exp(-*Dt*). However, the decay can be measured within one scan leading to a measurement time advantage over the Hahn echo method. (3) In addition to echoes exploiting mainly transverse magnetization, stimulated echo sequences are known, often being used in restricted diffusion experiments, where only the slower longitudinal relaxation time allows measurements at longer time delays. The disadvantage is again a longer measurement time.

Taking into account the specific prerequisites on experiments using single-sided NMR, the multi echo approach seems to be the most promising in an industrial environment. In Figure 2, the pulse sequence is shown, which was developed for the special needs of fat and water differentiation in quality control [7]: In the first few echoes using small echo times τ_1 the total magnetization of the sample in the sensitive volume is observed except for magnetization contributions due to components with $T_2 < 100$ µs, which are essentially solid like materials as for example packing materials. Several echoes are averaged in order to improve the S/N ratio. In the second interval the diffusion filter is applied such, that at the end only the signal of the fat component remains. In a third part several echoes are averaged for improvement of the S/N ratio of the fat signal. The ratio of the fat signal and the total signal results in the fat content which can be calibrated against reference values in order to provide absolute numbers and to correct for inherent systematic errors. Finally, in the case of $k = n = 0$ (see Figure 2), the case of the CPMG [6] sequence, the complete echo decay is correlated with the fat content, rather than just the calculated ratios of echoes at particular times. This method can also be applied in fat content measurements in fat and water mixtures [8]. As an example, the correlation diagram of fat content of coffee creams determined by this single-sided NMR method with the reference values given by the manufacturer is shown in Figure 3. The surface probe was used for achieving the best possible S/N ratio. The packing material is not influencing the ratio much, because it is relatively thin and the polymer material exhibits a short T_2 relaxation time. The measurement time was about 1 min. The correlation coefficient was determined to 0.996, which allows a reasonable prediction of the fat content through the packaging! It is obvious that

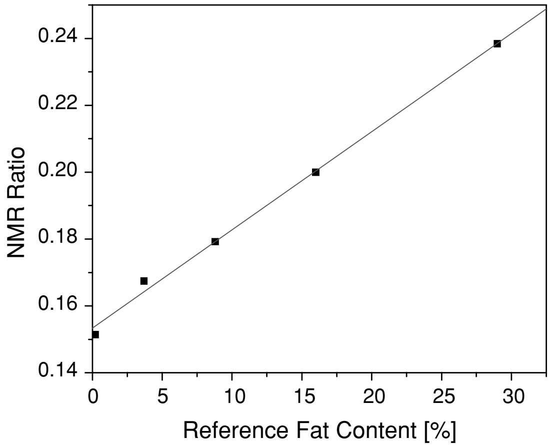

Fig. 3. Correlation diagram of the NMR ratio with the fat content of some coffee creams. The correlation coefficient is 0.996. The sequence used for this experiment is the diffusion weighted ratio method shown in Figure 2. The measurements were performed using the surface insert. (See also Plate 140 on page XXVIII in the Color Plate Section.)

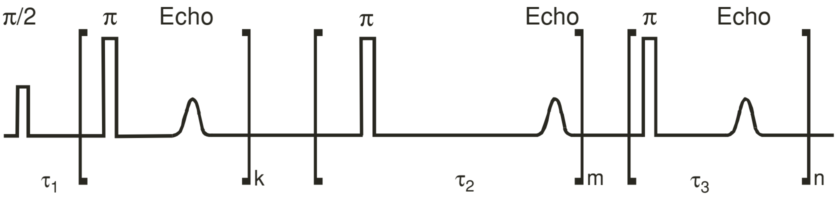

Fig. 2. Pulse sequence for measuring transverse magnetization decays, which are influenced by relaxation processes and diffusion with single-sided NMR.

the S/N of the measurement directly influences the quality of the calibration curve, i.e. the precision of the measurement. The S/N can be improved by increasing the number of repetitions of the experiment, however, leading to longer measurement times. Obviously, the accuracy also depends strongly on the quality of the reference values, which were taken from the nutrition facts on the labels.

Relaxation Time Approach

As discussed in Part B: Time-Domain NMR in Quality Control: Advanced Applications in Food, the relaxation time differences of fat and water protons can be exploited to generate sufficient contrast to allow the contents determination. The same is true in case of single-sided NMR. For a more detailed description we refer to Part B: Time-Domain NMR in Quality Control: Advanced Applications in Food. Again, both NMR relaxation parameters are considered, thus increasing the contrast. In [8], only the transverse relaxation was considered which already leads to reasonable results together with the chemometric data processing. It is essential for the method presented here that the sensitive volume is covered completely and filling factors can be neglected thus circumventing the need of weight of that part of sample contributing to the NMR signal. Again the data processing is performed using a chemometric approach in order to facilitate the analysis of hundreds of data points. A correlation coefficient R of 0.991 was obtained, slightly less than R of the surface measurements using the diffusion weighted ratio method in Figure 3. The measurements were performed in a depth of 3 mm, leading to an inherent decrease of the S/N by a factor of about 3–4. This means that the measurement time should be increased by a factor of 9 for obtaining the same S/N. Here, the measurement time was limited to 5 min due to tempering issues. Of course, an rf insert could be constructed with less pronounced depth selectivity releasing the S/N restriction.

In order to compare the overall analysis time, measurements in homogeneous fields (TD-NMR 20 MHz system) were conducted on the same samples. The measurement time could be reduced to about 1 min. However, the sample preparation time has to be taken into account as well, leading to only small differences in the overall analysis time. The correlation coefficient established with the measurements in the homogeneous field was determined to be slightly higher (0.997 compared to 0.991), which could be due to the mentioned inherent S/N disadvantage of the single-sided NMR devices.

Conclusion

The single-sided NMR can be used for measuring the fat content in packaged products as well as *in vivo*. Two NMR methods were discussed, which may also be applied in other fields when dealing with substances of different relaxation or diffusion properties. The S/N critically determines the quality of the measurement and the correlation, as long as the temperature stability is guaranteed. Improvements of the S/N, i.e. the correlation, or reduction of the measurement time can be achieved by increasing the resonance frequency and by increasing the measurement volume. The major advantage of single-sided NMR measurements is that sample preparation is not required. Products can be examined "as is," even through the packaging in finished dairy products. It should be pointed out that the same measurements can be performed *in vivo* in order to exploit different tissues in surface near regions.

As the single-sided NMR devices use only stray fields, the relatively low S/N is an inherent feature. Several research activities are in progress regarding this issue.

Applications of NMR in the Studies of Starch Systems

Imad A. Farhat
Division of Food Sciences, University of Nottingham, Loughborough, LE12 5RD, UK

Introduction

This chapter reviews the main contributions of NMR spectroscopy to the understanding of the biosynthesis, structure, processing, and performance of starch. The chapter is written from an "NMR user"/Food Science perspective rather from an "NMR specialist"/Spectroscopy one. Because of the context, i.e. a magnetic resonance handbook, a relatively detailed introduction of starch as a material is included for the benefit of readers who may not be familiar with starch.

Starch

Starch is one of the most widely present natural polymers, second only to another glucose polymer, cellulose. It is of major economical importance. The world market size for 2000 was estimated at ~48.5 million tons [1]. While starch constitutes the major proportion of most human and animal diets, the majority of its consumption (~70%) is related to non-food applications such as paper and board manufacturing, textiles, adhesives, pharmaceuticals, etc. [2].

Starch is found mainly in the storage organs of plants in the form of granules. Regardless of their botanical source, starch granules are primarily composed of two glucose polymers, the mainly linear poly $\alpha(1\text{–}4)$ D-glucopyranosyl, amylose, and the highly branched amylopectin with branching from the linear poly $\alpha(1\text{–}4)$ D-glucopyranosyl chains through $\alpha(1\text{–}6)$ bonds [3,4]. The degree of polymerization (DP) of amylose ranges typically between 570 and 4920 depending on the botanical source [3] while amylopectin is a much larger macromolecule with DPs ranging between 3×10^5 – 3×10^6 g/mol [3]. Native starch granules have a concentric alternating amorphous and semi-crystalline growth rings structure (Figure 1). The size, shape, and composition of the granule are strongly dependent on its botanical source. For example, rice starch contains 14–32% amylose depending on variety and growth conditions, its granules are polyhedral and irregular with particle size in the 3–8 μm range while wheat starch (26–31% amylose) granules range between 2 and 38 μm with two granules populations called A and B according to their size. Potato starch contains typically typically ~23% amylose and its granules are smooth ellipsoidal and can be up to 75 μm (Figure 1a) [4,5].

Starch Processing and Storage

Starch is extracted from grains, tubers, and other plant materials through milling/shredding followed by a series of consecutive washing procedures owing to the lack of solubility of the native granules in water at ambient temperature. During processing and subsequent use, starch undergoes a range of physical and chemical modifications.

Starch gelatinization, which results from the input of heat in the presence of water, is by far the most common transformation of starch (pasting, baking, cereal processing, etc.). During gelatinization, water enters the granule and plasticises its amorphous component, which undergoes a glass to rubber transition. The increased mobility of the amorphous phase and the continuing heat input enables the disruption/melting of the dispersed crystallites leading to a loss of molecular order and the swelling of the granule [6,7]. Both the extent of swelling and the temperature at which gelatinization occurs depend strongly on many parameters including botanical source, concentration and the presence and amount of co-solutes such as sugars, salts, etc. Gelatinization leads to dramatic changes of many functional properties, e.g. viscosity, solubility, digestibility, etc.

Post-gelatinization and if the starch polymers retain sufficient molecular mobility i.e. in the rubbery state, retrogradation occurs. Retrogradation is essentially a gelation process involving a disorder to order transition of amylose, a rapid process occurring mostly during cooling and early storage and amylopectin, a slower process occurring over hours–months depending on storage conditions [8]. Retrogradation leads to significant changes to mechanical (e.g. staling of baked foods) and digestibility of starch systems [8–10].

A range of other physical and chemical modifications can be applied to starch to change its functional proprieties such as gelatinization temperature, viscosity, freeze-thaw stability, retrogradation, solubility, surface properties, etc. A reviewing of all existing modified starches is beyond the scope of this chapter. The most common ones include: cross-linking for example using phosphorous oxychloride, sodium trimetaphosphate or adipic anhydride to

(b) Schematic representation of the starch granule with alternating semi-crystalline and amorphous growth rings. (c) The basic chemical structure of amylopectin. (d) The semi-crystalline growth rings are made of blocklets which contain a large number of repeats of crystalline (2D arrays of amylopectin double helices) and amorphous lamellae (double helices junction zones) [11]. The thickness of a crystalline and an amorphous lamellae is ~9 nm. (e) The relationship between amylopectin, amylose, and endogenous lipids (typically phospholipids; potato starch contains negligible amounts of lipids) [12]. (f) The crystalline structure of A (typically from cereals) and B type (typically from tubers) starches [13].

control swelling and improve shear stability, "stabilization" through the grafting of acetates, phosphates, and hydroxypropyl to limit retrogradation or a combination of modifications [2].

NMR Studies of Starch Systems

NMR is widely used to study starch and starch-based foods. In the following, some of these studies will be reviewed under four headings, which roughly map on four classes of NMR methods. This review cannot be exhaustive due to the broadness of the topic.

Chemical Structure and Composition Using Solution State High-Resolution NMR

The extremely high molecular weight of both amylopectin and amylose hinders their characterization by solution state high-resolution NMR. Such studies are often performed using solid-state techniques as discussed later in this chapter.

The main contributions of solution state high-resolution techniques falls into three categories.

Understanding Starch Biosynthesis

Nearly 25 years ago, Meredith and co-workers [14] analyzed the saccharide composition of 80% ethanol extracts of wheat grains sampled periodically during development using ^{13}C NMR. Studies of plant metabolites during growth using NMR, principally by monitoring labeled metabolites (typically glucose, fructose, or sucrose) using HPLC-^{13}C NMR [15–17] or subsequent starch hydrolysates using ^{13}C-^{1}H 2D techniques [18] are widely reported.

Hyphenated HPLC-^{13}C NMR led to useful information on the changes to starch in potato tubers during storage [19]. More recently, the technique was employed to assess genetically modified potato lines where starch biosynthesis was one of the modifications [20]. The results, however, did not detect conclusive effects of the genetic modifications.

In a somehow related context (reverse process), Amato *et al.* [21] studied starch amylosis (hydrolysis by amylase enzymes) in hydrated wheat flours using a combination of High-Resolution Magic Angle Spinning (HR-MAS) (for the flour) and standard high-resolution ^{1}H-NMR spectroscopy (for the liquid extracts). This elegant approach, coupled with multivariate data analysis enabled the authors to study the kinetics of amylosis and detect differences in starch susceptibility to degradation depending on the type of wheat flour.

Characterization of Starch Structure

Only limited number of studies used solutions state NMR to characterize the structure of starch itself. Nilsson *et al.* [22] used ^{1}H-NMR, ^{1}H-^{13}C, and 2D NMR (COSY) to study the degree of branching of amylopectin in normal and genetically modified potatoes. These authors also obtained good agreement between estimates of molecular weight of hydrolyzed starch using NMR and those measured with the more traditional method of size exclusion chromatography.

^{31}P NMR proved to be a very powerful tool in characterizing the phosphorus associated with the starch granule. In starch, organic phosphorus can be broadly divided into two types: phospholipids and phosphate monoesters on the glucosyl units of the starch polysaccharides [23,24]. Cereal starches tend to have higher amounts of phospholipids and less phosphate monoesters on the glucosyl units while tuber starches and in particular potato (~0.9% phosphate monoesters), show the opposite pattern. Phosphate monoesters for most starches tend to be preferentially located on the primary carbon C6 rather than on C3 of the glucosyl unit [23]. Phosphorus content is an important parameter as both phospholipids and phosphate-monoesters affect greatly the functional properties of the starch in terms of swelling, retrogradation, etc. [25].

Characterization of Chemically Modified Starches

The technology of chemically modifying starches is extensively developed and productions are often at industrial scales. The structure of chemically modified starches is often assessed by NMR. In this section, we will limit the review to typical examples of such studies. de Graaf *et al.* [26] described simple (1D ^{1}H-NMR) and rapid (32 scans) methods for the determination of the molar substitution of acetylated and hydroxypropylated potato starches which showed excellent correlation with traditional, time-consuming chemical methods. Not surprisingly, NMR is proving particularly useful in the efforts to selectively derivatise starch [27].

Molecular and Supramolecular Structures Using Solid-State High-Field NMR

High-resolution Magic Angle Spinning and in particular Cross Polarization (CP) MAS techniques have seen extensive applications in studies of starch. The pioneering work of Gidley and co-workers [28–30] and Veregin *et al.* [31,32] laid the foundation for the use of ^{13}C CP-MAS NMR for the study of the organization of amylopectin and amylose at a molecular level. Solid-state NMR is discussed in more details elsewhere in the book, and will only be highlighted in this chapter in the interest of completeness of this review. The main areas of application of the technique in the study of starch systems are,

(i) Polymorphism of crystalline or semi-crystalline starch polysaccharides, particularly through the lineshape of the C1 chemical shift (~102 ppm) which yields a singlet in amorphous systems, a doublet in the case of the B-polymorph and a triplet in the case of the A-polymorph [13,33].
(ii) Consolidation of the concept of short-range molecular order vs. long-range crystalline order, this was particularly important in addressing inconsistencies between two of the most widely established methods in starch characterization, wide-angle X-ray diffraction (crystallinity) and differential scanning calorimetry (melting/molecular order dissociation enthalpy), and improving the understanding of important processes such as gelatinization, retrogradation, digestibility, etc. [4,7,30,34].
(iii) The study of starch–ligand interaction, in particular the formation of complex between amylose (and its derivatives) and hydrophobic ligands such as fatty acids, monoacylglycerides, saturated alcohols, ketones, etc. [29,33,35].
(iv) Molecular dynamics of starch polysaccharides, typically through the behavior of ^{1}H T_1, $T_{1\rho}$, and T_2 and through relaxation edited ^{13}C spectra acquired as a function of variables such as starch botanical source, water content, and temperature [36–38].

Molecular Dynamics Using Time Domain NMR

The characterization of the dynamics of starch biopolymers and water is one of the most established and prolific areas of the application of NMR to starch-based foods. Early reports from Lechert and co-workers [39–41] and Caplin and Blanshard [42] on the dynamics of starch and water protons in starch systems including potato and wheat starches and bread were very detailed and made significant progress in assigning the different ^{1}H populations according to their mobility. These studies also discussed several of the still current issues in the field, such as ^{1}H exchange between starch and water OH groups, using D_2O exchange.

NMR studies of molecular dynamics in starch systems fall into one of the following categories.

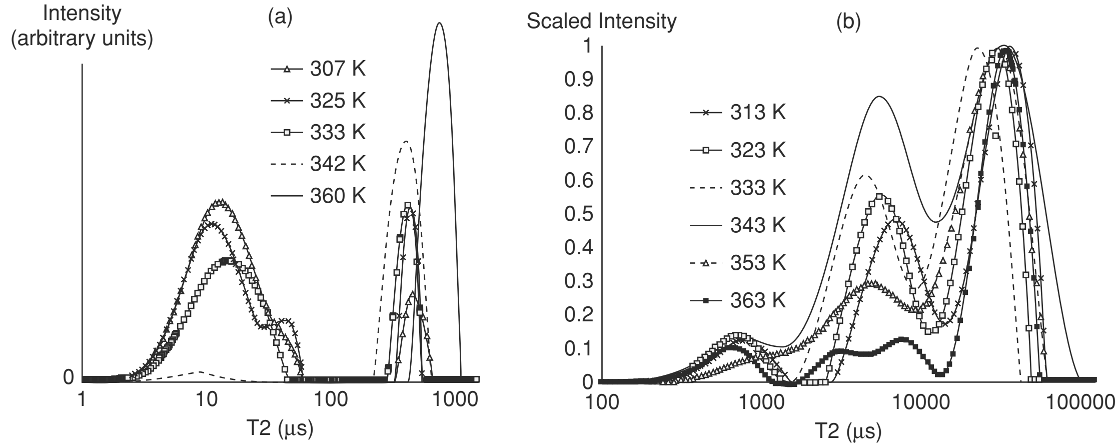

Fig. 2. ^{1}H spin–spin relaxation distributions of potato starch granules (adapted from [43]) at different temperatures. (a) "Non-exchangeable" ^{1}H analysis from FID acquired after D_2O exchange. (b) Water ^{1}H relaxation from CPMG acquired in H_2O. Typically, gelatinization of potato starch occurs in the range ~333–343 K when measured by DSC in excess water conditions [55].

Effect of Temperature (and Water+Temperature) on Starch Properties

Starch gelatinization where, under the effect of increasing temperature and in the presence of water, the amorphous components of starch undergo a glass–rubber transition followed by the melting of the crystalline fraction [6] is one of the most important aspects of this material. Surprisingly, starch gelatinization has received limited attention from an NMR viewpoint despite the fact this was one of the early applications of NMR in that field. As early as 1976, Henning *et al.* [40] studied the gelatinization of potato starch in D_2O through the CPMG decay of the CH protons. More recently, Tang *et al.* [43] reported a comprehensive study of the topic where they fitted FID and CPMG decays of potato starch granules acquired at different temperatures in the presence of either H_2O or D_2O to continuous distributions of exponentials. The "non-exchangeable" protons, i.e. those of CH groups, were monitored through the T_2distributions of the FID and CPMG decays acquired after D_2O exchange of the native granules. The authors assigned the two FID relaxation distributions observed (at ~10 and ~700 μs) (Figure 2a) to CHs of crystalline amylopectin in the semi-crystalline lamellae and to amorphous amylopectin in the amorphous growth rings respectively. They also assigned a CPMG component decaying at ~80ms to amylose CHs. This interpretation suffers from two main weaknesses. First, it assigns the FID signals to amylopectin because a similar pattern was observed for waxy maize starch (a starch containing more than 98% amylopectin). However the mobility of amylopectin and amylose protons in the native granule is unlikely to be significantly different and hence resolved by the technique. This is indirectly alluded to by the same authors in a previous study [44]. Secondly, the exchange of some OH protons in the native granule is unlikely to happen readily as some of these protons are involved in the H-bonded network of the double helical/crystal structures and hence will contribute to the rigid components of the FID below gelatinization but can exchange with water after gelatinization complicating the assignment. Furthermore, it is difficult to imagine such a high mobility of amylose in the native granule, even in the presence of high amounts of water, as it is a high molecular weight polymer ($>10^5$ g/mol in the case of potato), which is known to entangle and possibly co-crystallize with amylopectin in the native granule. The FID component with a T_2 centred at ~10 μs disappeared at temperatures above 342 K, i.e. as gelatinization occurred. This is compatible with the expected increase in mobility as amylopectin crystallites undergo a solid-liquid transition. The CPMG relaxation distributions for the granules in H_2O are often used to study the behavior of water (Figure 2b). It is important to remember that fast ^{1}H exchange between water and starch O–H inevitably makes CPMG decays sensitive to the molecular dynamics of the starch biopolymers. Three main relaxation times were observed; the shortest T_2 distribution was assigned to water in the semi-crystalline lamellae, the intermediate T_2 distribution to water inside the granule, most probably in the amorphous parts of the granule and the longest T_2 distribution to free water outside the granule. As gelatinization proceeds, water enters first the amorphous regions of the granule, hence the increase in the magnitude of the middle distribution. Gelatinization leads to the unfolding of amylopectin

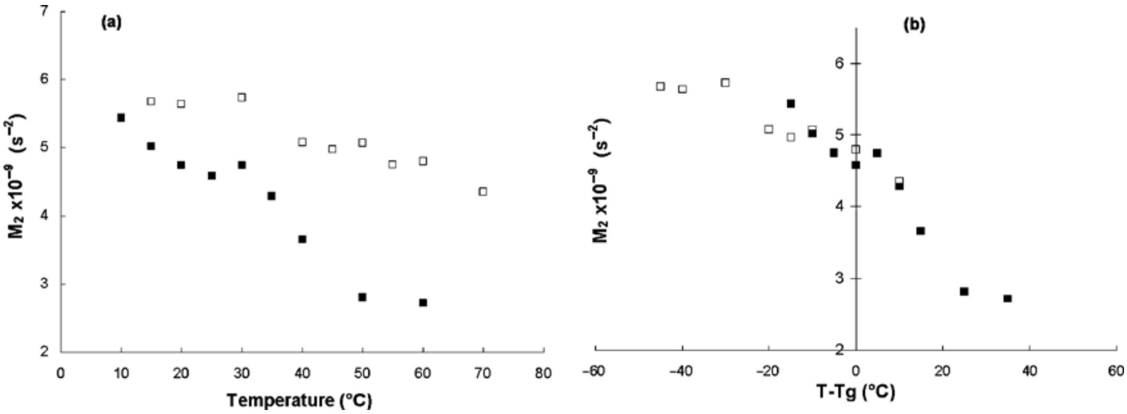

Fig. 3. Effect of temperature on the second moment of milled amylose films containing ~17% (□) and 21% (■) water (wwb) (A). The same data plotted as a function of the "shifted temperature" $T - T_g$ where T_g is the glass transition temperature measured by differential scanning calorimetry (Partanen and Farhat, unpublished).

and the leaching of amylose outside the granule, both of events would contribute to the decreased water mobility through increasing local viscosity and subsequently the shortening of the T_2 of the slowest decaying component (Figure 2b). It is worth noting that the authors were able to extend this approach to monitor the linterization process, i.e. the acid hydrolysis of native starch granules.

Other approaches using multivariate analysis of the CPMG decay [45] led to comparable findings regarding changes in water mobility during gelatinization.

Another aspect of the use of NMR relaxometry to monitor starch molecular dynamics is the ability of relaxation parameters such as the FID second moment (M_2), and the relaxation times T_2 and T_1 to sense changes in molecular mobility at or around the glass-rubber transition in processed fully or partly amorphous systems [46–48]. This is particularly important as the concept of glass-transition and the measurement of the temperature at which it occurs is now widely used by scientists and technologists in the food and pharmaceutical fields to predict processing and stability performance.

Starch–Water Interactions

NMR studies of the interaction of water with starch can be divided broadly into two types depending on whether they dealt with native or processed starch granules.

Hills and co-workers [43,44,49,50] have reported a series of extensive studies of the behavior of water in native and processed starch systems from different botanical sources. Their main findings in terms of assignments of time-domain NMR signals and the dynamics of water were discussed in the previous section. The relaxometry studies were supported by pulsed field gradient studies of self-diffusion of water and q-space imaging [44,49].

Several other studies utilized the self-diffusion coefficient of water in starch systems, measured using a variety of pulsed field gradient techniques, to study stability [51, 52], probe gel structure [53] and impact of co-solutes such sugars [54].

The effect of hydration on the properties of low water content processed starch systems, i.e. typically in the glassy state, is often studied using NMR relaxometry [46–48]. The ability of water to plasticize starch biopolymers leads to effects on NMR relaxation parameters of the polymer, e.g. the second moment (M_2) of the solid component of the FID (Figure 3), similar to those obtained when temperature is increased, with pronounced effect at conditions (temperature, water, and other plasticizers content) where the glass-rubber transition occurs.

Ageing of Intermediate Water Content Starch Systems, Starch Retrogradation

When stored in the rubbery state, i.e. for room temperature conditions, at water contents greater than ~25%, amylose and amylopectin undergo (at different rates) a reordering transition, also known as gelation. This gelation, can ultimately lead to a recrystallization and is one of the processes occurring during the staling, for example, of baked goods and cooked grains [9,56]. A range of NMR techniques have been applied to study starch retrogradation and its impact on the molecular dynamics of starch and water [9,25,45,56–59]. In terms of NMR relaxation parameters, starch retrogradation is reflected typically by:

(i) Increased rigidity of the polymer leading to shorter T_2 of the solid-like component of the FID, an increase of T_1 and an increase of the relative contribution of the solid-like component to the NMR signal.

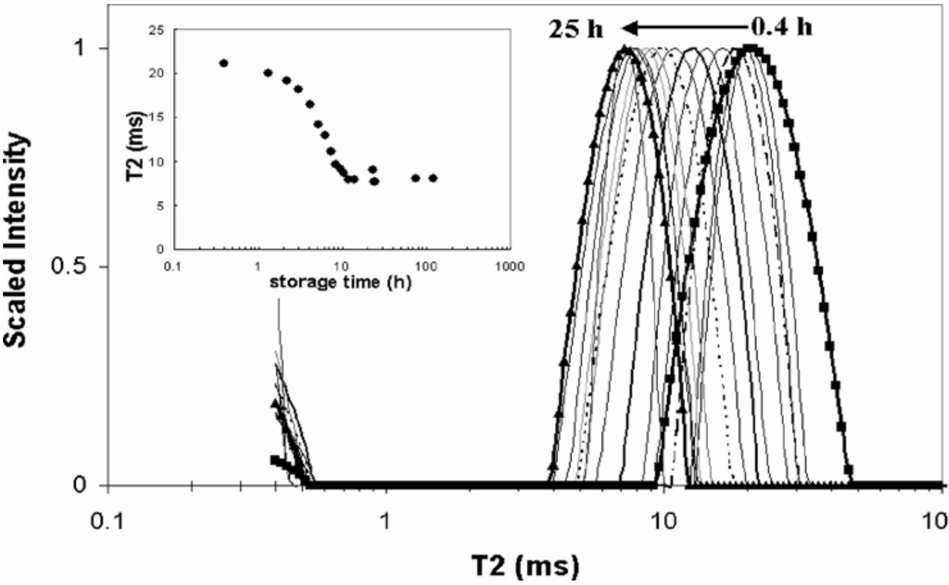

Fig. 4. Effect of amylopectin retrogradation on the relaxation spectrum. Insert, T_2 of main relaxation distribution (adapted from [56]).

(ii) Decreased mobility of water reflected by a decrease in its T_2 often measured using the CPMG pulse sequence (Figure 4). This decrease is believed to reflect the impact of the gelation of the biopolymer matrix and the effect of proton exchange between water and the hydroxyl groups of a less mobile retrograded network of amylopectin and amylose.

(iii) In fully retrograded systems at the low end of the water content range, a beat pattern becomes noticeable in the FID [48] reflecting a solid-like behavior with significant dipolar interactions.

It is interesting to note that these effects, which are very pronounced in starch systems, are much less significant in bread (Farhat *et al.*, unpublished) [59] for similar levels of starch retrogradation. The origin of this observation is not fully understood and it was suggested that it maybe linked to concurrent processes affecting water mobility: strach retrogradation changes to gluten structure, redistribution of water [59].

Imaging

Magnetic resonance imaging has seen numerous applications in food science and has been the subject of many reviews [60,61]. The main applications of the technique in starch systems, involved the study of water migration from or into starch systems during drying or rehydration processes, for example the boiling of grains in water [62,63] compared to steam processing [64] and the drying/hydration of extruded pasta systems [65,66].

Hopkinson *et al.* [67] used Stray Field NMR Imaging (STRAFI) to image water ingress inside amylose pellets and concluded that water migration from vapour followed a Fickian or Case I diffusion process while when the pellet was in contact with liquid water, the diffusion was non-Fickian or Case II. These findings are in-line with those of Stapley *et al.* [63,64]. Comparable findings on high-amylose starch tablets were also reported by Baille and co-workers [68]. STRAFI and other single-point imaging techniques [69] should provide a better handle on water migration inside glassy starch systems where fast water relaxation rarely allows for spin-echo type imaging studies. The main limitation with such studies is that only a minor and somehow superficial links are made to phase/state transitions (e.g. glass-rubber transition) and other molecular relaxation processes occurring during heating and water addition or removal.

The development of flow-imaging techniques [70,71] and the so-called rheo-NMR [72] could offer valuable insights into the behavior of starch dispersion and solutions. Of particular interest would be the behavior of starch granules and subsequent melts in the shear fields of extruders. Attempts have been made by various groups (e.g. McCarthy M.J, unpublished, [73]) where single screw extruders, for example made of polyetheretherketone (PEEK) were used. However, these devices remain rare and unrepresentative of the operational conditions of typical process extruders.

Conclusion

It is clear from this review and the other contributions on the subject of NMR studies of starch systems that the technique in its multiple facets has, like in many other fields, provided valuable and often unique insights to the various aspects of starch and its products, from biosynthesis to structure, processing, and stability. Several areas remain however not fully explored and NMR could lead to significant progress in many of them. Potential areas from a starch technology perspective, could include

- Understanding starch self-assembly during biosynthesis using solid-state techniques.
- Probing molecular dynamics in real-time during thermal/shear/pressure processing.
- Probing the dynamics of "structural water" in native and recrystallized starch systems.
- Monitoring changes in water mobility and redistribution during staling of intermediate water content starch foods in relations with sensory perception.
- Capitalising on the use of 2D techniques relaxation–relaxation, relaxation–diffusion and diffusion–diffusion techniques.
